INSTRUCTIONS TO ABSTRACTORS,

GIVING THE

NOMENCLATURE AND SYSTEM OF NOTATION

ADOPTED IN THE ABSTRACTS.

---

1. Before beginning to write an abstract, it is desirable to read through the whole of the original paper, in order to form a judgment as to its importance, and as to the scale on which the abstract should accordingly be made.

2. The abstract should mainly consist of the expression, in the abstractor's own words, of the substance of the paper.

3. The abstract should be made as concise as possible, consistently with a clear and accurate statement of the author's results or theories, due regard being paid to their import.

4. If an abstract of a paper on the same subject, either by the author of the paper abstracted, or by some other author, has already appeared, note should as a rule be made of this fact. Important references to the researches of others quoted by an author should be reproduced in the abstract. Always employ figures instead of Roman numerals for references, thus:—*Annalen*, **221**, 92, instead of ccxxi, 92.

5. If an abstractor is acquainted with papers previously published by other authors containing statements either practically identical with, or opposed to, those in the paper abstracted, and to which no reference is made, he should notice their agreement or contradiction in a foot-note.

6. As a rule, details of methods of preparation or analysis, or generally speaking of work, may be omitted, unless such details are essential to the understanding of the results, or have some independent value.

Nomenclature.

7. Employ names such as *sodium chloride*, *potassium sulphate*, *ethyl acetate*, and use the terminals *ous* and *ic* only in distinguishing compounds of different orders derived from the same elementary radicle; such, for instance, as mercurous and mercuric chloride, sulphurous and sulphuric acid.

8. Term compounds of metallic and alcoholic radicles with the group OH, *hydroxides* and not hydrates; for example, potassium hydroxide, phenyl hydroxide, the name hydrate being reserved for compounds supposed to contain water of combination or crystallization. Compounds such as CH_3ONa, C_2H_5ONa, $C_7H_{15}ONa$, &c., should be termed sodium methoxide, ethoxide, heptyloxide, &c.

9. Apply the term *acid* only to compounds of hydrogen with negative radicles, such as HNO_3, H_2SO_4, H_3PO_4, and denote the oxides which form acids by names such as sulphuric anhydride, carbonic anhydride. Term salts containing an amount of metal equivalent to the displaceable hydrogen of the acid, *normal* and not neutral salts, and assign names such as hydrogen sodium sulphate, hydrogen disodium phosphate, &c., to the acid salts. Basic salts are as a rule best designated merely by their *formulæ*.

10. Use names such as *methane*, *ethane*, &c., for the normal paraffins or hydrocarbons of the C_nH_{2n+2} series of the form $CH_3{\cdot}[CH_2]_5{\cdot}CH_3$, &c. The isomeric hydrocarbons are usually most conveniently represented by names indicating their relation to methane; for example, $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_3$ = propylmethane; $CH_3{\cdot}CH(CH_3)_2$ = isopropylmethane or trimethylmethane; or, although less frequently, by names such as diisopropyl.

11. Term the hydrocarbons C_2H_4 and C_2H_2 *ethylene* and *acetylene* respectively (not ethene and ethine). Distinguish the homologues of ethylene, whenever possible, by names indicating their relation to it, such as methylethylene, dimethylethylene, &c., denoting the di-derivatives of the form $C_nH_{2n+1}{\cdot}CH{:}CH{\cdot}C_nH_{2n+2}$ as α-, and those of the form $CH_2{:}C(C_nH_{2n+1})_2$ as β-compounds, thus: $CH_3{\cdot}CH{:}CH{\cdot}CH_3$ = α-dimethylethylene; $CH_2{:}C(CH_3)_2$ = β-dimethylethylene. Similarly, use names such as methylacetylene and dimethylacetylene for the homologues of acetylene of the form $CH{:}C{\cdot}C_nH_{2n+1}$ and $C_nH_{2n+1}{\cdot}C{:}C{\cdot}C_nH_{2n+1}$. Adopt the same *allene* for the hydrocarbon $CH_2{:}C{:}CH_2$, and indicate the relation which its homologues bear to it in the same manner as pointed out for acetylene.

12. Distinguish all alcohols, that is, hydroxyl-derivatives of hydrocarbons, by names ending in *ol*; such as quinol, catechol, resorcinol, saligenol, glycerol, erythrol, mannitol, instead of hydroquinone, pyrocatechin, resorcin, saligenin, glycerin, erythrite, mannite. Compounds which are not alcohols, but which are at present distinguished by names ending in *ol*, may be represented by names ending in *ole*, if a systematic name cannot be given. For example, write indole instead of indol: furfuraldehyde instead of furfurol; fucusaldehyde instead of fucusol. Ethers derived from phenols, such as $C_6H_5{\cdot}OCH_3$, &c., hitherto called anisol, anethol, &c., may be distinguished by names ending in *oïl*, as anisoïl and anethoïl.

Alcohols should be spoken of as mono-, di-, tri-, or n-*hydric*, according to the number of OH groups.

13. Compounds analogous to the acids of the lactic series containing the group OH should be termed *hydroxy*-derivatives, and not oxy-derivatives; for example, hydroxyacetic and not oxyacetic acid. Compounds containing the analogous groups C_2H_5O, C_6H_5O, $CH_3{\cdot}COO$, &c., should in like manner be termed ethoxy-, phenoxy-, acetoxy- derivatives. Thus

ethoxypropionic acid instead of ethyl-lactic acid; 3 : 4 diethoxybenzoic acid instead of diethylprotocatechuic acid; and acetoxypropionic acid instead of acetyl-lactic acid. Terms such as diethylprotocatechuic acid should be understood to mean a compound formed by the displacement of hydrogen-atoms in the hydrocarbon radicle of protocatechuic acid by ethyl, viz., $C_6H(C_2H_5)_2(OH)_2{\cdot}COOH$, and not $C_6H_3(OC_2H_5)_2{\cdot}COOH$, just as dibromoprotocatechuic acid is understood to be the name of a compound of the formula $C_6HBr_2(OH)_2{\cdot}COOH$.

14. The term *ether* should be restricted to the oxides of hydrocarbon radicles, and the so-called compound ethers should be represented by names similar to those given to the analogously constituted metallic salts (comp. 12).

15. Compounds of the radicle SO_3H should, whenever possible, be termed *sulphonic* acids, or failing this, *sulpho-compounds*: as benzenesulphonic acid, sulphobenzoic acid, and not sulfi-compounds. Compounds of the radicle $SO_2{\cdot}NH_2$ should be termed sulphonamides.

16. Basic substances should invariably be indicated by names ending in *ine*, as aniline, instead of anilin, the termination *in* being restricted to certain neutral compounds, viz., glycerides, glucosides, bitter principles, and proteids, such as palmitin, amygdalin, albumin. The compounds of basic substances with hydrogen chloride, bromide, or iodide should always receive names ending in *ide* and not *ate*, as morphine hydrochloride and not morphine hydrochlorate.

Notation.

17. Equations should *be omitted* unless essential to the understanding of the results; they, as a rule, should *not* be written on a separate line, but should "run on" with the text.

18. To economise space, it is desirable: 1, that *dots* should be used *instead of dashes* in connecting contiguous symbols or radicles, whenever this does not interfere with the clearness of the formula; 2, that formulæ should be shortened by the judicious employment of the symbols Me for CH_3, Et for C_2H_5, Pr^{α} for $CH_2{\cdot}CH_2{\cdot}CH_3$, Pr^{β} for $CH(CH_3)_2$, Ph for C_6H_5, Ac for $CO{\cdot}CH_3$, and Bz for $CO{\cdot}C_6H_5$; and 3, that formulæ should be written *in one line* whenever this can be done without obscuring their meaning. For example:

$CCl_3{\cdot}CH(OEt)_2$ instead of $CCl_3{-}CH{<}\begin{matrix}OC_2H_5\\OC_2H_5\end{matrix}$

$[CCl_3{\cdot}CH(OH)]_2S$ instead of $\begin{matrix}CCl_3{-}CHOH\\CCl_3{-}CHOH\end{matrix}{>}S$

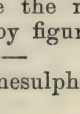
$CH_2 : CH_2$ instead of $CH_2{=}CH_2$

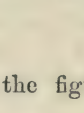
$CH : CH$ instead of $CH{\equiv}CH$

$CH : C{\cdot}CH_2{\cdot}CH_2{\cdot}C : CH$ instead of $\begin{matrix}CH_2{-}C{\equiv}CH\\|\\CH_2{-}C{\equiv}CH\end{matrix}$

$CHMe : CHPr^{\alpha}$ instead of $CH_2{\cdot}CH{=}CH{\cdot}CH_2{\cdot}CH_2{\cdot}CH_3$

$COOH{\cdot}CH : CMe{\cdot}COOH$ instead of $\begin{matrix} CH_3{-}C{=}CH \\ \quad\quad | \quad\quad | \\ COOH \quad COOH \end{matrix}$



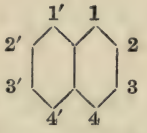


$CH_2Br{\cdot}CBrMe$ instead of $\begin{matrix} CH_3CH_3 \\ \diagdown\diagup \\ CBr \\ | \\ CH_2Br \end{matrix}$

$CEt_2Ac{\cdot}COOEt$ instead of $\begin{matrix} CH_3 \\ | \\ CO \\ | \\ C{<}\begin{matrix} C_2H_5 \\ C_2H_5 \end{matrix} \\ | \\ COOC_2H_5 \end{matrix}$

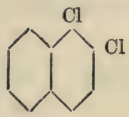
$\begin{matrix} CH_2{\cdot}CHMe \\ | \quad\quad > O$ instead of $\begin{matrix} CH_2{-}CH{\cdot}CH_3 \\ | \quad\quad\quad > O, \\ CH_2{-}CH{\cdot}CH_3 \end{matrix}$

$CHPh(OBz){\cdot}CH(OBz){\cdot}COOEt$ instead of
$C_6H_5{\cdot}CH(O{\cdot}CO{\cdot}C_6H_5){\cdot}CH(O{\cdot}COC_6H_5){\cdot}COOC_2H_5$.

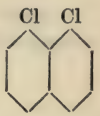


19. In representing the constitution of benzene-derivatives, as a rule, merely indicate the relative positions of the radicles in the symbol of benzene by figures, instead of by means of the hexagon symbol, for example:—

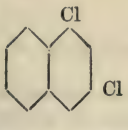
Paradibromobenzenesulphonic acid, $C_6H_3Br_2{\cdot}SO_3H$[Br : SO_3H : Br = 1 : 2 : 4] instead of  the figures always being used in the order 



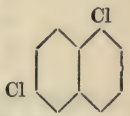
Relatively to the position 1, the positions 2 and 6 should always be spoken of as *ortho*-positions, 3 and 5 as *meta*-positions, and 4 as the *para*-position. It is better, however, in speaking of the derivatives of benzene, to express their constitution by giving them names such as 1 : 2 dibromobenzene, 1 : 3 dibromobenzene, &c., rather than by terming them ortho- or meta-dibromobenzene, &c.



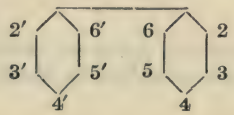
20. Moreover, in representing the constitution of derivatives of other "closed-chain" hydrocarbons do not, as a rule, employ graphic formulæ, but merely indicate the position of the radicles introduced in the following manner:—



In the case of naphthulene, express the position of the radicles introduced in place of hydrogen relatively to the carbon-atoms common to the two "rings," and number the positions in the one ring 1, 2, 3, 4, and those in the other 1′, 2′, 3′, 4′ in the order shown by the annexed symbol:—



The dichloronaphthalenes, for example, are spoken of simply as 1 : 2 dichloronaphthalene, or dichloronaphthalene[Cl : Cl = 1 : 2], &c., thus:—



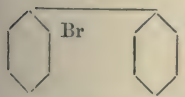
1 : 2 dichloronaphthalene = 

1 : 1′ dichloronaphthalene = 

1 : 3 dichloronaphthalene = 

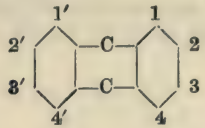
1 : 3′ dichloronaphthalene = 

In the case of diphenyl, indicate the position of the radicles relatively to the carbon-atom of one C_6 group which is associated with the other C_6 group, and number the positions in the one group by the figures, 2, 3, 4, 5, 6, and the corresponding positions in the other group by the figures 2′, 3′, 4′, 5′, 6′. as shown by the following symbol:



Thus the mono-derivatives, the bromodiphenyls, for example, are represented as

Bromodiphenyl [Br = 2]
„ [Br = 3]
„ [Br = 4]



and the two dibromodiphenyls 

and

are respectively dibromodiphenyl [Br : Br = 2 : 3] and dibromodiphenyl [Br : Br = 2 : 6′].

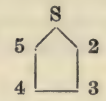
In the case of anthracene, employ the following symbol, and indicate the position of the radicles relatively to the central C_2-group:

Examples:

Alizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 2].

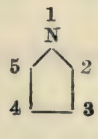
Quinizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 4].

Anthraflavic acid, $C_6H_3(OH) : C_2O_2 : C_6H_3(OH)$ [OH : OH = 2 : 3′].



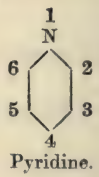
Purpurin, $C_6H_4 : C_2O_2 : C_6H(OH)_3$ [OH : OH : OH = 1 : 2 : 4].

In speaking of compounds such as these, their constitution may be represented by the names



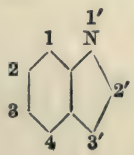
1 : 2 Dihydroxyanthraquinone		= Alizarin.
1 : 4	„	= Quinizarin.
2 : 3′	„	= Anthraflavic acid.
1 : 2 : 4 Trihydroxyanthraquinone		= Purpurin.

Always include the letters and figures indicating the constitution of derivatives of closed-chain hydrocarbons in square brackets.

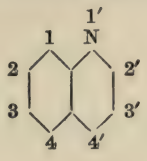


21. *In the case of thiophen*, express the position of the radicles introduced relatively to the sulphur-atom by numbers, as shown by the following symbol:

In the cases of pyrroline and pyridine, indicate the position relatively to the nitrogen-atoms as shown by the following symbols:



Pyrroline.



Pyridine.

In the case of indole, positions should be numbered as shown in the following symbol:—

In the case of quinoline, express the positions relatively to the carbon-atoms common to the two rings, and number the positions in the carbon ring 1, 2, 3, 4, and those in the nitrogen ring 1′, 2′, 3′, 4′ in the order shown by the annexed symbol :—

The Editor's decision, in all matters connected with the Abstracts, must be considered final.

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN BRITISH AND FOREIGN JOURNALS.

General and Physical Chemistry.

Refraction and Dispersion of Sodium Chlorate. By F. Dussaud (*Compt. rend.*, **113**, 291—292).—The measurements were made with several different forms of refractometer, but the divergences between the results obtained with different instruments did not seem to follow any definite law. The following are the indices of refraction at 23° :—

a.	B.	C.	D.	*b*.	F.
1·51097	1·51163	1·51267	1·51510	1·51933	1·52161
Cd_9.	Cu_{10}.	Cd_{11}.	Cd_{12}.	Cd_{17}.	Cd_{18}.
1·53883	1·54242	1·54421	1·54700	1·57203	1·58500

The mean variation of the index of refraction is −0·000057 per degree, and seems to be practically the same for all the visible rays.

C. H. B.

Relation between the Index of Refraction, Density, Molecular Weight, and Diathermanous Power of a Substance. By Aymonnet (*Compt. rend.*, **113**, 418—421).—If A is the diathermanous conductivity of a certain substance, $A = \frac{1}{2}MV^2$, where M is the mass contained in unit area of substance of thickness $k\lambda$, and V is the mean velocity. $M = k\lambda d$, d being the density of the liquid. If k is proportional to the thickness ϵ of a molecule, $k = C\epsilon$, where C is a constant. If the molecule is spherical, $\epsilon = (e/d)^{\frac{1}{3}}$, e being the molecular weight. Suppose $V = n - 1$, where n is the index of refraction, then

$$AP = \tfrac{1}{2}Ce^{\frac{1}{3}}d^{\frac{2}{3}}(n-1)^2\lambda,$$

where P is a correction applied on account of reflection.

The author verifies the above formula by observations with water, alcohol, benzene, chloroform, and carbon bisulphide. H. C.

Emission Spectra of Neodymium and Præseodymium Oxides and of Luminous Solids containing Neodymium. By L. HAITINGER (*Monatsh.*, **12**, 362—367).—Welsbach found that præseodymium oxide gives a continuous emission spectrum, and neodymium oxide a discontinuous spectrum similar to that noticed by Bunsen in the case of didymium oxide. The author confirms Welsbach's observations with neodymium oxide, using this oxide mixed with aluminium oxide for the production of the spectrum. The lines are found to vary somewhat, both in intensity and position, on long-continued heating of the mixed oxides, and also if magnesium is substituted for aluminium oxide. Præseodymium oxide, which alone has no emission spectrum, shows one when mixed with aluminium oxide. This behaviour may, perhaps, be explained by assuming that a higher oxide is formed when the salt is heated alone, but not when mixed with other oxides. No emission spectrum was, however, obtained on heating præseodymium oxide in a reducing atmosphere. The presence of a trace of neodymium in calcium sulphide causes a phosphorescence, the spectrum of which is similar to the absorption spectrum of concentrated solutions of neodymium salts. H. C.

Study of the Chemical Neutralisation of Acids and Bases, by means of their Electrical Conductivities. By D. BERTHELOT (*Compt. rend.*, **113**, 261—263).—A summary of the results of the researches previously published. Potassium hydroxide, a strong base, with hydrochloric acid, acetic acid, or phenol gives compounds which have almost identical conductivities, behave as true salts, are stable in solution, and are not decomposed by water. Ammonia, a feebler base, with hydrochloric acid and acetic acid gives stable compounds, but with phenol only an unstable compound with a higher resistance than the normal salts, and, to a large extent, dissociated by water. Aniline, a still feebler base, gives with hydrochloric acid a stable compound that is a good conductor; with acetic acid an unstable compound with a considerably higher resistance; and with phenol only a non-conducting mixture without any trace of combination.

Experiments with the hydroxybenzoic acids, which unite the functions of an acid and a phenol, show that, whilst the presence of the two functions can be readily recognised, they affect one another in a manner more or less marked according to their relative positions in the molecule. C. H. B.

Calculation of the Specific Heat of Liquids. By G. HINRICHS (*Compt. rend.*, **113**, 468—471).—In the liquid state, molecules rotate round the natural axis, for which the moment of inertia is a minimum. If i is the moment of inertia, M the mass of the molecule, and ρ the radius of gyration, $i = M\rho^2$. The total energy, ϵ, of the molecule of a liquid is the sum of the energy of rotation and of the potential energy, which is a function ϕ of the absolute temperature T,

$$\epsilon = kT + M\phi(T) = Me,$$

where $e = k\rho^2T + \phi(T)$, the total energy of unit mass. The specific heat, c, of unit mass will be obtained by differentiation of e with regard to T,

$$c = K\rho^2 + \phi'(T).$$

The author shows that a formula of this kind holds in the case of the ethereal salts of the fatty acids, taking Schiff's observations of the specific heats of salts of this series. H. C.

Second Law of Thermodynamics and its Application to Chemical Phenomena. By H. Le Chatelier (*Bull. Soc. Chim.* [3], **5**, 837—840).—Carnot's principle is directly applicable to chemical changes, if all restriction as to the nature of the equilibrium established by the change is removed. The same reasoning which is applied to the establishment of heat equilibrium may then be applied to chemical equilibrium. The available energy obtainable from two different states of the same system will be the same for all reversible transformations of the one state into the other, and independent of the means employed for rendering this energy available, and will be greater for reversible than for non-reversible transformations. The author shows how from this principle may be deduced, in a very simple manner, the laws of isodissociation which he formerly obtained by a far more complicated process—starting from the two equivalent principles of Clausius. H. C.

New Isothermal Curves for Carbonic Anhydride. By E. H. Amagat (*Compt. rend.*, **113**, 446—451).—The author has determined the isothermals for carbonic anhydride for every 10° from 0° to 100°, and also for the temperatures 32°, 35°, 137°, 198°, and 258°. The pressures were taken up to 1000 atmospheres, and the method employed was that described in former communications. The results are given in tabular form, and the isothermal curves for each of the temperatures taken. The following table is given for the pressures of liquefaction of carbonic anhydride at the temperatures under examination:—

Temperature.....	0°	10°	20°	30°
Pressure in atmospheres	35·4	44·4	56·4	70·7

The full discussion of the results is reserved for a future paper. H. C.

Heat of Formation of Platinic Bromide and its principal Compounds. By L. Pigeon (*Compt. rend.*, **113**, 476—479).—Platinic bromide, prepared by carefully heating hydrogen platinic bromide, was dissolved in water, 9·86 Cal. being developed. The solution was then reduced by metallic cobalt, the heat developed being 93·59 Cal. By subtracting the heat of formation of the cobalt bromide, 145·88 Cal., we get for the heat of formation of dissolved platinic bromide 52·29 Cal., and from this the heat of formation of the solid salt, 42·43 Cal. Solid platinic bromide dissolved in hydrobromic acid solution (1 mol. in 4 litres) gives rise to a development of 15·27 Cal., from which the heat of formation of a solution of

hydrogen platinic bromide from platinum, bromine, and hydrobromic acid is 60·70 Cal. The formation of the crystalline salt $H_2PtBr_6 + 9H_2O$ is attended by the development of an additional 2·86 Cal.

The author draws attention to the fact that the heats of formation of the compounds of platinum and bromine are, when gaseous bromine is taken, very nearly equal to the heats of formation of the similar compounds of platinum and chlorine. H. C.

Heats of Combustion and Formation of Nitrobenzenes. By BERTHELOT and MATIGNON (*Compt. rend.*, **113**, 246—249) :—

	Heat of combustion, constant volume.	Heat of combustion, constant pressure.	Formation from elements.	Formation from nitric acid.
	Cal.	Cal.	Cal.	Cal.
Orthodinitrobenzene.....	+704·6	+703·5	+0·5	+58·3
Metadinitrobenzene	+698·1	+697·0	+6·8	+64·8
Paradinitrobenzene	+696·5	+695·4	+8·4	+66·4
Trinitrobenzene (1 : 3 : 5).....	+665·9	+663·8	+5·5	+90·9
Trinitrobenzene (1 : 2 : 4).....	+680·6	+678·5	−9·2	+76·2

It is clear that although the values for the various isomerides are very similar, as is usually the case, there are distinct differences, amounting to 1 per cent. in the case of the dinitro-derivatives, and to 2 per cent. in the case of trinitro-derivatives. The differences are also distinct in the case of the formation from nitric acid, and the heat developed becomes less the more advanced the substitution.

The heat of formation of a nitro-derivative is always but slightly different from that of the generating hydrocarbon; and it follows that the oxygen of the nitroxyl group has nearly the same combustible power as if it were in the free state. Since the heat of formation becomes less as nitration advances, it follows that the combustible energy of the oxygen gradually increases. The bearing of this result on the explosibility of nitro-derivatives is obvious.

C. H. B.

Calorific Value of Food Constituents and their Derivatives. By F. STOHMANN and H. LANGBEIN (*J. pr. Chem.* [2], **44**, 336—399). —Stohmann is surprised that Berthelot (*Ann. Chim. Phys.* [6], **22**, 5) has not quoted him as an authority on the thermochemistry of proteïds and made use of his work on the subject (compare Abstr., 1885, 857).

The authors have already dealt with the calorific values of animal fats (Abstr., 1891, 11); in this paper they summarise the calorific values which they obtain for various proteïds and the products of their change. Full data for the results, and details as to source of the compounds, are given. The following tables summarise the values,

	Calorific value per gram, cal.	Ultimate composition.						Atomic proportions.
		Carbon.	Hydrogen.	Nitrogen.	Sulphur.	Oxygen.	Chlorine.	
Elastin	5961·3	55·03	7·20	16·91	0·18	20·68	—	$C_{720}H_{1129}N_{190}SO_{202}$.
Vegetable fibrin	5941·6	54·39	6·92	15·39	1·02	22·28	—	$C_{720}H_{1100}N_{175}S_5O_{221}$.
Serum albumin	5917·8	53·93	7·65	15·15	1·18	22·09	—	$C_{720}H_{1227}N_{173}S_6O_{221}$.
Syntonin	5907·8	53·64	7·44	15·76	1·09	22·07	—	$C_{720}H_{1198}N_{182}S_5O_{222}$.
Hæmoglobin	5885·1	54·73	6·06	16·50	0·46	22·25	—	$C_{720}H_{957}N_{186}S_2O_{219}$.
Milk caseïn, No. 1	5867·0	54·02	7·33	15·52	0·75	22·38	—	$C_{720}H_{1173}N_{178}S_4O_{224}$.
„ „ No. 2	5849·6	54·14	6·85	15·61	0·78	22·62	—	$C_{720}H_{1093}N_{179}S_4O_{225}$.
Yolk of egg	5840·9	53·50	7·31	15·26	1·11	22·82	—	$C_{720}H_{1180}N_{176}S_6O_{231}$.
Legumin	5793·1	53·22	7·17	15·18	0·46	23·97	—	$C_{720}H_{1165}N_{175}S_2O_{244}$.
Vitellin	5745·1	50·27	7·90	16·04	1·09	24·70	—	$C_{720}H_{1357}N_{198}S_6O_{264}$.
Egg albumin	5735·2	52·95	7·50	15·19	1·51	22·85	—	$C_{720}H_{1224}N_{178}S_8O_{233}$.
Flesh fibre, No. 5	5720·5	52·11	7·10	16·44	1·03	23·32	—	$C_{720}H_{1178}N_{194}S_5O_{242}$.
Crystallised albumin	5672·0	51·48	6·76	18·14	0·96	22·66	—	$C_{720}H_{1134}N_{218}S_5O_{248}$.

B and A = Berthelot and André, B and P = Berthelot and Petit, M = Matignon.

In connection with the first of these tables, the authors give another table showing the results which were obtained by Berthelot and André for some of the proteïds in the authors' table; this table appears to be quoted from *Ann. Chim. Phys.* [6], **22**, 25, which contains the same table as appears in Abstr., 1890, 937, but the numbers given here do not quite agree with those in the table referred to.

If the values for elastin, wool-fibre, skin-fibroïn, chondrin, osseïn, fibroïn, and chitin be excepted, the mean calorific value for the proteïds given in the first table is 5730·8 cal. Berthelot (Abstr., 1890, 938) found 5691 cal. for this number; the authors regard the mean, 5711 cal., as representing the real value. This value would be given by the formula $C_{720}H_{1161}N_{187}S_5O_{238}$; Lieberkühn's formula is $C_{72}H_{112}N_{18}SO_{22}$.

From the values given in the second table, the authors deduce the following generalisations:—(1) The substitution of CH_3 for a hydrogen atom in homologous series increases the calorific value by 156—157 Cal. (2) The calorific value of a methyl group attached to a nitrogen atom is higher than that of one attached to a carbon atom. (3) The displacement of a hydrogen atom in a CH_2 group by NH_2 raises the calorific value by 26·9 Cal. (4) The displacement of the hydroxyl in a carboxyl group by NH_2 raises the calorific value by 78·6 Cal. The heat of combustion of carbonic acid deduced from that of urea by means of this generalisation is −5·0 Cal. Longuinine (*Ann. Chim. Phys.* [6], **8**, 133) found −4·3 Cal. and −10·75 Cal. for this number.

A. G. B.

Maximum Density of Water. By H. M. Vernon (*Phil. Mag.* [5], **31**, 387—392).—The author investigated the rate of cooling of quantities of water from 30° down to 0°. His thermometer was read to 0·01° by means of a cathetometer. When the water was not stirred, there was a sudden break in the cooling curve about 4·7°, which is therefore to be considered the point of maximum density. No break appeared when the water was stirred, the natural convection currents not then having free play; but from the form of the curve it would seem that the specific heat of water between 0° and 12° is about 3 per cent. greater than between 16° and 30°. Both the increased specific heat and the maximum density are considered by the author to have their cause in an aggregation of $(H_2O)_2$ molecules to $(H_2O)_4$ molecules about 4° as the water cools. J. W.

Expansion of Water. By C. Scheel (*Chem. Centr.*, 1891, ii, 409—410; *Inaug. Diss., Berlin*).—The author has determined the expansion of water between 0° and 33° by means of a glass apparatus, the volume being read off on a capillary tube. (For a complete description of it, see the original paper.) The absolute expansion of water was found to be 0·0408059, the minimum being at 4·058°.

J. W. L.

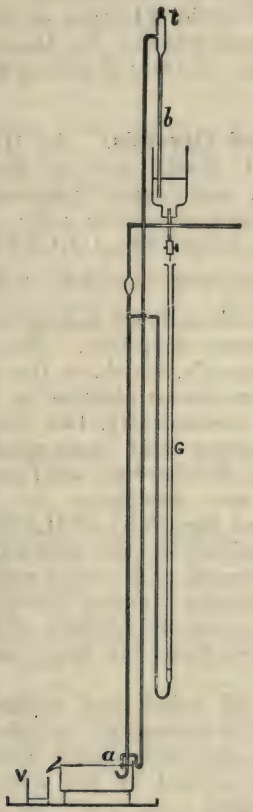
Dilatation of Phosphorus and its Change of Volume at the Melting Point. By A. Leduc (*Compt. rend.*, **113**, 259—261).—Phosphorus expands almost regularly up to its melting point, which is 44·2° on the mercurial thermometer, and 44·1° on the normal thermometer. At this point, without any appreciable change of temperature, there is a considerable expansion, the ratio of the volume of the solid phosphorus to that of the liquid phosphorus being 1 : 1·0345. Kopp's number was 1·0343.

The expansion of either solid or liquid phosphorus can only be represented by a formula with three terms, but the author is not able to state the coefficients precisely. The value of the mean coefficients on the normal thermometer between 0° and 44·1° is 0·000372, and between 26° and 50°, 0·000560, the latter being calculated on the volume at 0°. These values differ considerably from those given by Kopp. C. H. B.

Capillary Constants of Salts at their Melting Points. By J. Traube (*Ber.*, **24**, 3074—3080).—The author has determined the capillary constants of a large number of salts at temperatures just above their melting points. The method adopted was that of weighing the drops which fell from a single perforation in a small disc that formed the end surface of a short cylinder let in to the bottom of a platinum or porcelain crucible. This crucible was so heated, by means of an ordinary gas flame or by the blowpipe, that the flame did not come in contact with the hanging drop. The salts investigated were potassium and sodium salts, and the ratios (T) of the weight of the drops to the weight of the water-drop at 0° from the same vessel are tabulated.

From his results, the author deduces the following conclusions:—Capillarity may be considered a "colligative" property. The con-

stants for the salts of the fatty acids are unusually small, diminishing rapidly as the series is ascended. For the other salts the constants (T) of the potassium salts of monobasic acids lie between 112 and 157; of bibasic and multibasic acids, between 168 and 231. The limits for the constants of the corresponding sodium salts are 123—161, and 189—325. The difference $T_{Na} - T_K$ increases with the number of equivalents of the metal in the salts. It is doubtful if tri- and quadri-basic acids can, in this way, be distinguished from bibasic acids, but the author considers it always possible to distinguish between the latter and monobasic acids. The method points to the following formulæ as being correct :—K_2F_2, $K_2P_2O_6$, $Na_2P_2O_6$, $K_2As_2O_6$. J. W.



Mutual Solubility of Salts in Water. By W. W. J. Nicol (*Phil. Mag.* [5], **31**, 369—387).—Under the heading "The Mutual Solubility of Salts," the author groups the phenomena due to the mutual influence of two salts on each other's solubility in water. He gives an historical survey of the work done on the subject, and proceeds to communicate his own experiments on the chlorides and nitrates of sodium and potassium taken in all possible combinations of pairs with a common constituent. The method of experiment adopted was as follows:—A salt was taken, and solutions containing 1, 2, &c., gram-mols. of this salt in 100 gram-mols. of water were prepared. These solutions were then saturated at a definite temperature with the other salt added in excess, and the total salt in solution determined. Precisely similar determinations were made with definite molecular solutions of the other salt. The solubility of each salt separately in water was then determined, and finally, the solubility of both salts when simultaneously added in excess to water was also ascertained.

The results are presented in the form of tables, formulæ, and curves. In general, the presence of one salt diminishes the solubility of the other, but in the case of the nitrates of potassium and sodium, the presence of the one in solution increases the solubility of the other. (Compare Nernst, Abstr., 1890, 3; Le Blanc and Noyes, Abstr., 1891, 388.) J. W.

Cryoscopic Behaviour of Dilute Solutions. By J. Traube (*Ber.*, **24**, 3071—3074).—Eykmann and Arrhenius have pointed out (Abstr., 1891, 972 and 1148) that the observations of the author on the freezing point of dilute solutions, in particular of those of cane sugar, are not in accordance with their own experiments, or with those of Tammann and Pickering. The author upholds his numbers, and attributes the discrepancy to the other observers having cooled their solutions too far below the freezing point before making observations. J. W.

Automatic Replacement of Mercury in Sprengel Pumps. By A. Verneuil (*Bull. Soc. Chim.* [3], **5**, 748—750).—The mercury is continuously and automatically transferred from the lower to the upper reservoir by the action of a water-pressure or similar pump,

the suction-tube of which is attached to the upper end t of a small bulb, connected by tubes a, b to both reservoirs, and placed about 40 cm. above the upper one. The contents of the lower reservoir are thus forced into the bulb by atmospheric pressure, and allowed to

fall into the upper reservoir by their own weight. The tube a is 3 mm. in internal diameter, and is recurved at the lower end, the level of the mercury at that point being so adjusted that much air and little mercury passes up the tube; the tube b is 6 mm. in internal diameter.

The apparatus is applicable to most existing mercury pumps. It is not intended to be used at starting, as it is found more convenient to transfer any considerable quantity of mercury by hand than to make the apparatus of unnecessarily large dimensions. An incidental advantage is that the mercury is brought into contact with air under conditions favourable to the oxidation of impurities.

JN. W.

Block Support for Tubes. By A. GAWALOVSKI (*Zeit. anal. Chem.*, **30**, 581—583).—Two elongated blocks of hard wood, laid side

by side, have rectangular grooves ploughed in their contiguous faces, so as to form a channel, the cross section of which corresponds, approximately, with the shape of the bulbs of a Péligot's U-tube. The blocks are then united by screws. Upright pieces of wood, of various heights, shaped so as to fit and slide in the channels, can be inserted to give support to the U-tubes, or to carry horizontal tubes on their upper, grooved edges. To these pieces the tubes are attached by spring clips. A train of tube apparatus can thus be held by a single support. M. J. S.

Formation of Mixed Crystals. By H. Behrens (*Rec. Trav. Chim.*, **10**, 57—64).—1. *Double Salts of Mercuric Thiocyanate with Zinc, Cadmium, Cobalt, and Copper Thiocyanates.*—The salts having the following compositions, crystallise well:—$Hg(CNS)_2,Zn(CNS)_2$; $Hg(CNS)_2,Co(CNS)_2$; $2Hg(CNS)_2,Cd(CNS)_2$; and

$$Hg(CNS)_2,Cu(CNS)_2 + H_2O.$$

The zinc and cobalt double salts are homogeneous crystals, the former colourless, and the latter deep-blue. The cadmium salts afford analogous, pale-blue crystals, which, in the case of the double salts of zinc and cadmium, are almost identical in form with those of zinc mercury thiocyanate; consequently, two double cadmium mercury thiocyanates should exist and correspond with the formulæ $2Hg(CNS)_2,Cd(CNS)_2$ (Nordström's salt) and $Hg(CNS_2),Cd(CNS)_2$ respectively, which are analogous to the ammonium salts $Hg(CNS)_2,NH_4CNS$ and $Hg(CNS)_2,2NH_4CNS$.

From the liquid obtained by the addition of mixed solutions of cobalt and cadmium nitrates, or of cobalt and zinc nitrates, to a very dilute solution of ammonium mercury thiocyanate, colourless needles separate; these break up on the addition of ammonium thiocyanate, when the mother liquor affords the large, mixed, deep-blue crystals, noted above.

No mixed crystals of cobalt and copper compounds could be obtained. With the blue crystals of the cobalt salt, yellowish-green crystals of mercury copper thiocyanate occur, a result the author ascribes to a reaction induced by the water of crystallisation the double copper salt contains.

Addition of mercury ammonium thiocyanate to mixed solutions of copper, zinc, cobalt, and cadmium salts, determines the formation of mercury copper thiocyanate, and characteristic brown-violet crystals of mercury zinc copper thiocyanate, which contain no cobalt, and are isomorphous with the zinc compound. These do not alter when heated at 120°, whereas the dark-green needles of mercury copper thiocyanate become dark and opaque. The author concludes that, in presence of much zinc, mercury copper thiocyanate loses its water of crystallisation yielding mixed crystals with mercury zinc thiocyanate, whereas when mercury copper thiocyanate crystallises alone, it always contains a molecule of water of crystallisation.

2. *Silver Chromate and Silver Sulphate.*—The small, red crystals, forming the precipitate produced by the addition of potassium dichromate solution to a silver nitrate solution acidified with nitric

acid belong, like potassium dichromate, to the clinorhombic system. If silver sulphate be substituted for silver nitrate, the blood-red crystals yielded at first are monoclinic, but are succeeded by the deposition of orange-yellow, orthorhombic crystals of the mixed salt $Ag_2SO_4 + Ag_2CrO_4$, with liberation of chromic acid.

3. *Phosphates and Arsenates of the type* $NH_4MgPO_4 + 6H_2O$.—Salts of this type form hemimorphic orthorhombs. The corresponding hemimorphic double phosphates of magnesium, manganese, cobalt, and nickel are known, and the author has prepared the analogous arsenates of calcium, zinc, and copper. He describes and figures crystals obtained by him in endeavouring to produce mixed crystals of these salts, in order to determine if their constitution was of the same type as the magnesium derivative. Although in this respect his results are not conclusive, yet from the development of the crystals he concludes that neither a central point nor a plane of symmetry is necessary to the development of hemimorphic crystals, since they originate equally well from a lateral plane or a summit.

Inorganic Chemistry.

Revised Hydrochloric Acid Tables. By G. Lunge and L. Marchlewski (*Zeit. ang. Chem.*, 1891, 133—135).—The authors have constructed a very useful table, giving the specific gravities (reduced by Kohlrausch's formula to vacuum and 4° C.), the corresponding degrees of Baume's and Twaddell's hydrometers, the percentage of hydrogen chloride by weight, the percentage of weight of 18°, 19°, 20°, 21°, and 22° acid, and the number of kilograms of the said acids contained in 1 litre. The specific gravities were taken with the utmost care in a specific gravity bottle, provided with an accurate thermometer, and are guaranteed to be accurate within 0·0001. The acid was analysed by titration with N/5 solution of sodium hydroxide, which had been standardised with N/5 hydrochloric acid. This acid was standardised with pure sodium carbonate, and the results were verified by a gravimetric estimation as silver chloride. The titrations were done with the greatest care, and the experimental error never exceeded 0·02 per cent. with the weaker acids, and 0·05 per cent. with the stronger ones. The weaker acids were weighed in a Winkler's stop-cock pipette; the fuming ones in sealed glass bulbs.

L. de K.

The Place of Fluorine in the Classification of the Elements. By H. Moissan (*Bull. Soc. Chim.* [3], **5**, 880—885).—Whilst fluorine in many respects behaves as the most energetic member of the chlorine family, in some ways it is markedly distinguished from chlorine, and seems almost to bear a remote analogy to oxygen; as instances in point are cited, the ready combustibility of charcoal in fluorine, the dissimilarity of calcium fluoride from the chloride, and its

resemblance to the oxide, the solubility of silver fluoride in water, and the stability of aluminium fluoride towards water. It is pointed out also that, whilst the compounds of fluorine with the non-metallic elements, including its organic compounds, are uniformly more volatile than the corresponding compounds of chlorine, its metallic salts require, as a rule, a higher temperature for fusion than the corresponding chlorides. Comparative numerical data are given.

Jn. W.

Action of Fluorine on Phosphorus Trifluoride. By H. Moissan (*Bull. Soc. Chim.* [3], **5**, 880).—In order to study the action of fluorine on other gaseous substances, the two gases were admitted by separate tubes to the central portion of a platinum tube 15 cm. long, the ends of which were closed by transparent plates of fluorspar, and the resulting gaseous product was conducted to the water or mercury trough by a third tube near the end. When fluorine comes in contact with phosphorus trifluoride, a yellow flame of low temperature is seen, and the product of the reaction is mainly phosphorus pentafluoride, the residue consisting of unchanged trifluoride.

Jn. W.

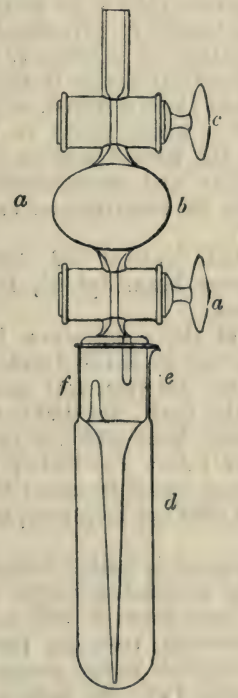
Persulphates. By Berthelot (*Compt. rend.*, **112**, 1481—1483; see also Berthelot, *Compt. rend.*, **86**, 20, 71, and 277; Marshall, Trans., 1891, 771; Mendeléeff, *Bull. Soc. Chim.*, **38**, 168; Traube, *Ber.*, **22**, 1518, and **24**, 1764).—The mixture of persulphuric and sulphuric acids obtained by electrolysis, when neutralised by baryta-water or potash solution, yields a quantity of the normal persulphate, which is greater when the operation is carried on at a very low temperature. The neutralised solution rapidly becomes acid again, particularly on heating; at the same time losing oxygen. The quantity of active oxygen is proportional to the quantity of sulphuric acid formed in the decomposition.

Barium persulphate is soluble, and as neutral as the thiosulphate or permanganate; its decomposition proceeds according to the equation $BaS_2O_8 + H_2O = BaSO_4 + H_2SO_4 + O$.

In titrating the active oxygen by the usual reagents, it is necessary to take into account the hydrogen peroxide often coexistent with persulphuric acid, or capable of being formed during the dilutions and other operations. The proportion of hydrogen peroxide present has been found to vary from 0 to 2 mols. for each mol. of persulphuric acid. Viewing the whole of the active oxygen present in the extreme case as united to the sulphur, the complex acid would have the formula S_2O_9,nH_2O. There is no proof of the existence of a neutral and anhydrous compound, such as the holoxide, SO_4, of Traube.

The salts of persulphuric acid are distinct and definite, and comparable with the permanganates, perchlorates, permolybdates, and pertungstates.

W. T.



Thiosulphates. By A. Fock and K. Klüss (*Ber.*, **24**, 3016—3017).—*Potassium calcium thiosulphate*, $3K_2S_2O_3,CaS_2O_3 + 5H_2O$, is obtained in colourless, monosymmetric crystals, by evaporating on the water-bath a mixture of potassium and calcium thiosulphate solutions.

The axial relation of the crystals is $a : b : c = 1{\cdot}7010 : 1 : 0{\cdot}8931$; $\beta = 80° 2'$.

Potassium strontium thiosulphate, $K_2S_2O_3,SrS_2O_3 + 5H_2O$, is prepared in a similar manner to the calcium salt; it is readily soluble in water, and crystallises in slender, lustrous, silky needles, which are not well adapted for crystallographic measurements. J. B. T.

Ammonium Dithionate Hydrochloride. By A. Fock and K. Klüss (*Ber.*, **24**, 3017—3018).—On mixing solutions of ammonium dithionate and ammonium chloride in molecular proportions, and evaporating, a compound of the formula $(NH_4)_2S_2O_6,HCl$, is deposited in rhombic crystals. The axial relation is $a : b : c = 0{\cdot}09827 : 1 : 0{\cdot}9612$. The same substance is also formed in presence of two or more molecular proportions of ammonium chloride. J. B. T.

Revised Nitric Acid Tables. By G. Lunge and H. Rey (*Zeit. ang. Chem.*, 1891, 165—170).—The tables are constructed on similar lines to the revised hydrochloric acid tables (compare this vol., p. 11), and similar processes were employed in their construction, but instead of weighing the acid in glass bulbs, or in a Winkler's stop-

cock pipette, a new form of weighing pipette, shown in the figure, was used.

Above the stop-cock *a* is fixed a bulb *b*, of about 2 cm. diameter, connected with a second stop-cock *c*. The lower part of the pipette fits into a glass tube *d*, which has a ground neck. When the pipette is wanted for use, the stop-cock *a* is closed; suction with the mouth is applied to the top, and the stop-cock *c* immediately closed, by which means a diminished pressure will be obtained inside the bulb *b*. The point of the pipette is now dipped into the acid, the stop-cock *a* opened, and the acid allowed to ascend as far as the stop-cock, which is then immediately turned off. After wiping the pipette, it is fixed into the tube *d* and weighed. The pipette is now turned round, so as to open communication between the channels *e* and *f*. The stop-cock *c* is opened, water is squirted into the bulb *b*, and then allowed to flow through *a* into the pipette. The diluted acid runs into the tube *d*, the air of which escapes through *e* and *f*. The acid is finally emptied into a beaker and titrated. By using this apparatus, any loss of nitric fumes is avoided. L. DE K.

Compounds of Sulphur and Phosphorus. By J. MAI (*Annalen*, **265**, 192—208).—The object of these experiments was to ascertain whether the boiling point of triphosphorus hexasulphide, P_3S_6, was sufficiently below that of stannous chloride (606°), and above that of phosphorus pentasulphide (518°), to allow of its advantageous employment as a heating vapour in pyrochemical investigations.

When an intimate mixture of sulphur (2 atoms) and amorphous phosphorus (1 atom) is carefully heated in an atmosphere of carbonic anhydride, and the product then distilled, a yellow, crystalline substance (b. p. about 410°), which seems to contain the compound P_4S_3, passes over first; the later fractions consist of a mixture of triphosphorus hexasulphide and phosphorus pentasulphide, which cannot be separated into its constituents, as they boil at the same temperature (about 508°).

Phosphorus pentasulphide boils at 332—340° under a pressure of 10—11 mm.; triphosphorus hexasulphide, P_3S_6, boils at 335—340° under the same conditions.

When the compound of the composition P_4S_3, prepared from its elements by the usual method, is distilled under a pressure of 11 mm., a yellow liquid passes over between 230° and 240°, and amorphous phosphorus remains in the flask; the distillate is almost completely soluble in carbon bisulphide, from which it is gradually deposited in crystals of the composition P_4S_3. The boiling point of this compound under the ordinary pressure would be about 408—418°; it begins to soften at 130—135°, but does not melt completely until the temperature has risen above 160°.

When phosphorus (2 atoms) is melted with sulphur (3 atoms), and the product submitted to distillation under a pressure of 11 mm., almost the whole passes over between 285° and 335°; the distillate slowly solidifies to a yellowish, resinous, pasty mass, which, when digested with carbon bisulphide under pressure, yields a crystalline compound of the composition P_4S_7; the mother liquors from this compound contain a crystalline substance, which seems to be a mixture of phosphorus trisulphide with P_4S_5. F. S. K.

New Method of Preparing Carbon Oxysulphide. By J. Nuricsán (*Ber.*, **24**, 2967—2974).—Carbon oxysulphide is obtained when carbonyl chloride is passed through concentrated sulphuric acid to dry it, and then through a tube 50 cm. long, filled with ignited asbestos well mixed with finely pulverised cadmium sulphide, the tube being placed in a combustion furnace and heated. The author finds that even when no external heat is applied a small quantity of carbonyl sulphide is formed, but the most favourable temperature for its formation appears to be 260—280°. The gas thus produced was found on analysis to contain COS, 94·87 per cent.; CO, 3·98 per cent.: air, 1·15 per cent. A quantity of crystals, which were identified as cadmium chloride, were observed in a tube previously charged with a layer of cadmium sulphide and heated in a flame during the passage of a current of carbonyl chloride; the reaction, therefore, appears to be a double decomposition.

A. R. L.

Allotropic Silver. III. Blue Silver. By M. C. Lea (*Phil. Mag.* [5], **31**, 497—504; compare Abstr., 1891, 803).—When silver nitrate is added to a solution of dextrin made alkaline with sodium or potassium hydroxide, the alkali being kept in moderate excess, the silver is first precipitated as the ordinary brown oxide, but the colour gradually changes to reddish-chocolate, and the silver begins to dissolve, and in a few minutes has completely dissolved to form an almost black liquid, a few drops of which, when added to a large quantity of water, give a splendid red liquid, that spectroscopic examination shows to be a perfect solution. Different specimens of dextrin behave differently, and the common brown form seems to give the best results. Convenient proportions are 20 grams of sodium hydroxide and 20 grams of dextrin in 1000 c.c. of water, 14 grams of silver nitrate previously dissolved in a small quantity of water being gradually added.

It is interesting to observe that allotropic silver can be formed and can exist in solution in neutral, acid, and alkaline liquids. The alkaline solution spontaneously deposits allotropic silver after some time, and precipitation is immediate on the addition of dilute nitric or sulphuric acid. Even with a large excess of acetic acid, however, precipitation is incomplete. When the precipitate has once formed, it is almost insoluble, but on washing dissolves to a very small extent, forming a rose-red liquid.

A small quantity of sodium phosphate, when added to the alkaline solution, precipitates the whole of the allotropic silver with a ruby-copper colour, which after prolonged washing changes to deep Nile-green, and becomes slightly soluble, forming a wine-red solution.

The various forms of allotropic silver show different body and surface colours, which tend to be complementary. The precipitate by sodium phosphate, for example, when spread thickly on paper, dries with a bright-green, metallic colour, but after it has been changed to deep green by washing, films dry with a dark gold or copper surface-colour.

Although the dry substance has all the appearance of a metal, it

may contain 8 to 10 per cent. of organic matter that cannot be removed, even by prolonged washing with hot water under pressure. Four specimens of carefully purified material contained respectively 93·77, 94·27, 92·86, and 96·64 per cent. of metallic silver. When the allotropic forms are heated, a vapour is evolved which condenses in small, brownish drops, with an empyreumatic odour. The residue consists of bright white metallic silver, and when dissolved in nitric acid, leaves a residue of black flakes of carbon. When the allotropic silver is dissolved in dilute nitric acid, and the silver precipitated by hydrochloric acid, the filtrate, on evaporation, leaves a small residue of a yellowish, gummy substance.

Tannin reduces silver nitrate to allotropic silver more readily than does dextrin, and gives better results in presence of sodium or potassium carbonate than with the caustic alkalis. 24 grams of anhydrous sodium carbonate are dissolved in 1200 c.c. of water, and mixed with 72 c.c. of a filtered 4 per cent. solution of tannin. 24 grams of silver nitrate dissolved in a small quantity of water is added gradually, and solution of the silver takes place immediately. After standing for a day or two, the intensely dark-coloured liquid may be poured off from a small quantity of black precipitate. On adding a small quantity of dilute acid, the allotropic silver is precipitated, and in films dries with a bluish, steel-grey, surface-colour.

Blue allotropic silver (including the green and steel-grey varieties) shows endless variations, and cannot be reduced to one type. Slight differences in the conditions of formation result in very different products. Of ten products obtained by the action of tannin and sodium carbonate in various proportions, several were easily and completely soluble in ammonia, whilst some dissolved slightly, and others not at all. Some of the specimens, insoluble in water, when treated with phosphoric acid, did not dissolve, but on washing away the acid, were found to have become soluble in water; other insoluble specimens did not behave in this way. Some of the solutions were scarcely affected by acetic acid, whilst others were partially, and others almost completely, precipitated.

The films on paper vary greatly in their sensitiveness to light, and in the ease with which they are converted into the yellow, intermediate form. The least sensitive modification is that precipitated by nitric acid; it dries with a steel-grey colour. The modifications precipitated by acetic acid tend to have a greenish metallic surface, and are more sensitive. Permanency varies greatly in different specimens, and is increased by thorough washing.

The blue, grey, and green forms are related to the black, or dark-grey normal silver, and tend to pass into it, whilst the gold-coloured modification tends to change into bright white metallic silver on the surface, with dark, or even black, silver underneath.

Tannin likewise reduces silver nitrate in presence of lithium, ammonium, magnesium, barium, calcium, and strontium carbonates. The product with strontium carbonate is dark-red whilst moist, but dries with a rich, bluish-green, metallic surface-colour in thick films, but is red and transparent in thin films.

The intermediate golden-yellow form produced during the passage of the gold-coloured allotropic form to white normal silver has none of the properties of the original form, except its colour and lustre. It is hard and tough, is not converted into normal silver by friction and high pressure, and offers as much resistance as normal silver to the action of oxidising and chlorinating agents. The difference between the original form and the intermediate form lies in the fact that the latter has a crystalline structure, which becomes evident on treating the film with ferric chloride solution.

When the blue form is gently heated, it also first becomes yellow, and then changes to white normal silver. A film on glass begins to change from blue to yellow at about 180°, and the same change is produced by the action of light, some specimens requiring a few hours' exposure to sunlight, whilst others require several days.

The author considers that in these allotropic forms the silver exists in a state of atomic division, and that this is true also of the pyrophoric forms of various metals. He points out that there is a difference between chemical and mechanical division, and that a metal may form a compact mass, and yet be in a state of atomic division, whilst on the other hand it may be in a fine state of mechanical division, and yet possess a high degree of molecular complexity. C. H. B.

Characteristics of the Alkaline Earths. By G. Brügelmann (*Zeit. anal. Chem.*, **30**, 579—580).—In his attempts to prepare baryta by igniting the hydroxide in graphite crucibles, the author has been unable to obtain a pure product, the crucible being always attacked. The supposition of the dimorphism of barium oxide, and the assumed catalytic action of platinum (Abstr., 1890, 850), must therefore be abandoned, since the substance obtained as a felted mass of needles showing chromatic polarisation can no longer be regarded as baryta. Since a similar action occurs with lime and strontia, all statements respecting the specific gravity, &c., of the alkaline earths prepared in other than platinum vessels, must be withdrawn. The statements of Fresenius and others, that strontium carbonate fuses while decomposing, cannot be confirmed. Much contraction occurs, but the oxide produced retains the form of the original mass of carbonate, and is, at most, slightly sintered. M. J. S.

Composition of a Boiler Incrustation. By A. Christ (*Zeit. ang. Chem.*, 1891, 77).—The author communicates an analysis of a curious boiler deposit, which owed its origin partly to the use of an animal or a vegetable lubricating oil. CaO, 11·09; MgO, 9·79; Fe_2O_3, 5·60; Al_2O_3, 1·10; PbO, 0·98; CuO, trace; SiO_2, 16·00; SO_3, 1·71; fatty acids, 22·62; neutral fats, 23·84; moisture, 2·69; combined water and organic matter, 5·22 per cent. L. de K.

Action of Hydrogen Peroxide and of Water saturated with Carbonic Anhydride on Magnesium. By G. Giorgis (*Gazzetta*, **21**, 510—514).—According to Weltzien (*Annalen*, **138**, 132), hydrogen peroxide acts slowly on magnesium, forming an alkaline liquid, which contains the normal hydroxide, $Mg(OH)_2$, and on evaporation to dry-

ness leaves a white, strongly alkaline mass, completely soluble in water. The author has also observed the slow action of hydrogen peroxide on magnesium and the alkalinity of the solution, but finds that, after remaining for a few days, acicular crystals are deposited, which effervesce on treatment with hydrochloric acid. On treating metallic magnesium in a vacuum with hydrogen peroxide free from carbonic anhydride, the liquid after a time becomes slightly alkaline, and on evaporating to dryness in a vacuum, a flocculent precipitate separates, which is only very sparingly soluble in water free from carbonic anhydride. On the other hand, when magnesium is treated with distilled water saturated with pure carbonic anhydride, the liquid soon becomes strongly alkaline, and the metal is energetically attacked with evolution of hydrogen; the reaction slackens very gradually, and gas ceases to come off after about 10 or 12 hours. The solution, after a time, deposits acicular crystals having the composition $MgCO_3 + 3H_2O$.

The evolution of hydrogen by the action of an aqueous solution of carbonic anhydride on magnesium is noteworthy; the reaction also provides an easy method for the preparation of the normal carbonate of magnesium. S. B. A. A.

Cuprammonium Oxide. By PRUD'HOMME (*Chem. Centr.*, 1891, ii, 339—340; from *Mon. Sci.* [4], **5**, 681).—Cuprammonium oxide is a more powerful oxidising agent than hydrogen peroxide; it acts more rapidly on cellulose, and converts it into oxycellulose; it also decolorises indigo-blue more rapidly than hydrogen peroxide. With "mercerised" cotton wool, it acts like hydrogen peroxide.

In preparing it, by agitating copper turnings with ammonia and air, both cupric oxide and nitrous anhydride are formed; the nitrous anhydride is, however, only formed at a later stage of the reaction. Ammonium nitrite oxidises copper, and nitric peroxide is formed in the first instance; ammonia is also liberated by the reaction, and when this occurs, free nitrogen is formed instead of nitric peroxide. The liquid becomes intensely blue; an excess of water precipitates cupric hydroxide; dilute acetic acid precipitates cupric oxide as soon as the ammonia is exactly neutralised. J. W. L.

Action of Ferric Chloride on Metallic Sulphides. By CAMMERER (*Chem. Centr.*, 1891, ii, 370; from *Berg. Hütten Zeit.*, **50**, 261—264, 282—284).—In a sealed tube, ferric chloride reacts with both cupric and cuprous sulphides, cupric chloride, ferrous chloride, and sulphur being formed. With precipitated ferrous sulphide or iron pyrites, ferrous chloride and sulphur are the products; with copper pyrites, cupric chloride, ferrous chloride, and sulphur are formed. With arsenious sulphide, ferrous chloride, sulphur, and arsenious chloride are first formed; the latter, however, is further oxidised to arsenic anhydride by the continued action of excess of ferric chloride. With either precipitated or native antimony trisulphide, antimonious chloride, ferrous chloride, and sulphur are formed. With stannous sulphide, stannic chloride, ferrous chloride, and sulphur are formed.

J. W. L.

Manganese Tetrachloride. By H. M. Vernon (*Phil. Mag.* [5], **31**, 469—484).—Fisher (Trans., 1878, 409) endeavoured to show that the dark-brown liquid obtained on dissolving manganese dioxide in hydrochloric acid contains manganese tetrachloride. Pickering, who repeated Fisher's experiments, and made, in addition, a number of his own (Trans., 1879, 654), thought that the evidence was in favour of the existence of Mn_2Cl_6 in the solution, and not of $MnCl_4$.

The author now attempts to decide between these views by experiments on the rate at which the "available" chlorine is evolved at different temperatures. If Mn_2Cl_6 is really formed in the solution, half the available chlorine should be much more easily removed by means of a current of air passed through the solution than the other half, whereas, if $MnCl_4$ is present, the rate of removal should be more regular. The curves obtained from the experimental results at various temperatures show no break at the point where half the available chlorine has been driven out, so the author concludes that when Mn_3O_4, Mn_2O_3, or MnO_2 is dissolved in hydrochloric acid, the only higher chloride formed is $MnCl_4$. The brown solution is much more stable at $-26°$ than at ordinary temperatures.

Pickering found that the presence of $MnCl_2$ in the solution from the beginning rendered it more stable. This the author accounts for on the supposition that the $MnCl_4$ dissociates directly into $MnCl_2$ and Cl_2, so that the presence in excess of $MnCl_2$, one of the products of dissociation, would diminish the actual amount of dissociation.

J. W.

Calorimetric Researches on the Condition of Silicon and of Aluminium in Cast Iron. By F. Osmond (*Compt. rend.*, **113**, 474—476).—The heat developed on dissolving 1 gram of cast iron containing different amounts of silicon in a saturated solution of the double chloride of copper and ammonium was measured. From the results, it appears that when the silicon is present in sufficient quantity, it combines with the iron with the development of heat and formation of a compound which is dissociated by an excess of iron, and therefore only exists when the amount of silicon in the alloy is sufficiently great. Hence the difference between the quantities of heat found and those calculated in the above experiments changes sign when the amount of silicon present reaches a percentage somewhere between 4·1 and 7·3.

Samples of cast iron containing aluminium were also examined in the above manner. The results show that aluminium dissolves in cast iron with the absorption of heat. H. C.

Attempts to Prepare Metallic Chromium from Chromic Fluoride. By W. P. Evans (*Zeit. ang. Chem.*, 1891, 18—20).—The author tried the effect of metallic sodium, metallic zinc, and mixed carbon and silica on chromic fluoride at a very high temperature, in the hope of getting metallic chromium.

1. Action of Sodium.—The metal was heated at 400° in a porcelain tube, and the fluoride passed over it. The latter was prepared by distilling a mixture of lead chromate, calcium fluoride, and sulphuric acid. A very strong reaction took place and the tube became

red-hot, but was soon stopped up. After cooling, the excess of sodium was dissolved out by water, and the residue examined for metallic chromium. But very little was found, and this was chiefly in combination with silicon. The experiment was repeated in an iron apparatus, in which the vapour of about 70 grams of metallic sodium was brought in contact, at a temperature of 900—1000°, with the fluoride. The chief products obtained were amorphous, green chromic oxide, bright-green particles of sodium-chromic fluoride, and a greyish, brittle, spongy mass, which was chiefly located near the fluoride delivery tube. On analysis, it proved to be an alloy of sodium with about 25 per cent. of chromium intermixed with a little chromic oxide and a trace of iron. The experiment was repeated, and, this time, to avoid contamination with iron, in a Hessian crucible. The crucible and the delivery tubes were well lined inside with a mixture of 6 parts of alumina and 1 part of potassium chloride. After being kept red-hot for half an hour, the experiment came to a premature end through the tube getting stopped up. After cooling, there was found adhering to the tube a greyish, stalactitic mass, which for the greater part dissolved in hot water. The insoluble portion consisted of fairly pure, crystalline, metallic chromium.

2. Action of Zinc.—About 200 grams of zinc was heated to boiling under a layer of salt, and the fluoride was passed in through a porcelain delivery tube. The greater part of the fluoride was taken up by the salt with formation of sodium chromate. The zinc regulus dissolved slowly in nitric acid, which gradually acquired a greenish tinge. No chromium could be detected in the insoluble residue. There was, however, good reason to believe that an alloy of zinc with about 0·67—1·80 per cent. of chromium had been formed. In the porcelain tube, however, a lustrous, steel-like substance was found, which on analysis proved to be practically pure metallic chromium.

3. Action of Carbon and Silica.—The fluoride was passed through a strongly heated porcelain tube containing small granules of a mixture of 9 parts of amorphous silica and 4 parts of powdered charcoal. Abundant vapours of silicon fluoride made their escape, and on opening the tube, sharp, shining, hexagonal crystals of chromic oxide were found; besides this, an almost black, brittle mass, which on analysis yielded Cr, 30·13; SiO_2, 48·53; C, 11·39; O, 9·95, containing, therefore, 8·39 per cent. of metallic chromium.

From these experiments, it seems that although there is not the slightest doubt about the reduction of the chromic fluoride by the processes described, it is not possible to prepare the metal on the large scale in this way. L. DE K.

Pure Bismuth. By A. CLASSEN (*J. pr. Chem.* [2], **44**, 411—414; compare Abstr., 1891, 271, 525, 1324).—This is another chapter in the controversy between Schneider and Classen as to pure bismuth. Against Schneider's analyses of commercially pure bismuth (Abstr., 1891, 1324), the author puts in two analyses, the one of "chemically pure bismuth for scientific investigations," which gave some 10 grams of lead chloride from 500 grams of the metal, the other of "bismuth

purissimum," from the same factory, which contained, besides lead (undetermined), 1·56 per cent. of copper and 0·45 per cent. of iron.

The author's electrolytic bismuth melts at 264°; "bismuth puriss." from Tromsdorff melted at 271·8°, and another sample at 273°; "absolutely pure bismuth" from Tromsdorff melted at 265—266°; "bismuth puriss." from Schering melted at 269—270°. This is further evidence of the impurity of commercial "pure bismuth."

The rest of the paper deals with Marignac's method and material, and is purely polemical. A. G. B.

Mineralogical Chemistry.

Asphalt in Utah and Colorado. By G. H. Stone (*Amer. J. Sci.*, **42**, 148—159).—In western Colorado and north-eastern Utah, asphalt deposits of four classes are represented: (1) asphaltic sand-rock, known also as sand-asphalt and bituminous rock, the most abundant of all the asphaltic deposits; (2) bituminous shales or marls; (3) bituminous limestones; and (4) outflow or overflow asphalt, including all forms of asphalt that have oozed out of the rock that originally contained them. These deposits are described in detail by the author, and the various theories that have been propounded to explain the origin of petroleum and asphalt are fully discussed. The author intends to complete a map of the asphalt exposures, and to publish a more complete account of them. B. H. B.

Gmelinite from Nova Scotia. By L. V. Pirsson (*Amer. J. Sci.*, **42**, 57—63).—The zeolites of Nova Scotia have long been noted for the size and perfection of their crystals, and amongst them gmelinite has held a prominent place. The author has consequently made a careful investigation of the crystalline form and physical properties of this mineral. The material employed was collected at Pinnacle Island, Nova Scotia. In order to control the crystallographic work, two analyses were made. In I the outer shell was analysed, and in II the inner nucleus, the results being as follows;—

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	K_2O.	Na_2O.	H_2O.	Total.
I.	50·35	18·33	0·26	1·01	0·15	9·76	20·23	100·09
II.	50·67	18·50	0·15	1·05	0·16	9·88	20·15	100·56

In considering the bearing of these results on the identity of this mineral with chabazite, there is an apparent discordance. The results of the crystallographic work point to a difference in axial ratios, and there is also a different habit and cleavage. On the other hand, the twinning and the chemical constitution indicate the identity of the species. These apparent discrepancies the author explains by the hypothesis that the effect of soda is to lengthen the vertical axis; the analyses of chabazite and gmelinite showing that soda and lime may

replace each other to any extent. According to this view, gmelinite would bear much the same relation to chabazite as enstatite does to hypersthene. Whether it should be considered a distinct species would be largely a matter of choice or convenience. B. H. B.

Newtonite and Rectorite, two new Minerals of the Kaolin Group. By R. N. Brackett and J. F. Williams (*Amer. J. Sci.*, **42**, 11—21).—The authors describe two hydrous silicates of aluminium which they believe have not before been observed. The mineral, which they term *newtonite*, is found on Sneed's Creek, Newton Co., Arkansas, in a dark-grey clay, of lower carboniferous age. It is a pure white, soft, compact, homogeneous substance, having a sp. gr. of 2·37. Analysis gave the following results :—

SiO_2.	Al_2O_3.	Loss on ignition.	Fe_2O_3.	CaO.	K_2O.	Na_2O.	Total.
40·22	35·27	22·89	0·21	0·54	0 99	0·73	100·85

These results are in accord with the formula $Al_2O_3,2SiO_2,4H_2O$. Under the microscope, the mineral is seen to be entirely made up of minute rhombs.

The second hydrous silicate of aluminium, *rectorite*, which is also to be regarded as new, is found in the Blue Mountain mining district, Arkansas. When pure, it is a soft, white mineral occurring in large leaves. Analysis gave the following results :—

SiO_2.	Al_2O_3.	Loss on ignition.	Total.
54·32	37·69	7·99	100·00

In this analysis, small proportions of ferric oxide, lime, magnesia, and alkalis have been disregarded. The formula of the mineral is $Al_2O_3,2SiO_2,H_2O$ + Aq.

From the authors' researches it is probable that three members of the kaolin series out of the possible four are known; and the present status of the series may be concisely stated as follows :—

1. Rectorite	$Al_2O_3,2SiO_2,H_2O$ + Aq	Monoclinic (?).
2. Kaolin and members	$Al_2O_3,2SiO_2,2H_2O$	Monoclinic or O.
of the kaolin group	$Al_2O_3,2SiO_2,2H_2O$ + Aq	O.
3. —	$Al_2O_3,2SiO_2,3H_2O$	—
4. Newtonite	$Al_2O_3,2SiO_2,4H_2O$ + Aq	Rhombohedral.

B. H. B.

New Analyses of Astrophyllite and Tscheffkinite. By L. G. Eakins (*Amer. J. Sci.*, **42**, 34—37).—1. *Astrophyllite.*—From a discussion of the analyses published by Bäckström and by König, Brögger deduces the general formula $R''_4R'_4Ti(SiO_4)_4$ for this mineral. The new analysis made by the author closely confirms this formula, agreeing with it better than those from which it was derived. Calculating the small amount of ferric oxide present in with the R'' group, the molecular ratios of the author's analysis give the following elementary proportions :—

$$Si_{587}O_{2389}Ti(Zr)_{153}R''_{536}R'_{234}H_{164}.$$

which reduces to

$$Si_4O_{16\cdot3}Ti_{1\cdot04}R''_{3\cdot65}(R'H)_{4\cdot7}.$$

2. *Tscheffkinite.*—A fragment of this rare mineral from Bedford Co., Virginia, analysed by the author, showed a distinctly banded structure of lustrous black and dull-black material. The analyses, however, show that these two bands are practically identical, the dull being somewhat more hydrated. The molecular ratios seem to lead to no definite or satisfactory formula, a result quite in accordance with the evidence furnished by the microscopic examination of sections.

B. H. B.

Minerals in Hollow Spherulites of Rhyolite. By J. P. Iddings and S. L. Penfield (*Amer. J. Sci.*, **42**, 39—46).—The occurrence of fayalite with other minerals in the lithophysæ and hollow spherulites at Obsidian Cliff has been described by the authors (Abstr., 1891, 26), and they have also called attention to the occurrence of fayalite in obsidian at Lipari and Vulcano (Abstr., 1891, 158). In the present paper, they contribute further to the knowledge of these aqueo-igneous products in siliceous lavas by describing a somewhat different development of hollow spherulites in rhyolites at Glade Creek, Wyoming. In this rhyolite, as in the obsidian of Obsidian Cliff, fayalite occurs in association with abundant quartz, as the result of the mineralising action of vapours in the cooling acid lavas. The quartz in both localities has an unusual, simple, and perfect development, and is accompanied by an uncommon form of sanidine and by tridymite. Moreover, in certain hollow spherulites the fayalite is replaced by hornblende and biotite.

B. H. B.

Siliceous Sand of Monte Soratte. By G. Giorgis (*Gazzetta*, **21**, 514—516).—At St. Oreste, near Monte Soratte, there is a deposit of quartzose sand of the pliocene age lying unconformably on the jurassic limestone of the district. Microscopically it is seen to consist of quartz, orthoclasic felspar, and small quantities of mica. Its composition is as follows:—

Water at 100° = 0·20 *per cent.*

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	Alkalis.
Dry residue.....	93·50	3·62	traces	traces	—	2·88
Ditto after levigation.....	94·48	2·99	0·11	—	—	2·42

S. B. A. A.

Reproduction of Acid Rocks. By H. Le Chatelier (*Compt. rend.*, **113**, 370—373).—The distinctness, purity, and uniform development of felspar crystals show undoubtedly that they have been formed within a fluid mass and not from a solid mass under the influence of mineralising agents, or from the devitrification of a glass The great pressure under which crystallisation takes place has prevented the felspar from becoming vitreous or amorphous, as it does when heated under atmospheric pressure. Experiments made under a pressure of

5000 atmos. gave only glasses, probably because cooling took place much too rapidly. C. H. B.

Kamacite, Tænite, and Plessite, from the Welland Meteoric Iron. By J. M. Davison (*Amer. J. Sci.*, **42**, 64—66).—The Welland siderolite was described by E. E. Howell (*Proc. Rochester Acad. Sci.*, 1890, 86—87). Its analysis gave 91·17 per cent. of iron, and 8·54 per cent. of nickel. It is singularly free from troilite and schreibersite, and thus offered a good opportunity for the analysis of its separated nickel-iron alloys. Between the decomposed outside and the compact centre there was a zone in which the oxidation was superficial, and confined to the planes of contact of the different alloys that form the Widmanstätten figures. It thus became possible to separate the kamacite and tænite in quantities sufficient for analysis. It was intended to analyse the plessite as a whole; but, on examination, its fine layers were so suggestive of kamacite and of tænite that an attempt was made to analyse them separately. The analytical results were as follows, the analyses of kamacite and tænite being given, each next to its corresponding part of the plessite:—

		Plessite.		
	Kamacite.	Kamacite-like part.	Tænite-like part.	Tænite.
Fe....	93·09	92·81	72·98	74·78
Ni ...	6·69	6·97	25·87	24·32
Co....	0·25	0·19	0·83	0·33
C	0·02	0·19	0·91	0·50
	100·05	100·16	100·59	99·93

The physical and chemical correspondences appear to justify the conclusion that in the Welland meteoric iron there are but two distinct nickel-iron alloys—kamacite and tænite, and that the so-called plessite consists merely of thin, alternating lamellæ of these two alloys. It is unsafe to generalise on a single analysis; but an examination of the markings of other meteoric irons suggests the thought that in them also there may be but two distinct alloys.

B. H. B.

A Gold-bearing Hot-spring Deposit. By W. H. Weed (*Amer. J. Sci.*, **42**, 166—169).—The author has examined a series of specimens from the Mount Morgan gold mine, Queensland, with a view to compare them with the siliceous sinters from the hot-spring region of the Yellowstone Park. These specimens possess unusual interest, inasmuch as the observations of the Government Geologist of Queensland show that the Mount Morgan mine, which paid a dividend of £1,200,000 in 1889, works a deposit of a hot spring, the ore being a siliceous sinter impregnated with auriferous hæmatite (compare Abstr., 1886, 21). The Steamboat Springs of Nevada are surrounded by deposits of sinter, in the fissures of which ore deposition is now taking place, a small amount of gold being found in these contemporaneous mineral veins. The Mount Morgan deposit is, however, the only hot-spring deposit known that has been found to contain

gold in workable quantities. A careful search for such deposits has been made for the past eight years in the Yellowstone Park, the most remarkable hot-spring district of the world, without bringing to light a single case of the sort. Hot-spring waters and deposits have been most carefully analysed, without indicating the presence of even a trace of the precious metals. B. H. B.

Note by Abstractor.—In discussing the origin of the Mount Morgan deposit, the author accepts Mr. R. L. Jack's theory, that the deposit is that of a geyser, without pointing out that the origin of this ore-deposit has been the theme of much controversy. According to some, the deposit is thought to be an auriferous zone traversed by a series of quartz veins of auriferous mundic. Others think that it is the decomposed cap of a large pyrites lode. The last contribution to the discussion is afforded by a paper read before the American Institute of Mining Engineers, in June, 1891, by Mr. T. A. Rickard, who advocates the theory of metamorphosis and replacement. The ore-deposit, he thinks, represents an altered portion of shattered country rock, which, by reason of its crushed condition, was readily acted on by mineral solutions, and that these solutions replaced the basic and felspathic with acid and quartzose material, which was also auriferous. It is its quartzose and permeable character which has saved from disintegration the mass thus affected, and has preserved it as an ore-body on the summit of the hill.

Analysis of a Hot Mineral Spring at Sclafani. By E. Paternò (*Gazzetta*, **21**, ii, 40—51).—This water issues at a temperature of 32·9°, and has a sp. gr. of 1·0074 compared with water at 0°. It contains 0·1982 gram per litre of free carbonic anhydride, 0·0171 gram of free hydrogen sulphide, and 16·9 c.c. of nitrogen per litre. The total weight of carbonic anhydride per litre is 0·3527 gram, and of hydrogen sulphide 0·0185 gram. The residue from a litre, when dried at 110°, weighs 12·510 grams.

One litre of the water contains in grams:

SiO_2.	SO_3.	Cl.	Br.	I.	CaO.	SrO.
0·0746	0·0790	6 6900	0·0148	0·0062	0·4720	0·1145

MgO.	Na_2O.	K_2O.	Fe_2O_3 and Al_2O_3.
0·3550	5·5512	0·0170	0·0015

together with 0·0003 gram of organic matter and traces of phosphoric acid, lithium, barium, and manganese. The results obtained differ considerably from those published by Cappa in 1847. W. J. P.

Organic Chemistry.

Constitution of Mercuric Fulminate. By A. F. Hollemann (*Rec. Trav. Chim.*, **10**, 65—84; compare Abstr., 1891, 64).—In order to determine whether mercuric fulminate contained the same empirical

group, $C_2N_2O_2$, as the "dinitrosacyls" (Abstr., 1889, 49), the author studied the action of benzoic chloride on dry mercuric fulminate, and found that a dibenzoylcarbamide was formed. In the course of further experimental work, which is here described at some length, he has determined this to be symmetrical and to be identical in melting point (197°) and physical characters with the dibenzoylcarbamide obtained by the action of guanidine carbonate on anhydrous benzoic acid (Creath, *Ber.*, **7**, 1739), and with that described by Buddéus (Abstr., 1890, 1253). Schmidt's statement that dibenzoylcarbamide yields benzamide when boiled with potassium hydroxide solution (this Journal, 1872, p. 718) is incorrect. The author has previously pointed out the analogy which this formation of a substituted carbamide presents to the conversion of isocyanic acid into an analogous substance, whilst Scholl (Abstr., 1891, 282) obtained acetylisocyanic acid by the action of acetic chloride on mercuric fulminate. From this it would seem that the formation of dibenzoylcarbamide is also due to the formation of an isocyanic derivative. Kekulé's formula, $CN{\cdot}CH_2{\cdot}NO_2$, neither explains these results nor the fact that carbamide is formed on the decomposition of copper ammonium fulminate by hydrogen sulphide (Gladstone, *Quart. Journ. Chem. Soc.*, **1**, 228), nor Steiner's observation (this Journal, 1875, p. 882), that urea and guanidine result from the action of ammonia on mercuric fulminate. Steiner's formula, $OH{\cdot}N{:}C{:}C{:}N{\cdot}OH$, explains these reactions, but not the formation of chloropicrin and of cyanogen chloride by the action of chlorine water on mercuric fulminate. Regarding fulminic acid as a desmotropic compound, the author suggests the following tautomeric formula, which he thinks Divers' results (Trans., 1884, 13) support:

$$\text{I.}\quad \begin{matrix} C{:}NOH \\ \| \\ C{:}NOH \end{matrix} \rightarrow \begin{matrix} HC{:}NO \\ | \\ HC{:}NO \end{matrix} \rightarrow \begin{matrix} H_2{\cdot}C{\cdot}N \\ | \\ CN \end{matrix} < \begin{matrix} O \\ | \\ O \end{matrix} \quad \text{II.}$$

To demonstrate the presence of the nitro-group in the molecule, an attempt was made to synthesise mercuric fulminate by the action of monobromonitroethane (1 mol.) on a solution of mercuric oxide (1 mol.) and mercuric cyanide (1 mol.), but a red precipitate of the compound $CHgBr_2NO_2$ was alone obtained, which neither detonated on percussion nor on heating, and yielded with potassium cyanide the salt $KBr,HgCy_2 + 2H_2O$. A further attempt to prove the presence of a nitro-group by the action of chlorine-water led to no definite result, a very complicated reaction ensuing.

Mercuric fulminate (1 mol.) absorbs dry chlorine (4 atoms) without evolution of any gaseous product, and is converted into a yellow mass of pungent odour which is soluble in cold water, and is probably dichloronitroacetonitrile. Bromine vapour is absorbed by the fulminate in the same ratio, and steam distillation of the resulting yellow mass affords a liquid of irritating odour, which soon solidifies to yield crystals of dibromacetonitrile melting at 60°; the latter can also be separated from a slight residue of mercuric bromide by exhausting the crude product of the reaction with light petroleum. Scholl and the author consider dinitroacetonitrile to be a nitro-derivative. Provided no oxidation occurred in the action of dry

chlorine on mercuric fulminate, the study of dinitroacetonitrile should determine the validity or otherwise of Kekulé's formula.

T. G. N.

Constitution of Allyl Cyanide. By F. Lippmann (*Monatsh.*, **12**, 402—409).—The so-called allyl cyanide was prepared according to the directions of Rinne and Tollens (*Annalen*, **159**, 105), excepting that allyl bromide was substituted for allyl iodide in the process; 50 per cent. of the theoretical yield of cyanide boiling at 118° was obtained. In order to prepare the dibromo-additive product, a quantity of the cyanide was cooled in ice, and gradually treated with a molecular proportion of bromine. After 1—2 days, the product, which no longer had the odour of bromine, was mixed with fuming hydrochloric acid, and allowed to remain for 2—3 days, until the liquid assumed a reddish-brown colour. It was then decomposed with water, and the crystalline precipitate thus formed recrystallised, first from ether and afterwards from hot chloroform, when silky scales of *αβ-dibromobutyramide*, $CHMeBr{\cdot}CHBr{\cdot}CO{\cdot}NH_2$, were obtained. It melts at 147—148°, is readily soluble in cold ether and in hot alcohol and chloroform, but loses hydrogen bromide when heated with water.

The acid solution from which the amide was separated by water was shaken with ether. The ethereal extract, on evaporation, gave a crystalline residue, part of which was insoluble in water, and consisted of a further quantity of the amide, whilst the remainder was readily soluble. The aqueous solution, on evaporation in a vacuum, gave white, needle-shaped crystals of *αβ-dibromobutyric acid*, $CHMeBr{\cdot}CHBr{\cdot}COOH$. This acid may be recrystallised from ether and water, in both of which it is readily soluble; it melts at 88—89°, and differs considerably in physical properties from normal dibromobutyric acid, $CH_2Me{\cdot}CBr_2{\cdot}COOH$, which is liquid at ordinary temperatures. The amide, melting at 147—148°, is readily converted into αβ-dibromobutyric acid when heated with fuming hydrochloric acid for five hours at 120°.

The formation of αβ-dibromobutyric acid from the so-called allyl cyanide shows that the constitution of the latter must be $CHMe{:}CH{\cdot}CN$. This is in harmony with the view of Kekulé and of Rinne (*Ber.*, **6**, 386), but does not agree with that of Pinner (*Ber.*, **12**, 2053).

G. T. M.

Direct Synthesis of Primary Alcohols. By P. Henry (*Compt. rend.*, **113**, 368—370).—Monochloromethyl ether, $CH_2Cl{\cdot}OMe$, and the corresponding ethyl compound $CH_2Cl{\cdot}OEt$, react energetically with the organo-zinc compounds. Zinc chloride separates, and, on treating the product with water and distilling, the primary alkyl oxide can be isolated.

The following ethers were prepared:—Primary methyl propyl ether boiling at 41° under a pressure of 761 mm.; sp. gr. = 0·7381 at 20°, by the action of zinc ethyl on monochloromethyl ether. Normal primary butyl methyl ether, by the action of zinc propyl on monochloromethyl ether; it is a colourless liquid with an agreeable

odour, insoluble in water, and boiling at 71° under a pressure of 759 mm.; sp. gr. at 20° = 0·7593. Normal ethyl propyl ether, by the action of monochloromethyl ethyl ether; it boils at 63—64°; sp. gr. at 20° = 0·7474. Ethyl butyl ether, by the action of zinc propyl on monochloromethyl ethyl ether; it boils at 92° under a pressure of 753 mm.

Zinc propyl is produced as easily as zinc ethyl by means of Gladstone and Tribe's zinc-copper couple, but the yield is only 70 to 75 per cent., propylene and propane being liberated.

C. H. B.

Oxidation of Tertiary Alcohols. By G. Wagner (*J. pr. Chem.* [2], **44**, 308—312).—The oxidation of the tertiary alcohols has heretofore always been effected by chromic acid mixture, which, however, is acknowledged to convert them, by dehydration, into corresponding olefines, so that the products of the oxidation have been those derived from the olefines, rather than true oxidation products of the tertiary alcohols (compare Abstr., 1883, 566; 1886, 437). For this reason the author has experimented with a neutral solution of potassium permanganate as an oxidising agent for tertiary alcohols. He finds that trimethylcarbinol is scarcely attacked by an alkaline 4 per cent. solution of potasssium permanganate even when warmed; and that tertiary amyl alcohol is oxidised by the same solution at the ordinary temperature, but even after a month, the reaction is not complete.

Dimethylisopropylcarbinol (b. p. 117—118°), however, is readily oxidised to pinacone by a neutral aqueous solution of potassium permanganate, and the process adopted is fully described in the paper. This is the first case in which a saturated monhydric alcohol has been directly converted into the corresponding dihydric alcohol.

From this result, the author concludes that the oxidation of tertiary alcohols results in the hydroxylising of one of the carbon atoms which are directly linked to the C(OH) group, a reaction similar to that observed in the oxidation of the ketones, and probably conforming to the same rules (compare this vol., p. 35). A. G. B.

Xylose. By G. Bertrand (*Bull. Soc. Chim.* [3], **5**, 554—557).—Xylose may be obtained from wheat or oat straw by the following process, which is stated to be less laborious than that used by Wheeler and Tollens (Abstr., 1889, 847) in preparing it from pine wood. The straw is extracted with tepid water, and is then boiled for several hours with dilute (1—2 per cent.) sulphuric acid. The liquor, after removal of the sulphuric acid by barium hydroxide, is concentrated on the water-bath, and treated with alcohol, thus yielding an extract from which xylose is obtained as a yellow syrup on removing the solvent. The syrup crystallises on the addition of a crystal of xylose, and the product is recrystallised from hot alcohol. The yield from wheat straw is 2 per cent., from oat straw 4 per cent.

When xylose is treated with sodium amalgam, *xylitol* is obtained as a syrup, which, like sorbitol and perseïtol, and unlike arabitol, gives, with benzaldehyde in the presence of sulphuric acid an abundant precipitate, which appears to have the composition $C_5H_8O_5(CHPh)_2$. The xylitol may be recovered from the compound

by hydrolysis, and, as thus obtained, is a rather sweet, faintly dextrorotatory syrup. *Pentacetylxylitol* is obtained as a syrup, when anhydrous xylitol is treated with acetic anhydride in the presence of zinc chloride.

Xylose is further distinguished from arabinose by the fact that the cadmium salt of its first oxidation product, xylonic acid, forms well-defined, crystalline, double salts with cadmium bromide and chloride; the reaction is very sensitive, as it is visible when only a few milligrams of the sugar is present. The xylose (1 part) dissolved in water (5 parts) is treated with bromine (1 part), and, after 24 hours, the excess of bromine is evaporated off. If the bromine compound is required, the residue is now saturated with cadmium carbonate, concentrated, and precipitated with alcohol; whilst, if the chlorine compound is wanted, the hydrogen bromide is removed by means of lead carbonate, cadmium carbonate and chloride are added to the impure *xylonic acid* thus obtained, and the operation is completed as before.

Jn. W.

Constitution of Xylitol and Xylose. By G. Bertrand (*Bull. Soc. Chim.* [3], **5**, 740—742; compare preceding abstract).—When xylitol is treated with a mixture of nitric and sulphuric acids, it yields a *pentanitrate*, $C_5H_7(NO_3)_5$, as a colourless, insoluble syrup, which is heavier than water, can be exploded by percussion, and burns rapidly without leaving any residue.

By heating xylitol with amorphous phosphorus and iodine in a stream of carbonic anhydride, it is converted into a secondary amyl iodide, which boils at 146°, and yields, on prolonged heating with lead hydroxide and water, methylpropylcarbinol, boiling at 119°.

Xylitol is thus an open-chain pentahydric alcohol, of which xylose is the aldehyde; the two substances being represented by the formulæ $OH{\cdot}CH_2{\cdot}[CH{\cdot}OH]_3{\cdot}CH_2{\cdot}OH$ and $OH{\cdot}CH_2{\cdot}[CH{\cdot}OH]_3{\cdot}CHO$.

Jn. W.

Epichloramine. By R. Schiff (*Gazzetta*, **21**, ii, 1—6).—Equivalent weights of epichlorhydrin and ethyl acetoacetate are mixed with excess of alcoholic ammonia solution and left for some hours; there is a slight development of heat, and the reaction is completed by heating on the water-bath for 15 minutes; on the addition of water, a colourless oil is obtained, which soon solidifies to acicular crystals. When recrystallised from dilute alcohol, the new compound has the composition $C_9H_{16}NO_3Cl$, melts at 95° without decomposition, and is not altered by heating for some time at 100—110°. It dissolves in acids to form salts, and is precipitated unchanged from the solution by alkalis; it is moderately soluble in absolute alcohol, less so in ether, and very sparingly in cold water; it separates from its hot aqueous solution in long needles. The solution is not precipitated by silver salts or by picric acid and sodium carbonate, and does not yield a platinochloride. No acetyl derivative could be prepared.

If, in the preparation of this substance, the heating on the water-bath be too prolonged, a whitish, slightly crystalline substance is deposited, which is insoluble in all ordinary solvents, and has the

composition $C_{12}H_{27}N_3Cl_2O_4$; it appears to be identical with the chlorhydrinimide of Claus (Abstr., 1873, 1121).

When the substance $C_9H_{16}NO_3Cl$, is dissolved in hot alcohol, and treated with oxalic acid in alcoholic solution, *epichloramine oxalate*, $(C_3H_8NOCl)_2,H_2C_2O_4$, is obtained as a voluminous, white precipitate, and is purified by solution in water and precipitation by absolute alcohol. It melts at 183—184° with evolution of carbonic anhydride, is moderately soluble in warm water, and almost insoluble in alcohol. In a similar manner, *epichloramine hydrochloride*, C_3H_8NOCl,HCl, is obtained by treating the condensation product with hot dilute hydrochloric acid; on evaporating the solution in a vacuum, the salt is obtained colourless and well crystallised; it is very soluble in water.

Free epichloramine is very soluble in water, and is decomposed by steam distillation with evolution of ammonia; it seems to be very readily converted into condensation products. The author regards it as formed by the condensation of a molecule each of ammonia, epichlorhydrin, and ethyl acetoacetate with elimination of water, and considers that it has probably the constitution

$$CH_2Cl\cdot CH(OH)\cdot CH_2\cdot N{:}CMe\cdot CH_2\cdot COOEt.$$

W. J. P.

Unsaturated Fatty Amines. By C. Paal and A. Heupel (*Ber.*, **24**, 3035—3048; compare Abstr., 1889, 116, and 1890, 399).—*Dibromopropylcarbamide*, $NH_2\cdot CO\cdot NH\cdot CH_2\cdot CHBr\cdot CH_2Br$, is prepared by mixing a concentrated aqueous solution of the hydrochloride of dibromopropylamine (compare Henry, *Ber.*, **8**, 399) with potassium cyanate. It melts at 163°, and dissolves easily in alcohol and hot water, sparingly in ether and cold water. An attempt to prepare the analogous thiocarbamide from the hydrobromide of the base and potassium thiocyanate was unsuccessful.

By acting on an alcoholic solution of free propargylamine with ethyl iodide, and allowing the mixture to evaporate in the absence of light, a crystalline residue is obtained, which is separated by treatment with alcohol into *propargylamine hydriodide*, $C_3H_3\cdot NH_2,HI$, which forms lustrous, large, white plates, melting at 205° and sparingly soluble in alcohol, and *diethylpropargylamine hydriodide*, $C_3H_3\cdot NEt_2,HI$, which is easily soluble in alcohol. The silver compound of propargylamine previously prepared was found to have a variable constitution, but undoubtedly contains oxygen. Propargylamine itself, when boiled with sodium nitrite and a little hydrochloric acid, yields propargyl alcohol; this can be distilled with steam, and if the distillate is collected in an ammoniacal silver solution, a white, explosive silver compound, $C_3H_2Ag\cdot OH$, is formed.

Propargyldithiocarbamic acid, $C_3H_3\cdot NH\cdot CSSH$, is obtained by boiling an alcoholic solution of free propargylamine with excess of carbon bisulphide in a reflux apparatus. It melts at 115°, has a feeble, unpleasant odour, and, when heated, smells like a thiocarbimide. It dissolves easily in aqueous alkalis, mineral acids, hot water, ether, alcohol, and benzene, sparingly in light petroleum and cold water. From dilute alcohol, it crystallises in white needles; from a mixture

of benzene and light petroleum in long plates. Acetic acid and dilute mineral acids precipitate it from solutions of its alkali salts. The barium salt forms a white, flocculent, the stannic a white, gelatinous, the copper a green, flocculent, the lead a white, granular, and the silver salt a white, flocculent precipitate. The silver salt yields silver sulphide when boiled with water. The acid itself is completely oxidised by silver or mercuric oxide.

Propargylphenylcarbamide, $NHPh{\cdot}CO{\cdot}NH{\cdot}C_3H_3$, is prepared by mixing an aqueous solution of propargylamine oxalate with rather less than the theoretical amount of phenyl cyanate, and adding to the cooled mixture a slight excess of a concentrated solution of potassium carbonate. After shaking for a time, a crystalline product is obtained containing a small quantity of symmetrical diphenylcarbamide, which is easily soluble in hot water, mixed with very sparingly soluble propargylphenylcarbamide; the latter crystallises from water in radiating groups of needles, melts at 133°, and dissolves easily in ether, alcohol, and benzene, sparingly in light petroleum and cold water.

Isobutylallylamine, $C_3H_5{\cdot}NH{\cdot}CH_2{\cdot}CHMe_2$, is prepared by digesting equivalent quantities of allylamine and isobutyl bromide for two or three days at first a gentle heat, finally on the water-bath. The product is diluted with water, acidified, separated from unattacked isobutyl bromide, and treated with caustic soda, and the bases thus liberated are dried with solid potash and fractionally distilled. Some *diisobutylallylamine*, $C_3H_5{\cdot}N(C_4H_9)_2$, boiling at about 165°, was isolated, but the main product is isobutylallylamine, a colourless, volatile liquid boiling at 123° (uncorr.), and having a penetrating odour resembling that of allylamine. It is soluble in water. The *hydrochloride*, $C_7H_{15}N,HCl$, crystallises in white, lustrous, hygroscopic plates which melt at 216°, and are fatty to the touch. The *aurochloride*, $C_7H_{15}N,HAuCl_4$, crystallises from hot water in splendid, yellow needles which melt at 140°, and slowly decompose when boiled with water. The *platinochloride*, $(C_7H_{15}N)_2,H_2PtCl_4$, crystallises from alcohol in splendid, red needles, melts at 182°, and dissolves easily in alcohol and water. The *hydrobromide*, $C_7H_{15}N,HBr$, crystallises from a mixture of alcohol and ether in white plates which have a silky lustre; it melts at 222° and dissolves readily in water and alcohol. The *acid oxalate*, $C_7H_{15}N,C_2H_2O_4$, crystallises from alcohol in small, white plates, melts at 221°, and dissolves fairly easily in water, sparingly in alcohol.

Isobutylallylphenylcarbamide, $C_4H_9{\cdot}N(C_3H_5){\cdot}CO{\cdot}NHPh$, is formed by the union of isobutylallylamine with phenyl cyanate at the ordinary temperature. A viscid, colourless oil is obtained, which very slowly becomes crystalline. It is insoluble in water, but soluble in alcohol, benzene, and light petroleum, and crystallises from the last solvent in aggregates with a radial structure which melt at 37—39°.

Isobutylallylphenylthiocarbamide, $C_4H_9{\cdot}N(C_3H_5){\cdot}CS{\cdot}NHPh$, is obtained by mixing equivalent quantities of isobutylallylamine and phenylthiocarbimide. It forms a viscid colourless oil which slowly crystallises in long, colourless needles grouped like ice-flowers. It melts at 41—43°, and dissolves readily in ether, ethyl acetate, alcohol, and benzene, sparingly in light petroleum and not at all in water.

Isobutylpropargylamine, $C_4H_9{\cdot}NH{\cdot}C_3H_3$, was prepared by gradually adding isobutyldibromopropylamine hydrobromide, $C_4H_9{\cdot}NH{\cdot}C_3H_5Br_2$, to a well-cooled alcoholic solution of sodium ethoxide, and finally heating the mixture in well-corked bottles in the water-bath. The contents were then diluted with water and distilled with steam until an oily base that was also formed began to come over. The distillate was concentrated, treated with a large excess of potassium carbonate, and the bases extracted with ether. The ethereal solution was dried with solid potash and fractionally distilled; by this means, isobutylpropargylamine was isolated as a colourless, volatile liquid, boiling at 134—136° (uncorr.), miscible in all proportions with water and having an odour which recalls that of ammonia, and at the same time that of camphor. Its aqueous solution precipitates iron hydroxide from a solution of the chloride, has no effect on an ammoniacal copper solution, and with an ammoniacal silver solution yields a silver compound as a white precipitate which is fairly stable while moist, but explodes easily when dry. The *oxalate*, $C_7H_{13}N,C_2H_2O_4$, forms lustrous, white needles or plates melting at 210°; it can be crystallised from alcohol or from water. It reduces a solution of gold chloride only very slowly (*allylamine oxalate* itself, $C_3H_5{\cdot}NH_2,C_2H_2O_4$, which forms radiating groups of white needles melting at 120°, effects this reduction even more slowly). The *hydrochloride*, $C_7H_{13}N,HCl$, crystallises from a mixture of alcohol and ether in large, lustrous, white plates melting at 148° and dissolving readily in water and alcohol. The *platinochloride*, $(C_7H_{13}N)_2,H_2PtCl_6$, separates from alcohol in ill-defined, red, crystalline aggregates which melt at 172°, and are decomposed when kept for a short time at 100°.

Isobutylpropylamine, $C_4H_9{\cdot}NHPr^{\alpha}$, is obtained by reducing isobutylpropargylamine in alcoholic solution with metallic sodium, the mixture being heated on the water-bath. The product formed was diluted with water and distilled with steam; the distillate acidified with hydrochloric acid, evaporated to a small bulk, and treated with potash; the oily layer was removed, dried with solid potash, and fractionally distilled, finally over metallic sodium. The base is a colourless, volatile liquid boiling at 123—125°, miscible with water in all proportions, and very similar to isobutylallylamine. The *hydrochloride*, $C_7H_{17}N,HCl$, dissolves easily in water and alcohol, and crystallises from a mixture of alcohol and ether in small plates which melt at 135°. The oxalate, $C_7H_{17}N,C_2H_2O_4$, crystallises from alcohol in small, white needles melting at 224°. C. F. B.

Crotonaldoxime. By T. Schindler (*Monatsh.*, **12**, 410—418).—This compound is obtained when 2 mols. of crotonaldehyde (compare Lieben and Zeisel, *Monatsh.*, **1**, 20) is slowly added during continued agitation to a cold solution of 3 mols. of hydroxylamine hydrochloride which has been carefully neutralised with sodium carbonate, and the resulting carbonic anhydride completely removed by shaking. The product is extracted with ether, and the ethereal solution distilled until the greater portion of the ether is removed. The concentrated solution is allowed to evaporate spontaneously, when an oil

having a characteristic odour separates, and in this oil a number of stout, closely striated prisms of *crotonaldoxime*, C_4H_7ON, slowly form. The compound is insoluble in water, but readily dissolves in ether, alcohol, chloroform, and hot benzene, and may be best recrystallised from the last-named solvent, when it forms colourless, odourless, volatile crystals which melt at 119—120°. On heating with acetic anhydride for two hours in a reflux apparatus, the aldoxime is converted into crotononitrile, C_4H_5N, a product which boils at 117·4—118·4°; has a sp. gr. of 0·8468 at 0° compared with water at 4°, and is apparently identical with that obtained by Rinne and Tollens (*Annalen*, **159**, 105) from allyl iodide and potassium cyanide. Tollens (*loc. cit.*) and Pinner (*Ber.*, **12**, 2053) have erroneously attributed the formula $CH_2{:}CH{\cdot}CH_2{\cdot}CN$ to this compound, which, as shown by its production from crotonaldoxime, $CHMe{:}CH{\cdot}CH{:}NOH$, must really be $CHMe{:}CH{\cdot}CN$ (compare Kekulé, *Ber.*, **6**, 386). On the addition of bromine and subsequent digestion with concentrated hydrochloric acid, the nitrile is converted into a mixture of *dibromobutyramide*, $CHMeBr{\cdot}CHBr{\cdot}CONH_2$, which melts at 148—149°, and *αβ-dibromobutyric acid*, $CHMeBr{\cdot}CHBr_2{\cdot}COOH$, which melts at 87—90° (compare Lippman, this vol., p. 27). When the aldoxime is reduced by Goldschmidt's method (Abstr., 1887, 568), crotylamine, $C_4H_7NH_2$, which boils at 81—85°, is obtained.

The oil from which the crotonaldoxime separates is a very inactive substance, and does not readily lend itself to purification. Since, on elementary analysis, it gives numbers which very closely correspond with those required for the formula of crotonaldoxime itself, the author suggests that it may possibly be the stereoisomeride of the formula $C_3H_5{\cdot}CH{:}N{\cdot}OH$ (compare Hantzsch, Abstr., 1891, 439).

G. T. M.

The Oximes of Chloral and Butyl Chloral. By R. Schiff and N. Tarugi (*Gazzetta*, **21**, ii, 6—12).—Nägeli (Abstr., 1883, 728) prepared a dichloroglyoxime, $OH{\cdot}N{:}CCl{\cdot}CCl{:}NOH$, in small quantities by the action of free hydroxylamine on chloral hydrate. The authors find that *chloraldoxime* is easily prepared by boiling an aqueous solution of equivalent proportions of chloral hydrate and hydroxylamine hydrochloride (compare V. Meyer, Abstr., 1891, 1181). On cooling, a yellowish or greenish oil separates, having an odour closely resembling that of free chlorine. It could not be obtained in a state sufficiently pure for analysis; if left to itself, or treated with hot water, it decomposes with evolution of hydrogen chloride and hydrogen cyanide, probably in accordance with the following equation:—$CCl_3{\cdot}CH{:}NOH = HCN + COCl_2 + HCl$.

Butylchloraldoxime, $CHMeCl{\cdot}CCl_2{\cdot}CH{:}NOH$, is readily prepared by pouring boiling water on a dry mixture of equivalent proportions of butyl chloral hydrate and hydroxylamine hydrochloride; the oxime separates as an oil which solidifies on cooling. A still better method of preparation is to pour the cold solution of the hydroxylamine hydrochloride on the dry butyl chloral hydrate, and allow it to remain for some days; the theoretical yield of pure oxime is thus obtained. Butyl chloraldoxime is fairly soluble in all the usual solvents excepting water; it crystallises from light petroleum in very

large, opaque octahedra, and melts at 65° without decomposition. It dissolves in cold, concentrated sulphuric acid, and is precipitated unaltered by water; on heating the solution, however, hydrogen chloride is evolved. It is extremely sensitive towards alkalis, and even when washed with ordinary tap-water, rapidly turns yellow and green. *Acetylbutyl chloraldoxime*, $C_6H_8Cl_3NO_2$, is obtained by gently heating the oxime in acetic anhydride solution; it is a white substance melting at 63—64°. If the heating be too prolonged, decomposition occurs with evolution of hydrogen chloride and hydrogen cyanide.

On heating with alkalis or alkali carbonates, butyl chloraldoxime becomes first green and finally bright yellow, hypochlorous acid being formed. If the reaction is arrested at the green stage, a yellow powder is obtained having the composition $C_8H_{12}Cl_3N_2O_3$.

When a few drops of glacial acetic acid are added to an alcoholic solution of the oxime (1 mol.) containing litharge (2 mols.), lead chloride is formed, and a colourless, well crystallised substance is obtained which melts with decomposition at 158°. This is probably *dichlorocrotonaldoxime*, CMeCl:CCl·CH:NOH.

The study of butyl chloraldoxime is being continued.

W. J. P.

Sulphinic Derivatives and their Analogies to Compounds of Organic Amines. By R. Nasini and T. Costa (*Gazzetta*, **21**, 554—565).—It was previously shown by the authors (Abstr., 1891, 1305) that the molecular refractive energy of sulphur in the derivatives of triethylsulphine is extremely high, and especial attention was drawn to the iodide, the molecular refractive energy of which remains constant when the concentration is varied, but varies when the solvent is changed. Similarly, aqueous solutions of trimethylsulphine bromide and iodide give very high results for the molecular refractive energy of sulphur. The authors consider that the theory of electric dissociation affords a simple explanation of these facts. Determinations of the molecular weights of the above-mentioned compounds by the cryoscopic method yield approximately normal numbers in aqueous solutions, but the acetic solutions of the chloride and bromide of triethylsulphine yield abnormal results. It is, however, noticeable that the hydrate, chloride, and iodide, which yield successively increasing values for the molecular refractive energy of sulphur, also appear to be successively less dissociated in their solutions. Similarly the iodide of trimethylsulphine appears to be less dissociated than that of triethylsulphine, and the sulphur in the former compound accordingly appears to have a smaller molecular refractive energy. The alcoholic solution of triethylsulphine iodide, in which electrical dissociation cannot take place, in like manner yields the highest value for the molecular refractive energy of sulphur. In acetic acid solutions, the molecule of triethylsulphine iodide appears to be more complex. The molecular weight of triethylsulphine bromide calculated from the rise of the boiling point of an alcoholic solution gave approximately normal results.

The molecular depression of tetrethylammonium iodide in aqueous solution is almost equal to that of the corresponding sulphinic de-

rivative. The refractive energy of tetrethylammonium iodide is greater than the sum of the refractive energies of triethylamine and ethyl iodide, exactly as the refractive energy of triethylsulphine iodide exceeds that of its constituents. The determination of the molecular weight of tetrethylammonium iodide from the rise of the boiling point of an alcoholic solution also yields a normal result.

S. B. A. A.

Oxidation of Mixed Ketones of the Fatty Series. By G. Wagner (*J. pr. Chem.* [2], **44**, 257—308).—Of Popoff's seven rules concerning the oxidation of ketones (*Annalen*, **161**, 299—301: *J. Russ. Chem. Soc.*, **4**, 67), the fourth, or that which is commonly known as "Popoff's rule," asserts that when a ketone whose alcohol radicles are of the same series, but not isomeric, is oxidised, the carbonyl remains linked to the alcohol radicle which is lowest in the series; the fifth states that in a ketone whose alcohol radicles are of the same series and are isomeric, that alcohol radicle in which the least hydrogenised carbon atom is attached to the carbonyl will be the first oxidised.

In this paper, the author details several experiments which are not in accordance with the above rules, and discusses them by the light of the work which has been done on the subject by various chemists.

The experiments, some of which have already been published in *J. Russ. Chem. Soc.*, **16**, 645 and 695 (compare Abstr., 1885, 1197), but have not been copied into other journals, may be summarised here.

Ethyl propyl ketone (b. p. 122—123° at 745 mm.), from the action of zinc ethyl on butyric chloride (b. p. 98—102°), yields butyric, propionic, and acetic acids when oxidised by potassium dichromate and sulphuric acid. The formation of butyric and acetic acids appears to be the primary reaction, the propionic acid resulting from a secondary one; two distinct reactions take place in this way in the oxidation of most mixed ketones, and the proportion of the primary to the secondary reaction approaches 2 : 1, as in this case. Popoff (*Annalen*, **161**, 289) and Völker (*Wien. Acad.* [2], **73**, 335) found that propionic acid was the only product of the oxidation of ethyl propyl ketone; the author can only conclude that they worked with too small quantities of the ketone, and failed to separate the acids.

Ethyl hexyl ketone, obtained by the oxidation of the corresponding secondary alcohol, itself obtained from the action of zinc ethyl on œnanthaldehyde, is a clear, refractive liquid with a sharp, aromatic odour; it crystallises at −8° in long prisms, and boils at 190° (752 mm.); its sp. gr. at 0° = 0·840, at 20°/0° = 0·825. The products of the oxidation of this ketone are œnanthylic and acetic acids from the primary reaction, and caproic and propionic acids from the secondary, the proportion between the two reactions being nearly 3 : 1.

Propyl hexyl ketone, obtained by the oxidation of the corresponding alcohol (b. p. 210—211° at 759 mm.), boils at 206—207° (753 mm.), and solidifies in a freezing mixture to clusters of needles which melt at −9·5° to −9°. Its odour is similar to that of ethyl hexyl ketone;

its sp. gr. at 0° = 0·839, at 20·5°/0° = 0·824. Only œnanthylic and propionic acids could be separated from the product of the oxidation of this ketone.

The above experiments disprove Popoff's fourth rule; the following concern the fifth rule:—

Ethyl isobutyl ketone is formed by the action of zinc ethyl on isopropylacetic chloride (b. p. 116—116·5°). It is a refractive liquid with an odour like peppermint; it boils at 134·5—135° (735 mm.); its sp. gr. at 0° = 0·829, at 17°/0° = 0·815. Isopropylacetic acid boils at 175° (749 mm.). When oxidised, the ketone yields, from the primary reaction, isopropylacetic acid and acetic acid; and from the secondary reaction, isobutyric acid and propionic acid, the primary reaction exceeding the secondary; acetone and dimethacrylic acid (?) are also obtained, probably as secondary oxidation products of the acids. This behaviour shows that the fifth rule is fallacious.

Propyl isobutyl ketone (b. p. 154—156° at 755 mm.) yields isopropylacetic acid, propionic acid, acetone, and acetic acid, when oxidised.

Ethyl isopropyl ketone is prepared from isobutyric chloride (b. p. 92—93°) and zinc ethyl; it boils at 113·75—114° (745 mm.), not 117—119° (Pawloff, *J. Russ. Chem. Soc.*, **8**, 242); its sp. gr. at 0° = 0·830, at 18°/0° = 0·814. It yields on oxidation acetone, propionic acid, isobutyric acid, and acetic acid (compare Pawloff, *loc. cit.*).

Methyl isobutyl ketone boils at 115·5° (745 mm.; Frankland, *Annalen*, **145**, 83, gives 114° at 758°), and has a sp. gr. at 0° = 0·8195 (Frankland gives 0·81892), at 19°/0° = 0·8034. When oxidised, it yields isobutyric and acetic acids from the primary reaction, and isopropylacetic acid and formic acid from the secondary.

Methyl isoamyl ketone (b. p. 144—144·5° at 752 mm.) yields isopropylacetic acid and isobutylacetic acid on oxidation; Popoff obtained valeric and acetic acids.

Methyl butyl ketone yields butyric acid and normal valeric acid on oxidation.

The author deduces the following generalisations from the results of his and of other experimenters' work on this subject:—

1. When a ketone of the fatty series is oxidised, the hydrogen atom attached to one of the carbon atoms linked to the carbonyl is hydroxylised; the molecule of hydroxyl compound thus formed is split up by further oxidation, 2 mols. of fatty acids, or 1 mol. of a fatty acid and 1 mol. of a ketone, being formed.

2. If only one of the carbon atoms linked to the carbonyl be hydrogenised, only this will be oxidised and detached. If, however, both be hydrogenised, chromic acid mixture at 100° will generally cause oxidation in two directions, so that in some molecules of the ketone the one, and in others the other, of these carbon atoms will be oxidised, and there will result a primary and a secondary reaction, regulated by the following conditions.

3. If the carbon atoms linked to the carbonyl be unequally hydrogenised, the one which has less hydrogen will be oxidised and eliminated in the primary reaction, and the one which is more hydrogenised, in the secondary reaction.

4. If the carbon atoms be equally hydrogenised but combined, the one with a secondary (or tertiary?), the other with a primary, alcohol radicle, the latter will be oxidised and eliminated.

5. If the carbon atoms linked to the carbonyl be equally hydrogenised and combined with radicles of the same series, but of different molecular weight, that which is combined with the radicle having less carbon will be preferably oxidised and eliminated.

These generalisations allude to the oxidation of ketones at 100° with chromic acid mixture. Experiments made with methyl butyl ketone showed that (1) the course of the oxidation of methyl butyl ketone is influenced by the temperature; (2) at low temperatures, the oxidation proceeds in one direction only, and the less hydrogenised carbon atom attached to the carbonyl is oxidised and eliminated; (3) at higher temperatures, the oxidation extends to both these carbon atoms; (4) it is thus probable that at very high temperatures, if the ketone could withstand such, the course of the oxidation would be in one direction only, and that would be the reverse of (2).

A. G. B.

Determination of the Affinity of Organic Acids by means of Lacmoïd. By F. Röhmann and W. Spitzer (*Ber.*, **24**, 3010—3015).—During the titration of organic acids with soda, the authors have observed that a drop of the liquid brought into contact with red lacmoïd paper produces a blue colour before sufficient soda has been added to form the normal salt; the solution will turn blue lacmoïd paper red, but this red colour disappears before the acid is entirely neutralised. This reaction depends on the fact that the alkali is divided between the lacmoïd and the organic acid in a definite proportion, which varies according to the nature of the acid; a method is thus afforded of determining the relative affinities of acids for alkali. Experiments have shown that the coefficient of neutrality s/s' of two acids is in inverse proportion to their affinity for alkali: s = the quantity of acid which is necessary to bring about the change in colour of the lacmoïd paper, and s' represents the amount of normal salt present. For the full details of calculation the original paper should be consulted.

The affinities of the following monobasic acids, compared with formic acid, agree closely with the values given in Ostwald's tables:—Acetic, propionic, butyric, isobutyric, valeric, hydroxypropionic, and hydroxyisobutyric. The method is also applicable to the bibasic acids, a similar agreement in the results, as compared with other methods, being obtained.

It is desirable to always determine the quantity of alkali which is required to be added to the acid in order to produce a blue colour on red lacmoïd paper, since the inverse procedure is more liable to experimental error.

J. B. T.

Behaviour on Dry Distillation of the Silver Salts of Organic Acids. By J. Kachler (*Monatsh.*, **12**, 338—349).—Silver acetate, on dry distillation, is decomposed according to the equation $4AgC_2H_3O_2 = 4Ag + 3C_2H_4O_2 + C + CO_2$, the reaction being complete at a temperature of 220—240°. The compound furnishes the same products,

and in practically the same proportions, when it is heated to a high temperature with water in sealed tubes.

Silver formate decomposes in accordance with the equation $2AgCHO_2 = CH_2O_2 + CO_2 + 2Ag$, when heated with water in sealed tubes.

The silver salts of isovaleric, normal caproic, and œnanthylic acids, on dry distillation, are approximately decomposed according to the equation $2n(AgC_nH_{2n-1}O_2) = (2n - 1)(C_nH_{2n}O_2) + (n - 1)C + CO_2 + 2nAg$; in fact, this equation appears to indicate the manner in which the silver salts of fatty acids are generally resolved under such conditions.

Silver palmitate, on distillation under reduced pressure (430 mm.), gives a considerable quantity of palmitic acid, and, similarly, the silver salts of lactic, α-hydroxyisobutyric, phenylacetic, and benzoic acids decompose with formation of the respective free acids.

The author confirms the statement of Klimenko (*J. Russ. Chem. Soc.*, **12**, 97), that silver lactate, when air-dried, crystallises with ½ mol. H_2O (compare Engelhardt and Maddrell, *Annalen*, **63**, 90).

G. T. M.

Action of Hydriodic Acid on Amido-acids. By A. Kwisda (*Monatsh.*, **12**, 419—430).—The author finds that the readiness with which hydrogen is substituted for amidogen, on treating the amido-acids with hydriodic acid, varies considerably with the constitution of the acid (see original). In his investigations, the acids under examination, namely, glycocine, α- and β-alanine, leucine, aspartic acid, glutamic acid, and ortho-, meta-, and para-amidobenzoic acids, were heated in sealed tubes with excess of hydriodic acid of sp. gr. 1·96. Monobasic, fatty acids, of the formula $NH_2{\cdot}C_nH_{2n}{\cdot}COOH$, are thereby decomposed, according to the equation $NH_2{\cdot}C_nH_{2n}{\cdot}COOH + 3HI = C_nH_{2n+1}COOH + NH_4I + I_2$, whilst such bibasic acids as aspartic and glutamic acids are converted into monobasic acids, thus:—$NH_2{\cdot}C_nH_{2n-1}(COOH)_2 + 3HI = C_nH_{2n+1}{\cdot}COOH + CO_2 + NH_4I + I_2$; ortho-, meta-, and para-amidobenzoic acids are not decomposed in the same way as the monobasic acids of the fatty series, for, in addition to the chief product, benzoic acid, small quantities of carbonic anhydride and of free hydrocarbons are obtained. The author has not been able to confirm the observation of Rosenstiehl (*Zeit. für Chem.*, 1869, 471) that toluidines are formed on heating amidobenzoic acids with hydriodic acid. G. T. M.

β-Trimethylethylidenelactic Acid. By C. Glücksmann (*Monatsh.*, **12**, 356—361; compare Abstr., 1890, 237).—A more convenient method of preparing trimethyllactic acid than that previously described is as follows:—20 grams of pinacone is suspended in 100 c.c. of 20 per cent. sodium hydroxide solution, and 63 grams of potassium permanganate in a 4—5 per cent. aqueous solution is slowly added to the well-cooled mixture. When the oxidation is complete, the product is filtered, neutralised with sulphuric acid, and evaporated to dryness on the water-bath. The residue is dissolved in the least possible quantity of water, and treated with 250 grams of 4 per cent. sodium amalgam, added a little at a time. The solution is filtered,

acidified with sulphuric acid, extracted with ether, the ethereal solution evaporated, and the residue steam distilled, until the distillate ceases to be acid. The residue, dried in a vacuum over sulphuric acid, consists of trimethyllactic acid.

On heating the acid (1 part) with 90 per cent. sulphuric acid (3—4 parts) in a reflux apparatus at 50°, it is resolved into carbon monoxide, water, and *trimethylacetaldehyde*, $CMe_3{\cdot}COH$ (yield 80 per cent.). The new aldehyde boils at 92—94°, reduces a solution of silver, restores the colour to magenta, which has previously been treated with sulphurous anhydride; and, on oxidation with chromic acid, appears to be converted into acetic acid. G. T. M.

Halogen Derivatives of Malonic Acid. By M. Conrad and C. Brückner (*Ber.*, **24**, 2993—3005).—*Ethyl dichloromalonate*, $CCl_2(COOEt)_2$, is prepared by treating ethyl chloromalonate with chlorine at 120°, removing the excess of the latter and the hydrogen chloride, first by heating on the water-bath, and subsequently by allowing the product to remain over soda-lime in a vacuum, and distilling, when the compound passes over at 231—234° with only slight decomposition as a colourless liquid, having a sp. gr. 1·268 at 17° compared with water at 15°. Treated with an excess of cold alcoholic potash, a mixture of potassium dichloromalonate and mesoxalate appears to be formed; whilst on mixing it with 6—10 times its volume of concentrated alcoholic ammonia, dichloromalonamide, melting at 202° (see Zincke and Kegel, Abstr., 1890, 490), separates after two days, and dichloracetamide (m. p. 98°) is obtained from the filtrate.

Ethyl chlorobromomalonate, $CClBr(COOEt)_2$, is obtained by brominating ethyl chloromalonate; it distils at 136—139° under a pressure of 35 mm., and boils at the ordinary pressure at 239—241° with partial decomposition; its sp. gr. is 1·467 at 16° compared with water at 15°. Treated with four times its volume of concentrated alcoholic ammonia, a compound melting at 160—165° separates, which is, perhaps, a mixture of chlorobromomalonamide and amidochloromalonamide; whilst *chlorobromacetamide* melting at 117° is obtained from the filtrate. Chlorobromacetamide has already been prepared by Cech and Steiner (this Journal, 1876, **1**, 373), and as it differs in melting point from the authors' compound, they have repeated Cech and Steiner's experiments, and find that neither chlorobromacetic acid nor the amide described by these chemists are homogeneous substances, but are contaminated with the dibromo-derivatives. Ethyl bromomalonate, $CHBr(COOEt)_2$ (Knoevenagel, Abstr., 1888, 707), has a sp. gr. of 1·426 at 15° compared with water at the same temperature.

Ethyl acetyltartronate, $OAc{\cdot}CH(COOEt)_2$, is produced together with the *compound* $C(COOEt)_2{:}C(COOEt)_2$, by heating ethyl bromomalonate (88 grams) and potassium acetate (40 grams) dissolved in absolute alcohol, at 40—50°; the former is a bright yellow oil, boiling at 158—163° (60 mm.), and has a sp. gr. 1·131 at 1·95° compared with water at 15°, whilst the latter is a solid compound melting at 56°. When ethyl acetyltartronate is dissolved in ether and treated with

sodium (1 eq.), and then heated for 10 seconds on the water-bath with ethyl iodide, the *ethyl derivative*, $OAc\cdot CEt(COOEt)_2$, boiling at 151—153° (30 mm.) is formed.

Ethyl mesoxalate, $C(OH)_2(COOEt)_2$, described by Petrieff as an oil, is obtained by treating ethyl acetyltartronate with somewhat more than one molecular proportion of bromine at 110°: it boils at 140—145° (50 mm.), solidifies after a time, and when crystallised from ether melts at 57°.

Ethyl phenyltartronate, $OPh\cdot CH(COOEt)_2$, is prepared by dissolving sodium (2·3 grams) in alcohol (35 c.c.), adding phenol (9·4 grams) and ethyl bromomalonate (24 grams), heating, distilling off the greater portion of the alcohol, adding water, and extracting the precipitated oil with ether; it distils under a pressure of 60 mm. at 230—240°. The acid obtained on hydrolysis with hydrochloric acid yields phenylglycollic acid (m. p. 96°) when heated at 180°.

Ethyl dibromomalonate, $CBr_2(COOEt)_2$ (J. Wislicenus, Abstr., 1888, 151), is obtained by brominating ethyl malonate in direct sunlight; it distils at 145—155° under a pressure of 25 mm.; when dissolved in half its volume of cooled, concentrated, alcoholic ammonia, crystals separate, after a time, of a compound which probably consists of *diamidomalonamide*, $C(NH_2)_2(CONH_2)_2$; this darkens at 150°, dissolves in water with decomposition, and loses ammonia when carefully heated at 90—100°, yielding *imidomalonamide*, $NH{:}C(CONH_2)_2$, a compound dissolving in water to a neutral solution, from which ammonia is evolved on heating. When ethyl dibromomalonate is heated with benzene and sodium in the form of wire, it yields the *compound* $C(COOEt)_2{:}C(COOEt)_2$ (see above); if digested with an alcoholic solution of potassium acetate, ethyl mesoxalate is formed; whilst when heated with a mixture of phenol and sodium ethoxide, *ethyl diphenoxymalonate*, $C(OPh_2)(COOEt)_2$, is obtained distilling at 250—260° under a pressure of 60 mm., and this, on boiling with alcoholic potash, yields the corresponding *acid*, which, after being crystallised from water, melts at 173°.

Bromethylmalonic acid, $CEtBr(COOH)_2$, is obtained in theoretical yield when ethylmalonic acid is heated on the water-bath with an excess of bromine; it melts at 104° with the evolution of carbonic anhydride and the formation of bromobutyric acid. A. R. L.

Action of Zinc on Ethyl Dibromosuccinate. By A. Michael (*J. pr. Chem.* [2], **44**, 399—403).—In this paper the author replies to the criticisms of Claus (Abstr., 1891, 1338) on the work which Michael and Schulthess published on the subject (Abstr., 1891, 1184). The discussion is now closed as far as the author is concerned.

A. G. B.

Decomposition of Glutaric Acid at a High Temperature. By A. Claus (*Annalen*, **265**, 247—253).—In reply to Wisbar (Abstr., 1891, 1011), the author states that a careful repetition of his previous experiments has proved conclusively that carbonic anhydride is evolved on heating glutaric acid under the conditions already described. When the acid is kept for a long time at 180—210°, it is converted into its anhydride; this compound is then completely

decomposed with evolution of carbonic anhydride, and there remains a porous, carbonaceous mass; the liquid distillate contains a considerable quantity of an acid, which is not butyric acid, as was first stated; the investigation of this product will be continued.

F. S. K.

Synthesis of Polybasic Fatty Acids. By K. Auwers, E. Köbner, and F. v. Meyenburg (*Ber.*, **24**, 2887—2901).—In a previous paper (Abstr., 1891, 307), Auwers has published a preliminary account of the synthesis of polybasic acids; the present communication gives a detailed account of the acids already prepared. The process employed is the same in all cases, and consists in warming a mixture of a solution or emulsion of the sodium compound of ethyl malonate or one of its alkyl derivatives with the ethyl salt of an unsaturated acid. The product is mixed with water and dilute sulphuric acid, and the oily, ethereal salt which separates washed, dried, fractionated under reduced pressure, and hydrolysed by boiling with a mixture of equal volumes of concentrated hydrochloric acid and water.

The preparation of symmetrical $\alpha\alpha$-dimethylglutaric acid has already been described (*loc. cit.*). *β-Methylglutaric acid*,

$$COOH\cdot CH_2\cdot CHMe\cdot CH_2\cdot COOH,$$

is formed by the action of ethyl crotonate on ethyl sodiomalonate, and hydrolysis of the crude ethyl salt first obtained; after crystallisation from ether and benzene, it melts at 86°. Ethyl sodiomalonate and ethyl fumarate yield as the first product *ethyl propanetetracarboxylate*, $CH(COOEt)_2\cdot CH(COOEt)\cdot CH_2\cdot COOEt$, which boils at 200—220° under a pressure of 25 mm., and on hydrolysis yields tricarballylic acid, $COOH\cdot CH_2\cdot CH(COOH)\cdot CH_2\cdot COOH$, melting at 162—164°. The authors confirm Emery's statement that this acid, on treatment with acetic acid, yields an *anhydrotricarballylic acid*, $C_6H_6O_5$, melting at 131° (Abstr., 1891, 689).

The product of the reaction of ethyl fumarate and ethyl sodiomethylmalonate is an ethyl salt which boils at 196—198° under a pressure of 20 mm., and has a sp. gr. of 1·1158 at 18°/4°. On hydrolysis, it yields two acids of the composition $C_7H_{10}O_6$, which must, from their mode of formation, both be *α-methyltricarballylic acid*, $COOH\cdot CHMeCH(COOH)\cdot CH_2\cdot COOH$, and represent stereometric isomerides, an acid of this formula having two asymmetrical carbon atoms. The acids are separated by crystallisation from water; the less soluble compound crystallises in compact, lustrous prisms, melts at 180°, is readily soluble in alcohol and acetone, but almost insoluble in benzene and light petroleum; its *silver* salt, $C_7H_7Ag_3O_6$, is a heavy, white precipitate. The more soluble acid is contained in the mother liquor of the previous acid, and is separated by repeated crystallisation from water; it still, however, contains ammonium chloride derived from the ethyl cyanacetate present in commercial ethyl malonate, and may be separated from it by treatment with anhydrous ether. It then melts at 134°, and in its other properties closely resembles the isomeric acid, into which it is partially converted by heating with hydrochloric acid at 200°.

The action of ethyl sodiomalonate on ethyl citraconate might proceed in two different ways, giving rise either to an α- or a β-methyltricarballylic acid. The intermediate ethereal salt boils at 226° under a pressure of 39 mm., and on hydrolysis yields in small quantity an acid which has the composition $C_7H_{10}O_6$, forms beautiful, transparent crystals, and melts at 164°. It is not identical with either of the foregoing acids, and must therefore be *β-methyltricarballylic acid*, $COOH{\cdot}CH_2{\cdot}CMe(COOH){\cdot}CH_2{\cdot}COOH$. If ethyl itaconate be substituted for ethyl citraconate, two reactions are also possible, leading to the formation of either β-methyltricarballylic acid or butanetricarboxylic acid. The intermediate ethyl salt was found to boil at 200—240° under 37 mm. pressure, whilst the acid formed from it crystallises in rosette-shaped aggregates of prisms, and melts at 116—120°. It differs, therefore, completely from β-methyltricarballylic acid, and must be *butanetricarboxylic acid*,

$$COOH{\cdot}CH_2{\cdot}CH_2{\cdot}CH(COOH){\cdot}CH_2{\cdot}COOH.$$

The two stereoisomeric *α-ethyltricarballylic acids*,

$$COOH{\cdot}CHEt{\cdot}CH(COOH){\cdot}CH_2{\cdot}COOH,$$

may be prepared in a manner exactly similar to the corresponding methyl compounds. The intermediate ethyl ethylpropanetetracarboxylate boils at 207—212° under a pressure of 25 mm. The less soluble acid forms spherical aggregates of thin, lustrous oblique prisms, and melts at 147—148°; its *silver* salt, $C_8H_9Ag_3O_6$, is a voluminous, white precipitate, very susceptible to the action of light. The more soluble acid was not obtained in sufficient quantity for complete purification.

Propyltricarballylic acid, $COOH{\cdot}CHPr^{\alpha}{\cdot}CH(COOH){\cdot}CH_2{\cdot}COOH$, and *isopropyltricarballylic acid*,

$$COOH{\cdot}CHPr^{\beta}{\cdot}CH(COOH){\cdot}CH_2{\cdot}COOH,$$

are readily obtained by heating ethyl fumarate with ethyl propyl- or isopropyl-sodiomalonate. The former crystallises from water on spontaneous evaporation in compact, lustrous prisms which contain water of crystallisation and melt below 100°; when rapidly crystallised, however, it forms nodules consisting of anhydrous plates, melts at 151—152°, and is soluble in alcohol and ether, but almost insoluble in benzene and light petroleum. The mother liquors contain lower melting products which could not be isolated. Isopropyltricarballylic acid crystallises in anhydrous nodules formed of plates or compact prisms, melts at 161—162°, and behaves towards solvents in the same manner as the previous acid.

Determinations of the conductivities of these acids have been made by Walden, and it appears that, as in the case of succinic acid, the introduction of alkyl groups into tricarballylic acid raises the conductivity to a considerable extent.

An attempt was made to bring about the combination of ethyl sodiomalonate and the ethyl salt of Δ'-tetrahydrophthalic acid, as the latter behaves in many respects as an unsaturated fatty acid.

No reaction, however, was found to take place on digesting the mixture for six hours at 100°. H. G. C.

Furfurylamine. By A. Deutzmann (*Chem. Centr.*, 1891, ii, 295—296; from *Diss. Berlin*).—The following compounds are described:—*Furfurylamine furfuryldithiocarbamate*,

$$C_4OH_3{\cdot}CH_2{\cdot}NH{\cdot}CSSH,NH_2{\cdot}CH_2{\cdot}C_4OH_3,$$

is prepared from 6·8 grams of carbon bisulphide dissolved in dry ether and 18 grams of furfurylamine; it is soluble in alcohol, ether, benzene, and light petroleum; when exposed to the air, it becomes yellow. *Furfurylthiocarbimide*, $CS{:}N{\cdot}CH_2{\cdot}C_4OH_3$, is prepared from the last-named salt by the action of mercuric chloride, which must not be in excess. *Difurfurylthiocarbamide*, $CS(NH{\cdot}CH_2{\cdot}C_4OH_3)_2$, prepared by heating the dithiocarbamate at 100°, melts at 85—86°. *Methylfurfurylthiocarbamide*, prepared from methylthiocarbimide and furfurylamine, melts at 83°. *Ethylfurfurylthiocarbamide* melts at 67°. *Allylfurfurylthiocarbamide* melts at 42—43°. *Phenylfurfurylthiocarbamide* melts at 128°; the *paratolylcarbamide* melts at 165°; the *metaxylylcarbamide* at 121·5°.

Furfurylcarbamide, $NH_2{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}C_4OH_3$, prepared from furfurylamine and potassium cyanate, melts at 110—111°; *difurfurylcarbamide*, prepared from furfurylamine, potassium hydroxide, and carbonyl chloride dissolved in benzene, melts at 128°. *Ethylfurfurylcarbamide* melts at 95—96°; *amylfurfurylcarbamide* at 120—121°. These were prepared by the aid of ethyl- and amyl-carbimide respectively. *Phenylfurfurylcarbamide* melts at 124°; the *orthotolylcarbamide* at 168—168·5°; the *metaxylylcarbamide* at 178°. From *difurfurylthiocarbamide*, by the action of mercuric oxide, cyanamide and furfurylamine are obtained, but not the corresponding guanidine.

The *hydrochloride of furfurylguanidine*, $C(NH_2)_2{:}N{\cdot}CH_2{\cdot}C_4OH_3$, may be prepared by heating cyanamide and furfurylamine hydrochloride at 100° in a sealed tube. Both it and the platinum salt were analysed.

Diphenylfurfurylguanidine, $C(NHPh)_2{:}N{\cdot}CH_2{\cdot}C_4OH_3$, is prepared from the last-named compound by heating it with aniline at 80—81°. By treating the amine with methyl iodide, *trimethylfurfurylammonium iodide*, $C_4OH_3{\cdot}CH_2{\cdot}NMe_3I$, is obtained.

By distilling furfurylamine hydrochloride, a liquid was obtained which probably contained furfuryl chloride. *Nitrofurfurylamine* is prepared by acting with nitric acid on acetylfurfurylamine in glacial acetic acid, and then distilling with steam. J. W. L.

Intramolecular Change of the Propyl Group. By O. Widman (*J. pr. Chem.* [2], **44**, 414—415; compare Abstr., 1891, 686, 1344).—Fileti (Abstr., 1891, 1344) quotes Widman as having pointed out that the nitration of cumenylacrylic acid produces paranitrocinnamic acid, orthonitroparisopropylcinnamic acid, and an isomeride of the latter which he called orthonitroparapropylcinnamic acid. Widman now points out that Fileti has missed the publications (Abstr., 1891, 69, 45) in which it is shown that this "orthonitroparapropylcinnamic" acid is really a mixture of about one-third metanitro-

cumenylacrylic acid and two-thirds orthonitrocumenylacrylic acid, the mixture having a constant melting point and crystallising in a definite form. A. G. B.

Isomeric Change in the Synthesis of Aromatic Amines and Phenols. By M. Seńkowski (*Ber.*, **24**, 2974—2977).—It is well known that the higher homologues of aniline, produced by heating its alkyl derivatives or the corresponding alcohols with its hydrochloride or stannochloride, invariably belong to the para-series; the same applies to the homologues of phenol obtained by the action of zinc chloride on a mixture of phenol and the alcohol. The experiments to be described were instituted to ascertain whether in these cases intramolecular changes occur similar to those observed in the synthesis of aromatic hydrocarbons by means of aluminium chloride.

Paratertiarybutylphenol (Abstr., 1890, 1296) is obtained by the action of zinc chloride and isobutyl alcohol on phenol in the manner described by A. Liebmann (Abstr., 1882, 171, 727).

Paramidophenyltrimethylmethane (*loc. cit.*, 1890) is formed by heating aniline hydrochloride with isobutyl alcohol in a sealed tube at 230°; it yields trimethylphenylmethane (*loc. cit.*, 1890) by the diazo-reaction.

The so-called isobutylbenzene boiling at 165—170° (Goldschmidt, Abstr., 1882, 952) is a mixture. When treated with bromine in direct sunlight until the colour of the bromine persists for several minutes, and, after washing the product with potash and drying, it is distilled over sodium, a small quantity of a hydrocarbon passes over at 167—168°, apparently identical with trimethylphenylmethane.

Isoamylaniline (Hofmann, this Journal, 1874, 807; Merz and Weith, Abstr., 1882, 179), when treated with one molecular proportion of bromine in sunlight and with a second, in the dark, at the temperature of the water-bath, yields Schramm's isoamylbenzene dibromide melting at 129° (Abstr., 1883, 977), and is, therefore, a normal product. A. R. L.

Action of Nitrous Acid on Resorcinol Diethyl Ether and on Triethylresorcinol. By A. Kraus (*Monatsh.*, **12**, 368—378).—When a solution of resorcinol diethyl ether (1 part) in acetic acid (10 parts) is saturated with hydrogen chloride, and treated in the cold with a large excess of alkaline nitrite, a very considerable quantity of a dark-green precipitate separates. The product is diluted with water and filtered, and the solid thus obtained treated with cold, dilute potash, whereby the greater portion dissolves, forming a dark-red solution, from which hydrochloric acid separates *nitrosoresorcinol ethyl ether*, $NO\cdot C_6H_3(OH)\cdot OEt$, in the form of a voluminous, light-yellow precipitate. The ether may be readily recrystallised from hot water and from hot alcohol (compare Aronheim, *Ber.*, **12**, 30), when it forms thin, pale-yellow scales which decompose at 150° without having previously melted. That part of the above-mentioned product which is insoluble in cold dilute potash is washed with cold alcohol, and dried in a vacuum. On elementary analysis, it gives

numbers corresponding with the formula for *nitrosoresorcinol diethyl ether*, $NO\cdot C_6H_3(OEt)_2$. It melts at 122—123°, is soluble in cold chloroform, benzene, and ether, but is decomposed when warmed with those solvents; it has a pale-rose colour, and gives an intense blue coloration with concentrated sulphuric and hydrochloric acids. The *benzoyl derivative* of nitrosoresorcinol ethyl ether, $NO\cdot C_6H_3(OEt)\cdot OBz$, is obtained in the form of yellow flocks on shaking a solution of the ether in soda with an excess of benzoic chloride. When recrystallised from alcohol, it forms beautiful, yellow crystals which melt at 155°.

Nitrosoethylresorcinol ethyl ether, $NO\cdot C_6H_2Et(OH)\cdot OEt$, is obtained when triethylresorcinol (compare Herzig and Zeisel, Abstr., 1890, 1404) is dissolved in ten times its weight of absolute alcohol, and the solution mixed with slightly more than the molecular equivalent of sodium nitrite, and decomposed with concentrated hydrochloric acid until the whole assumes a brownish-yellow colour. On the addition of water, a green, flocculent precipitate is formed, the colour of which gradually changes to reddish-yellow. The precipitate is dissolved in potash, and the solution exhausted with ether; the ethereal extract is acidified, and the yellow precipitate thus obtained crystallised from hot benzene, which furnishes the compound in the form of beautiful, yellow prisms. It dissolves when warmed with ordinary solvents, and decomposes at 150°, without having previously melted; it gives a stable base on treatment with reducing agents, is oxidised by nitric acid, first to a nitro-compound, and eventually to oxalic acid, and forms a well characterised *benzoyl derivative*,

$$NO\cdot C_6H_2Et(OEt)\cdot OBz,$$

which is insoluble in potash, and melts at 141—142°. G. T. M.

Hydroxyquinones. By Kowalski (*Chem. Centr.*, 1891, ii, 377; from *Schweiz. Wochenschr. Pharm.*, **29**, 265).—The author has observed the formation of hydroxyquinones from quinones, when the latter are left exposed to the action of aqueous alkali and air. From α-naphthaquinone and from thymoquinone the corresponding hydroxyquinones were obtained. J. W. L.

Isoeugenol, Diisoeugenol, and their Derivatives. By E. Tiemann (*Ber.*, **24**, 2870—2877).—In his researches on the products of oxidation of acetyleugenol (this vol., p. 59), the author was led to suppose that the eugenol employed might contain a hitherto unknown isomeride, or that such a compound might be formed as an intermediate product during its oxidation. He therefore examined the action of various reagents on eugenol, but only succeeded in converting it into the already known isomeride, isoeugenol,

$$CHMe{:}CH\cdot C_6H_3(OMe)\cdot OH\ [1:3:4].$$

This molecular interchange proceeds best when carried out as follows:—12·5 parts of potash are dissolved in 18 parts of amyl alcohol, 5 parts of eugenol added, the mixture heated for 16—20

hours at 140°, and the amyl alcohol removed by distillation in a current of steam. Sulphuric acid is then added, the isoeugenol separated, washed with sodium carbonate solution, and distilled in a current of steam. It then boils at 261° (uncorr.), and has all the properties assigned to it by Kraaz and Tiemann (Abstr., 1883, 201); in alcoholic solution, it is coloured olive-green by ferric chloride, and if left it becomes yellow, but much less rapidly than eugenol. Its coefficient of refraction is 1·5728, that of eugenol being 1·5438.

The substance described by Kraaz and Tiemann as benzoylisoeugenol is in reality a derivative of diisoeugenol, and not of isoeugenol. The monomolecular acetyl and benzoyl compounds can only be obtained under certain conditions. *Acetylisoeugenol*, $C_{10}H_{11}O_2Ac$, is prepared by boiling the phenol with acetic anhydride, and separates in lustrous, white needles on the addition of light petroleum to its benzene solution; it melts at 79—80°, boils at 282—283° (uncorr.), and is reconverted into isoeugenol by alkalis. *Benzoylisoeugenol*, $C_{10}H_{11}O_2Bz$, is formed by the action of benzoic chloride on a solution of isoeugenol in dilute soda, provided the liquid never becomes acid; it crystallises from alcohol in white prisms melting at 103—104°.

Diacetyldiisoeugenol, $C_{20}H_{22}O_4Ac_2$, is obtained by adding acetyl chloride to isoeugenol previously warmed to 54°, and raising the temperature to 80°, heating as long as hydrogen chloride is evolved. The product solidifies on cooling, and may be separated from adhering oil by means of ether; the residue is crystallised from boiling alcohol, and then forms white needles which melt at 150—151°, and are almost insoluble in water and ether. *Dibenzoyldiisoeugenol*, $C_{20}H_{22}O_4Bz_2$, is the compound previously described by Kraaz and Tiemann (*loc. cit.*) as benzoylisoeugenol. Both these substances on hydrolysis yield *diisoeugenol*, which may also be obtained by the action of mineral acids or acid salts on isoeugenol; it crystallises from 50 per cent. alcohol in slender needles, melts at 180—181°, is readily soluble in ether and chloroform, less easily in alcohol, and almost insoluble in water and light petroleum. Its alcoholic solution is coloured olive-green by ferric chloride.

The molecular weight of diisoeugenol, as found by Raoult's method, agrees with the above formula, but no evidence as to its constitution has yet been obtained. It might possibly be a tetramethylene derivative of a formula such as

$$\begin{array}{l} CHMe\cdot CH\cdot C_6H_3(OMe)\cdot OH \\ | \qquad\quad | \\ CHMe\cdot CH\cdot C_6H_3(OMe)\cdot OH' \end{array}$$

or it may be a diphenyl derivative. Further investigation of this compound is in progress. H. G. C.

Oxidation Products of Safrole. By F. Tiemann (*Ber.*, **24**, 2879—2886).—The results given in the preceding abstract and on p 59 show that acetyleugenol and acetylisoeugenol are compounds which readily undergo decomposition, and that in their oxidation several processes occur simultaneously; the exact investigation of these processes has been rendered still more difficult by the fact that in the secondary reactions the benzene nucleus itself has been attacked. The author

therefore wished to follow out the oxidation processes in a phenyl-allylene derivative, in which the action of the oxidising agent would be confined to the carbon side chain. Such a derivative has been found in safrole, which has been shown by Eykman (Abstr., 1886, 95) and Poleck (Abstr., 1884, 1339; 1886, 697) to have the constitution $CH_2<^{O\ (3)}_{O\ (4)}>C_6H_3\cdot CH_2\cdot CN{:}CH_2$ (1).

On carefully oxidising safrole with 1½ per cent. permanganate solution at 70—80°, it takes up two hydroxyl groups, forming *methylene-3 : 4-dihydroxybenzyl glycol*, $CH_2<^{O}_{O}>C_6H_3\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot OH$, which crystallises from benzene in white needles, melts at 82—83°, and is readily soluble in boiling water and ether, less easily in alcohol. Its *diacetate*, $C_{10}H_{10}O_4Ac_2$, is a pale-yellow oil boiling at 240° under a pressure of 15—20 mm.; and the *diphenylcarbamate*,

$$C_{10}H_{10}O_4(CO\cdot NHPh)_2,$$

obtained by the action of phenyl isocyanate on the glycol, crystallises in plates, and melts at 127°.

If 5 parts of safrole be warmed at 70—80° with 12·5 parts of permanganate, 5 parts of acetic acid, and 1000 parts of water, piperonal, piperonic acid, and α-homopiperonic acid are obtained. The first is removed by extracting the alkaline solution with ether, and the alkaline solution is then concentrated, acidified, and extracted with ether. The residue obtained from this extract, which contains piperonic and α-homopiperonic acids, is boiled with magnesium carbonate, resinous matters being removed by ether, the solution again acidified and taken up with ether, the latter evaporated, and the residual mixture of the two acids separated by fractional crystallisation from hot water.

α-Homopiperonic acid, $CH_2<^{O}_{O}>C_6H_3\cdot CH_2\cdot COOH$, crystallises in white needles, melts at 127—128°, and dissolves readily in boiling water, alcohol, ether, and hot benzene, scarcely at all in light petroleum. The *calcium* salt contains 2 mols. H_2O, which are given off at 100°; the *copper* salt, $(C_9H_7O_4)_2Cu$, forms a pale-green, crystalline powder; the *silver* salt, $C_9H_7O_4Ag$, a white, crystalline powder, which may be crystallised from hot water; the *zinc* salt, $(C_9H_7O_4)_2Zn$, is also white and crystalline. The *methyl* salt, $C_9H_7O_4Me$, and *ethyl* salt, $C_9H_7O_4Et$, are yellow oils boiling at 278—280° and 291° respectively, and the *amide*, $C_8H_7O_3\cdot CON\ H_2$, crystallises in needles melting at 172—173°. On treatment with nitric acid, α-homopiperonic acid yields a *nitro-compound*, $C_9H_7O_4\cdot NO_2$, which crystallises in yellow plates, and melts at 188°. Further oxidation converts the acid into piperonic acid and piperonal.

From these results, it appears that the allenyl group of safrole undergoes oxidation in a normal manner; the intermediate homopiperonal, $CH_2<^{O}_{O}>C_6H_3\cdot CH_2\cdot CHO$, has not been isolated, owing probably to its instability; so far also no indication of a compound corresponding with acetovanillone has been observed. H. G. C.

Action of Benzyl Chloride on Orthotoluidine. By C. Rabaut (*Bull. Soc. Chim.* [3], **5**, 742—743).—*Benzylorthotoluidine*, $C_6H_4Me{\cdot}NHPh$, is formed when benzyl chloride (1 mol.) is heated with orthotoluidine (2 mols.) in an open vessel for 40 hours at 175°. The crystalline product of the reaction is treated with aqueous sodium carbonate, and yields a dark, chestnut-coloured oil, which, on purification, becomes almost colourless. Benzylorthotoluidine boils at 210° under a pressure of 25 mm., crystallises from alcohol in tufts, melts at 56—57°, and is soluble in the ordinary menstrua. The *hydrochloride* forms white crystals, is soluble in alcohol and hot water, and unites with platinum chloride to form a yellow, crystalline *platinochloride*. The *acetate*, *sulphate*, *nitrate*, and *oxalate* are white.

When benzylorthotoluidine is treated with ethyl iodide, benzylethylorthotoluidine, $C_6H_4Me{\cdot}NEt{\cdot}CH_2Ph$, is obtained as a yellowish, neutral oil boiling at 230° under 25 mm. pressure.

Acetylbenzylorthotoluidine is solid at ordinary temperatures, and boils at 280—285° under a pressure of 20 mm. Jn. W.

Oxidation of Azo-compounds. By C. Lauth (*Compt. rend.*, **112**, 1512—1514).—Azo-compounds, when oxidised by various reagents in the cold, yield diazo-compounds together with quinones. Acid and alkaline reagents give similar results; the author has chiefly employed lead dioxide in the presence of sulphuric acid.

The sodium salt of benzeneazo-β-naphtholdisulphonic acid is dissolved in 30 parts of water; to the solution, 2 parts of sulphuric acid (66°) and 1 part of the lead dioxide are added; the red-orange solution rapidly becomes lemon-yellow, and there is no evolution of gas in the cold. Nitrogen is rapidly evolved on heating, and, when distilled, phenol comes over in the first portions of the distillate. The diazo-solution, on treatment with an alkaline solution of phenol, phenolsulphonates, or amines, gives azo-colouring matters; for example, the addition of β-naphtholdisulphonic acid regenerates benzene-azo-β-naphtholdisulphonic acid. Compounds substituted in the diazo-group react equally well: Orange I (the sodium salt of sulphobenzeneazo-α-naphthol) yields, similarly, a diazo-solution, giving, on distillation, phenylparasulphonic acid. Again, sulphobenzeneazo-phenol, by oxidation, yields a diazo-solution, which, on the addition of an alkaline solution of α-naphthol, gives Orange I.

The reaction has been applied to a large number of azo-compounds, including unsubstituted compounds, such as azobenzene, as well as compounds containing amido-, hydroxy-, or carboxyl-groups. No exception has been found to the general course of the reaction indicated above. The reaction may be considered to be characteristic of the azo-compounds.

When the liquid, after oxidation, is filtered from the lead sulphate formed, it yields a quinone in the case of sulphobenzeneazo-phenol; in other cases the residue contains most of the oxidation products.

The general reaction for the oxidation is of the type of

$$C_6H_5{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH + H_2SO_4 + O_2 = C_6H_5{\cdot}N_2{\cdot}SO_4H + C_{10}H_6O_2 + H_2O.$$

intermediate products may be obtained at the same time, if the oxidising agent is not present in sufficient quantity, as well as tetrazo-compounds. W. T.

Action of Phenylhydrazine on Phenols. By A. Seyewetz (*Compt. rend.*, **113**, 264—267).—Phenol, the cresols, and the naphthols do not yield compounds with phenylhydrazine in presence of various solvents, and under various conditions.

Dihydric phenols behave differently, and readily combine with phenylhydrazine, the reaction being so distinct in the case of orcinol that it would almost seem to indicate the presence of a ketonic or aldehydic group in this compound.

A concentrated aqueous solution of the phenol is mixed with a solution of phenylhydrazine in water slightly acidified with acetic acid. After agitating for some minutes, the compound separates, is washed with water containing a little acetic acid, and then recrystallised from benzene.

Quinol yields the compound $C_6H_4(OH)_2,2NHPh{\cdot}NH_2$, which crystallises from boiling benzene in small, white, nacreous plates melting at 70—71°. It gradually alters when exposed to the air, and becomes yellow, is slightly soluble in cold water, somewhat soluble in warm water, alcohol, chloroform, ether, and benzene, very slightly soluble in light petroleum. Alkalis liberate phenylhydrazine, even in the cold; acids liberate the phenol.

Resorcinol yields the compound described by Baeyer and Kochendoerfer.

Orcinol readily yields the compound $C_6H_3Me(OH)_2,2NHPh{\cdot}NH_2$, which forms white crystals melting at 61—62°, and similar in general properties to the quinol derivative.

Catechol seems not to form a corresponding compound, and this is true also of pyrogallol.

Salicylic acid, in presence of toluene, yields a compound crystallising in slender, white needles, and melting at 122—123°. In many cases, however, the finding of a suitable solvent constitutes a great difficulty. C. H. B.

Combination of Phenylhydrazine with Ethyl Oxalacetate. By W. Wislicenus and M. Scheidt (*Ber.*, **24**, 3006—3010).—On mixing together ethereal solutions of phenylhydrazine and ethyl oxalacetate in molecular proportion, and cooling, an additive compound is deposited in colourless, lustrous plates; it may be crystallised from absolute alcohol, and melts at 105—106°. This substance is distinguished from the hydrazone (m. p. 76—78°) by its colour, and by its insolubility in ether and in light petroleum. The additive compound is readily converted into the hydrazone by fusion, or by heating it in solution; at ordinary temperatures the change is more gradual. The constitution of this compound may be represented by the formula $COOEt{\cdot}C(OH)(NH{\cdot}NHPh)CH_2{\cdot}COOEt$, which would readily explain its conversion into the hydrazone; from the general properties of the substance, however, as well as from the fact that all efforts hitherto made to prepare similar substances from other

less acid, ketonic, ethereal salts have failed, the authors consider it to be an analogue of the ammonium salts, with the formula $COOEt{\cdot}CO{\cdot}CH(NH_3{\cdot}NHPh){\cdot}COOEt$ or

$$COOEt{\cdot}C(O{\cdot}NH_3{\cdot}NHPh):CH{\cdot}COOEt.$$

The same substance is also formed by the action of phenylhydrazine hydrochloride on ethyl sodoxalacetate in cold, concentrated, aqueous solution.

Methyl oxalacetate and ethyl ethoxyoxalacetate yield additive compounds with phenylhydrazine similar to the one described above, whilst ethyl methyloxalacetate, ethyl oxalsuccinate, ethyl acetoacetate, ethyl benzoylacetate, and ethyl levulinate do not react in this manner.

J. B. T.

Oximes and so-called Stereochemistry. By A. Claus (*J. pr. Chem.* [2], **44**, 312—335).—This paper deals with the isomerism of the hydroxylamine derivatives of benzile, and especially with the recent work of Anwers and Meyer on the subject (Abstr., 1889, 403, 609, 611, 713). The author concludes by claiming that he has incontrovertibly proved that all manifestations of isomerism among the products of the reaction of hydroxylamine with benzile can be efficiently and easily explained as cases of isomerism in structure, without having recourse to any stereochemical hypothesis.

A. G. B.

Intramolecular Change of some Isoaldoxime Derivatives. By R. Behrend (*Annalen*, **265**, 238—246).—When pure benzylisoparanitrobenzaldoxime (m. p. 118°) is dissolved in alcohol (9—10 parts), and the solution warmed with a few drops of a dilute alcoholic solution of sodium ethoxide, it is partially converted into paranitrobenzylisobenzaldoxime; this change is expressed by the equation

$$NO_2{\cdot}C_6H_4{\cdot}CH<^{O}_{-}>N{\cdot}CH_2Ph = NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}N<^{O}_{-}>CHPh,$$

and is, to a certain extent, reversible, as when paranitrobenzylisobenzaldoxime is treated with sodium ethoxide under the same conditions, it is in part transformed into benzylisoparanitrobenzaldoxime.

When benzylisometanitrobenzaldoxime, prepared by the condensation of metanitrobenzaldehyde with β benzylhydroxylamine, is warmed with a dilute alcoholic solution of sodium ethoxide, it is partially converted into the isomeric metanitrobenzylisobenzaldoxime, and on evaporating the solution, a mixture of the two isomerides is left; this is dissolved in alcohol (about 10 parts), and on keeping the solution for about 24 hours, the greater part of the unchanged benzylisonitrobenzaldoxime is deposited in crystals, whilst most of the isomeride remains in solution; the latter is obtained in a pure condition by repeated fractional crystallisation from alcohol.

Metanitrobenzylisobenzaldoxime, $C_{14}H_{12}N_2O_3$, purified in the manner just described, crystallises from hot alcohol and benzene, in both of

which it is readily soluble, in lustrous, pale-yellow needles, melts at 114—115°, and is only sparingly soluble in ether, and almost insoluble in light petroleum. It seems to be unchanged by a warm solution of sodium ethoxide, but when heated with hydrochloric acid, it is decomposed into benzaldehyde and *β-metanitrobenzylhydroxylamine hydrochloride;* the latter is readily soluble in water, but more sparingly in alcohol, from which it is precipitated on the addition of ether, as a colourless, crystalline powder, melting at 145—146°, with previous softening; the melting point of the salt which has once been melted is much higher. The free *base* crystallises from hot water in needles, melts at 79·5—80·5°, and reduces Fehling's solution.

Benzylisoanisaldoxime is not acted on by sodium ethoxide under the conditions described above. F. S. K.

Amidines. By W. Lossen (*Annalen*, **265**, 129—178).—The interesting results obtained on treating benzenylamidine and other amidines with nitrous acid (Abstr., 1891, 1038—1042) have led the author and his pupils (Mierau, Kobbert, Neubert, C. Lossen, Kirschnick, and Grabowski) to subject the amidines to a somewhat extended investigation, in order to determine (1) which of these compounds form dioxytetrazotic acids and stable nitrites, and (2) how the properties of the amidines compare with those of the amidoximes.

Benzenylamidine sulphate, $(C_7H_8N_2)_2,H_2SO_4 + H_2O$, is easily obtained by evaporating a solution of the nitrite with the theoretical quantity of sulphuric acid, and extracting the residue with alcohol and ether successively; the insoluble sulphate is then dissolved in water and reprecipitated by the addition of alcohol; it loses its water at 80—81°, and decomposes into benzonitrile and ammonium sulphate on further heating. The *formate*, $C_7H_8N_2,CH_2O_2 + H_2O$, prepared by decomposing the sulphate with barium formate, crystallises well, is readily soluble in alcohol and water, and loses its water over sulphuric acid. The *acetate*, $C_7H_8N_2,C_2H_4O_2$, forms monoclinic crystals, $a : b : c = 1·099 : 1 : ?$, $\beta = 120° 13'$, and is readily soluble in water and alcohol. The *nitrite*, $C_7H_8N_2,HNO_2 + H_2O$, can be obtained by evaporating a solution of equivalent quantities of benzenylamidine hydrochloride and sodium nitrite; it crystallises from alcohol in monoclinic (or rhombic ?) plates, $a : b : c = 3·467 : 1 : 3·425$, $\beta = 94° 32'$, and decomposes below 70° with formation of benzonitrile; it is readily soluble in water and alcohol, but insoluble in ether.

Phenylbenzenylamidine can be prepared by triturating benzimidoethyl ether hydrochloride (1 mol.) with warm aniline (1 mol.), and also by treating benzanilide imidochloride with anhydrous ammonia in light petroleum solution; it melts at 112°, and is identical with the compound obtained by Bernthsen (*Annalen*, **184**, 348; **192**, 29) by treating aniline hydrochloride with thiobenzamide, or with benzonitrile; its constitution is probably expressed by the formula $NH_2·CPh:NPh$. When this amidine is treated with nitrous acid under various conditions, it yields benzanilide as the sole product, a fact which shows that the nitrite of the base is very unstable.

Phenylbenzimidoethyl ether, NPh:CPh·OEt, is formed in preparing phenylbenzenylamidine by the action of aniline on benzimidoethyl ether hydrochloride; it is an oily liquid, the hydrochloride of which decomposes at about 60° into benzanilide and ethyl chloride. When the oil is heated at about 70° with phosphorus pentachloride, it undergoes decomposition into ethyl chloride and benzanilideimido chloride, CClPh:NPh.

Metanitrobenzimidoethyl ether hydrochloride, identical with the compound described by Tafel and Enoch (Abstr., 1890, 973), can be prepared by passing hydrogen chloride into a well-cooled, alcoholic benzene solution of metanitrobenzonitrile; the *platinochloride*,

$$(C_9H_{10}N_2O_3)_2,H_2PtCl_6,$$

is a reddish-yellow compound.

When metanitrobenzimidoethyl ether hydrochloride is treated with alcoholic ammonia, it is converted into metanitrobenzenylamidine hydrochloride (compare Tafel and Enoch, *loc. cit.*). The corresponding *sulphate*, $[NO_2\cdot C_6H_4\cdot C(NH_2):NH]_2,H_2SO_4$, prepared from the nitrite, is soluble in water and alcohol. The *nitrite*,

$$NO_2\cdot C_6H_4\cdot C(NH_2):NH,HNO_2,$$

is obtained when a concentrated solution of the hydrochloride is treated with silver nitrite, and the filtrate evaporated at 30—40°; it crystallises in prisms, and decomposes when heated, yielding metanitrobenzonitrile, water, and nitrogen.

Metanitrobenzoylbenzamide, $NO_2\cdot C_6H_4\cdot CO\cdot NH\cdot COPh$, is formed when metanitrobenzenylamidine is treated with benzoic chloride and potash; it crystallises from alcohol in plates, and melts at 133—134°. An *ethyl* derivative of metanitrobenzenylamidine can be obtained by treating the amidine with ethyl iodide in ethereal solution; its *platinochloride* has the composition $(NO_2\cdot C_6H_4\cdot N_2H_2Et)_2,H_2PtCl_6$. When metanitrobenzenylamidine is treated with hydroxylamine, it is converted into the corresponding amidoxime.

Phenylmetanitrobenzimido ether, $NO_2\cdot C_6H_4\cdot C(:NPh)\cdot OH$, is formed, together with phenylmetanitrobenzenylamidine, when metanitrobenzimido ether hydrochloride is warmed with aniline; it crystallises in yellow prisms, melts at 55—56°, and is readily soluble in cold hydrochloric acid; when heated with alcoholic ammonia at 100°, it is decomposed into aniline and metanitrobenzonitrile.

Phenylmetanitrobenzenylamidine, $NO_2\cdot C_6H_4\cdot C(:NPh)\cdot NH_2 + H_2O$, can also be obtained by heating metanitrobenzonitrile with aniline hydrochloride; it crystallises from ether in yellow prisms, melts at 72—73°, and decomposes at 100°. The *hydrochloride*,

$$NO_2\cdot C_6H_4\cdot CN_2H_2Ph,HCl,$$

melts at about 251°. When an ethereal solution of the amidine is heated at 100° with ethyl iodide, a yellow, crystalline salt of the composition $NO_2\cdot C_6H_4\cdot CN_2HPhEt,HI$ is formed.

Symmetrical diphenylbenzenylamidine is not acted on by nitrous acid; when anhydrous asymmetrical diphenylbenzenylamidine is warmed with amyl nitrite, or treated with nitrous acid in aqueous solution, it is converted into diphenylbenzamide (m. p. 175°).

Ethylbenzenylamidine, CN_2H_2PhEt, is formed when benzimido ether hydrochloride is treated with a 25 per cent. solution of ethylamine, but it cannot be obtained in a pure condition. The *hydrochloride*, CN_2H_2PhEt,HCl, crystallises from alcoholic ether in needles, melts at 161°, and decomposes above 200° with formation of benzonitrile and ethylamine hydrochloride; it is very readily soluble in water and alcohol. The *platinochloride*, $(CN_2H_2PhEt)_2,H_2PtCl_6$, crystallises from alcohol in microscopic, reddish-yellow prisms. The *nitrate*,

$$CN_2H_2PhEt,HNO_3,$$

is deposited in long needles when a solution of the nitrite in fuming nitric acid is evaporated at the ordinary temperature; it is very readily soluble in water. The *nitrite*, CN_2H_2PhEt,HNO_2, prepared by treating an aqueous solution of the hydrochloride with silver nitrite, crystallises from alcohol in slender needles, melts at 122°, and is very readily soluble in water and alcohol, but almost insoluble in ether; it is only slowly decomposed by boiling water, and it is stable in presence of nitrous acid. The *benzoyl* derivative, $C_{16}H_{16}N_2O$, crystallises from dilute alcohol in needles, melts at 88°, and is only moderately easily soluble in ether. The *diethyl* derivative is formed when the amidine is heated at 100—110° with an ethereal solution of ethyl iodide; its *hydriodide*, $C_{11}H_{16}N_2,HI$, is a colourless, crystalline compound, but turns yellow on keeping.

Acetamidine nitrite, CN_2H_3Me,HNO_2, prepared by treating a concentrated aqueous solution of acetamidine hydrochloride with silver nitrite, melts at 148° with decomposition, and is soluble in water and alcohol, but insoluble in ether.

Propionamidine nitrite, CN_2H_3Et,HNO_2, obtained in like manner, separates from alcohol in crystals, melts at 116°, and is readily soluble in water and alcohol.

Paratolenylamidine nitrite, $C_6H_4Me{\cdot}CN_2H_3,HNO_2$, crystallises in needles, melts at 133°, and is readily soluble in alcohol and water, but insoluble in ether.

Isophthalamidine nitrite, $C_6H_4(CN_2H_3)_2,2HNO_2$, crystallises from water in lustrous needles.

Succinimidine nitrite, $C_2H_4<\begin{matrix}C(NH)\\C(NH)\end{matrix}>NH,HNO_2 + \frac{1}{2}H_2O$, is formed when a solution of a mixture of the hydrochlorides of succinamidine and succinimidine is treated with silver nitrite; it crystallises in small, yellow plates.

Guanidine nitrite, CH_5N_3,HNO_2, can be obtained by evaporating a solution of guanidine sulphate with sodium nitrite, and extracting the residue with alcohol, from which the nitrite is deposited in crystals; it melts at 76—78·5°, decomposes at about 120°, and is readily soluble in water and alcohol, but insoluble in ether.

From the results of the experiments described above, the author concludes that the substituted amidines cannot be converted into dioxytetrazotic acids. The strongly basic amidines combine unchanged with nitrous acid, but when, by the substitution of a phenyl group for hydrogen, they are converted into feeble bases, they become less stable towards nitrous acid. F. S. K.

Thio-derivatives of Orthamidobenzamide. By A. Stewart (*J. pr. Chem.* [2], **44**, 415—416).—The *compound* $C_{11}H_{10}N_2SO$ is obtained by heating orthamidobenzamide with allylthiocarbamide (equivalent proportions) in benzene for several hours. It crystallises from hot alcohol, ether, or benzene in colourless needles and tables, and melts with decomposition at 198—199°. It dissolves in alkalis, and is reprecipitated by acids unchanged; its solution in benzene has a blue fluorescence.

A compound which crystallises in colourless, silky tables is formed when phenylthiocarbimide is substituted for the allyl compound in the above reaction.

By heating orthamidobenzamide with thiocarbamide in an oil-bath at 180—200°, until no more ammonium sulphide is given off, the *compound* $C_8H_6N_2SO$ is formed; it crystallises from alcohol in creamy-white nodules, dissolves in ether and benzene, and melts at 280—281°. It dissolves in alkalis, and is reprecipitated by acids. When heated for 2—3 hours with methyl iodide (2 mols.) and sodium (2 mols.) in a tube at about 130°, a smell of mercaptan is perceived, and beautiful, colourless, six-sided prisms crystallise out; they contain sulphur, dissolve in alkalis, and are unchanged at 300°.

A colourless, crystalline substance is obtained when thiocarbamide is heated with anthranilic acid.

The author suggests constitutional formulæ for some of the above compounds, but does not support them. The investigation is proceeding. A. G. B.

Condensation of Anilpyruvic Acid. By C. Böttinger (*Annalen*, **265**, 253—256).—In the conversion of anilpyruvic acid into aniluvitonic acid by treatment with concentrated sulphuric acid, a very small quantity of a compound, which is insoluble in alkalis, is formed; this substance has the composition $C_{17}H_{16}N_2O$, melts at 194—195°, and is identical with the compound obtained by Lazarus by treating aniline with pyruvic acid at a high temperature. The condensation product of paratoluidine and pyruvic acid has consequently the composition $C_{19}H_{20}N_2O$, and not $C_{16}H_{20}N_2O$, as given by Lazarus. F. S. K.

Tartranilide. By H. Polikier (*Ber.*, **24**, 2959—2962).—Tartranilide is obtained in almost theoretical yield by gradually adding tartaric acid (1 part) to boiling aniline (5 parts), and after a time distilling off the excess of aniline from the solution, washing the solid residue successively with dilute hydrochloric acid, boiling water, and a little alcohol, and finally crystallising from alcohol; it melts above 250° with decomposition. The *diacetyl derivative*,

$$C_2H_2(OAc)_2(CO\cdot NHPh)_2,$$

is formed when tartranilide is boiled in a reflux apparatus with acetic anhydride until the solution commences to darken; it crystallises in needles, melts at 227°, and is more soluble in alcohol, ether, and chloroform than tartranilide. The *triacetyl derivative*, $C_{22}H_{22}O_7N_2$, is

produced by heating tartranilide with acetic anhydride in a sealed tube at 150° for two hours; it forms delicate, lustrous, white needles, melts at 216°, and is readily soluble in alcohol, ether, and glacial acetic acid. The *tetracetyl derivative*, $C_2H_2(OAc)_2(CO{\cdot}NAcPh)_2$, is obtained when tartranilide (3 grams) is heated with acetic chloride (5 grams) in a sealed tube at 140° for two hours, the product being washed with a little glacial acetic acid, and repeatedly crystallised from alcohol; it forms colourless needles, melts at 137°, and is more easily soluble in all solvents than the di- and tri-derivatives.

When tartranilide is submitted to dry distillation, or better, when a mixture of tartaric acid (1 part) and aniline (4 parts) is heated for half an hour at the boiling point of aniline, then distilled over a free flame until nothing but a carbonaceous mass remains, the distillate again treated with tartaric acid, and the same operation repeated several times, on adding dilute hydrochloric acid to the last distillate, dianilidosuccinanilide, $C_2H_2(NHPh)_2(CO{\cdot}NHPh)_2$, melting at 220°, is precipitated, the yield being at most 20 per cent. It is very stable, being attacked neither by acids nor alkalis, and boiling at about 300°. The *acetyl derivative*,

$$NPhAc{\cdot}CH(CO{\cdot}NHPh){\cdot}CH(NHPh){\cdot}CO{\cdot}NHPh,$$

is prepared by boiling dianilidosuccinanilide with acetic anhydride in a reflux apparatus for two hours; it crystallises in large, yellow leaves, and melts at 252°. A. R. L.

Aromatic Dithiocarbamates. By S. M. Losanitsch (*Ber.*, **24**, 3021—3028).—Ammonium phenyldithiocarbamate, $NHPh{\cdot}CS{\cdot}SNH_4$, is prepared by the interaction of aniline, carbon bisulphide, and ammonia or ammonium sulphide, in dilute alcoholic solution at ordinary temperatures; it crystallises in large, yellow, transparent prisms, and is soluble in aqueous ammonia or ammonium sulphide, but decomposes when dissolved in alcohol or water. Ammonium sulphide, ammonium thiocarbonate, carbon bisulphide, thiocarbanilide, and aniline are formed on heating the compound at 100°. Ammonium phenyldithiocarbamate appears to be identical with the "phenylammonium thiouramate" of Hlasiwetz and Kachler.

Phenyldithiocarbamic thioanhydride, $(CS{\cdot}NHPh)_2S$, is obtained by the action of iodine in excess on ammonium phenyldithiocarbamate; it crystallises from benzene in yellow, lustrous needles, melts at 136—138°, and is not affected by acids, but is converted into thiocarbanilide on treatment with potash. *Barium phenyldithiocarbamate*, $(NHPh{\cdot}CSS)_2Ba$, is insoluble in alcohol or water at ordinary temperatures, and crystallises in yellow plates. The *potassium salt*, $NHPh{\cdot}CSSK$, is deposited in long, thin, colourless needles; the *nickel* salt forms yellow, lustrous plates. The remaining salts are sparingly soluble, and on heating are decomposed quantitatively into the metallic sulphide and phenylthiocarbimide.

Methyl phenyldithiocarbamate, $NHPh{\cdot}CSSMe$, prepared from methyl iodide and ammonium phenyldithiocarbamate, crystallises from alcohol in large, white needles; it melts at 93·5°, not at 87—88°, as stated by Will. The *ethyl salt* melts at 59·5°.

By the interaction of carbon bisulphide, aniline, and tetramethylammonium hydroxide in alcoholic solution, a compound is obtained which crystallises in yellow needles and melts at 152—153°; this substance is not a phenyldithiocarbamate, and is being further investigated.

Ammonium paratoluyldithiocarbamate, $C_6H_4Me\cdot NH\cdot CS\cdot SNH_4$, is prepared in a similar manner to the phenyl derivative, and crystallises in large, yellow prisms. The *barium* salt is deposited in colourless needles; the *nickel* salt forms brown needles. The observations of Will and Bilschowski on the methyl and ethyl salts of the above compound are confirmed.

Barium metatoluyldithiocarbamate resembles the para-compound; it is soluble in water, but not in alcohol. The *nickel* salt crystallises in yellowish-brown, lustrous plates. The *methyl* salt,

$$C_6H_4Me\cdot NH\cdot CSSMe,$$

crystallises from alcohol in colourless needles, and melts at 89°.

Barium orthotoluyldithiocarbamate is obtained in colourless plates, which are insoluble in water or alcohol; the *nickel salt* forms brown needles. The *methyl* salt crystallises from alcohol in colourless needles, and melts at 132°.

Barium α-naphthyldithiocarbamate is prepared in a manner similar to the preceding compounds, and is deposited in colourless, insoluble needles; the *nickel salt* crystallises in yellowish-brown needles.

Barium β-naphthyldithiocarbamate forms yellow, crystalline plates; the *nickel salt* resembles that of the α-derivative.

The difference in behaviour between aliphatic and aromatic amines towards carbon bisulphide appears to be due to the extremely feeble basic properties of the aromatic ammonium group (NH_3X), since, in presence of a base, the aromatic amines react in a manner similar to the aliphatic amines, yielding dithiocarbamates. J. B. T.

Ethyl Acetoacetate Aldehydeuramides. By P. Biginelli (*Ber.*, **24**, 2962—2967; compare Abstr., 1891, 908).—When salicyldiureïde (Schiff, *Annalen*, **151**, 199) which has been previously dehydrated, first in a vacuum, and then by heating at 90—100°, is boiled with absolute alcohol and ethyl acetoacetate (2 mols.), ethyl β-uramidocrotonate, and a substance having the composition $C_{14}H_{16}N_2O_4$, are obtained; the latter is also formed when carbamide, salicylaldehyde, and ethyl acetoacetate are boiled together, in molecular proportion, with a little alcohol; it appears to be a mixture of two isomerides, and separates from alcohol in small needles melting at 199—200°, and large prisms melting at 203—204°, these having probably the constitutions $OH\cdot C_6H_4\cdot CH{:}N\cdot CO\cdot N{:}CMe\cdot CH_2\cdot COOEt$ and

$$OH\cdot C_6H_4\cdot CH{:}N\cdot CO\cdot NH\cdot CMe\cdot CH\cdot COOEt$$

respectively. If the prisms are dissolved in hot alcohol, the needles separate out on cooling, whereas if the latter are allowed to remain in contact with this solvent they change by degrees into the former. The substance is insoluble in water, and decomposes when boiled with it; it,

however, dissolves in dilute potassium hydroxide, but the solution becomes yellow after a time, owing to decomposition. When a current of carbonic anhydride is passed through the alkaline solution until the substance commences to separate out, hydrochloric acid precipitates the compound $C_{11}H_{12}N_2O_2$, which crystallises from alcohol in white needles, decomposes at 260—270° without melting, and is insoluble in alkalis; it probably has the constitution $CHMe<\begin{matrix}NH\cdot CO\cdot N{:}CH\\ CH_2\text{--}O\text{---}C_6H_4\end{matrix}$; it is formed more readily from the isomeride of lower melting point.

Cumindiureïde, $C_6H_4Pr^{\beta}\cdot CH(NH\cdot CO\cdot NH_2)_2$, is prepared by adding sufficient alcohol to a concentrated aqueous solution of carbamide to enable it to dissolve cumaldehyde, allowing the mixture to remain for two days, collecting the precipitated compound, drying, and washing with ether; it is a colourless, crystalline powder, insoluble in water, only slightly soluble in boiling alcohol, and melts at 175—176°. The compound $C_{17}H_{22}N_2O_3$ is obtained when a solution of cumindiureïde and ethyl acetoacetate in absolute alcohol, or one of carbamide, cumaldehyde, and ethyl acetoacetate in the same solvent is boiled; it crystallises from alcohol in delicate needles, and melts at 161—162°; if left for some days in contact with the solvent, or if repeatedly fused, it changes its form to octahedra, and then melts at 164—165°.

Cinnamdiureïde, $CHPh{:}CH\cdot CH(NH\cdot CO\cdot NH_2)_2$, separates as a white, crystalline substance, when a concentrated aqueous solution of carbamide is shaken with cinnamaldehyde; it melts at 172° with decomposition.

Tricinnamtetraureïde, $C_9H_8(NH\cdot CO\cdot NH\cdot C_9H_8\cdot NH\cdot CO\cdot NH_2)_2$, is obtained by gently heating a solution of carbamide and cinnamaldehyde in alcohol; it is a yellowish powder, and melts at 183—184° with decomposition. Both ureïdes are decomposed on boiling with water, or more quickly by dilute acids; nitrous acid occasions complete decomposition, and when suspended in ether they absorb bromine. When cinnamaldehyde is shaken with a very dilute solution of carbamide at a moderate temperature for a long time, a ureïde melting at 212° is formed; but if an excess of cinnamaldehyde is digested with a concentrated solution of carbamide at 50—60° for an hour, a ureïde melting at 115—116° is produced. When either of the cinnamureïdes is heated with ethyl acetoacetate, the *compound* $C_{16}H_{18}N_2O_3$, crystallising from alcohol in needles, and melting at 243—244°, is obtained; this appears also to exist in two forms, the melting points of which are very close. Although, as Schiff has shown, furfuraldehyde does not yield a ureïde, when this aldehyde is heated with carbamide and ethyl acetoacetate, *ethyl β-furfuramidocrotonate*, $C_4OH_3\cdot CH{:}N\cdot CO\cdot NH\cdot CMe{:}CH\cdot COOEt$, is formed. When the benzuramide derivative (m. p. 207—208°; Abstr., 1891, 908) is crystallised from hot alcohol, needles are obtained having the melting point 206—206·5°. A. R. L.

Ethylation of Salicylaldehyde. By M. Löw (*Monatsh.*, 12, 393—401).—The author has ethylated salicylaldehyde by slowly

adding a mixture of it (1 mol.) with ethyl iodide (3 mols.) to a boiling solution of alcoholic potash (3 mols.), exhausting the product with ether, and distilling the residue from the ethereal extract under a pressure of 25 mm. The ethyl compound thus obtained (yield 54 per cent. of theory) boiled at 143—147° (25 mm.), and melted at 20—22°.

Orthethoxybenzaldoxime, $OEt{\cdot}C_6H_4{\cdot}CH{:}NOH$, is formed when ethylsalicylaldehyde is heated with hydroxylamine hydrochloride and excess of soda. It is readily soluble in alcohol, ether, and benzene, sparingly so in water, slightly volatile in a current of steam, has a characteristic odour, and crystallises from light petroleum in colourless, compact prisms which melt at 57—59°.

The *hydrochloride*, $OEt{\cdot}C_6H_4{\cdot}CH{:}NOH,HCl$, separates in the form of small, yellow needles, when the base is dissolved in ether and the solution treated with dry hydrogen chloride. It melts at 123—125°, and is reconverted into orthethoxybenzaldoxime on warming with water.

Orthethoxybenzylamine, $OEt{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH_2$, is obtained on dissolving the aldoxime in a little alcohol, and reducing with 4 per cent. sodium amalgam, keeping the solution always slightly acid with acetic acid. The *platinochloride*, $OEt{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH_2,H_2PtCl_6$, is a crystalline, yellow precipitate, and melts at 182°.

Orthethoxybenzonitrile, $OEt{\cdot}C_6H_4{\cdot}CN$, is formed on heating in a reflux apparatus a mixture of orthethoxybenzaldoxime (1 mol.) and acetic anhydride (4 mols.). The product is neutralised with soda, extracted with ether, and the ethereal solution distilled, when the compound separates as a colourless oil which boils at 252—254° (260·7° corr.). On heating with alcoholic potash in sealed tubes, it is converted into a mixture of orthethoxybenzoic acid, $OEt{\cdot}C_6H_4{\cdot}COOH$, and orthethoxybenzamide, $OEt{\cdot}C_6H_4{\cdot}CONH_2$. The latter crystallises from hot water in flat, silky needles, and melts at 132—133°.

With phenylhydrazine, ethylsalicylaldehyde forms a very unstable compound, which is readily oxidised, even by atmospheric oxygen.

The formation of the above-described compounds confirms Perkin's view (*Annalen*, 1868, 306) that the product of ethylation of salicylaldehyde is really orthethoxybenzaldehyde, and shows that the ethyl is not directly attached to a carbon atom (compare Herzig and Zeisel, Abstr., 1888, 822; 1889, 247 and 966). G. T. M.

Pæonol. By W. N. Nagai (*Ber.*, **24**, 2847—2853).—Pæonol was first obtained by Martin and Yagi (*Arch. Pharm.*, **10**), from the bark of the root of *Pæonia moutan*, a drug frequently used in Japan and China. In order to prepare it, the finely-powdered bark is extracted with ether, the extract shaken with sodium carbonate solution to remove impurities, and then with aqueous soda, which takes up the pæonol; the alkaline solution is acidified with sulphuric acid, again extracted with ether, and the residue obtained on evaporating the latter is recrystallised from alcohol. Pæonol is thus obtained in colourless, lustrous needles, having the composition $C_9H_{10}O_3$, and melting at 50°; it has an aromatic odour and burning taste, is sparingly soluble in cold water, readily in alcohol, ether, and benzene. It gives a reddish-violet coloration with ferric chloride, but dissolves

in sulphuric acid without alteration of colour; it also dissolves readily in caustic alkalis, but not in ammonia or solutions of alkali carbonates, which agrees with the supposition that it is a phenol.

When fused with potash, it yields 1 : 2 : 4-dihydroxyacetophenone (resacetophenone), $C_6H_3Ac(OH)_2$, α-resorcylic acid, $COOH\cdot C_6H_3(OH)_2$ [1 : 2 : 4], and resorcinol; the first is probably the primary product, the other compounds being formed from it by the further action of alkali. Hydriodic acid converts it into methyl iodide and resacetophenone, of which it must therefore be the methyl ether. To ascertain which of the hydroxyl groups is methylated, the acetyl derivative was prepared by boiling pæonol with acetic anhydride for 30 hours, extracting any unaltered pæonol with light petroleum (b. p. 55—57°), and recrystallising the residue from alcohol. *Acetylpæonol*, $C_9H_9O_3Ac$, is thus obtained in flat, lustrous needles melting at 46·5°. If instead of acetic anhydride a mixture of this compound with anhydrous sodium acetate is employed, two condensation products are obtained, melting at 130° and 160° respectively; these are being further examined.

By oxidation with alkaline potassium permanganate, acetylpæonol yields paramethoxyacetylsalicylic acid, $COOH\cdot C_6H_3(OAc)\cdot OMe$ [1 : 2 : 4], which, on treatment with strong aqueous potash, is converted into paramethoxysalicylic acid, $COOH\cdot C_6H_3(OH)\cdot OMe$ [1 : 2 : 4], the properties of which were found to agree with previous statements (Abstr., 1881, 270; *Ber.*, **14**, 847), except as regards the melting point, which the author finds to be 156°. The formation of this acid shows conclusively that the methoxyl group occupies the para-position with respect to the acetyl group, and hence pæonol may be termed *paramethoxyorthohydroxyacetophenone*, $OH\cdot C_6H_3Ac\cdot OMe$ [= 2 : 1 : 4]. H. G. C.

Pæonol Phenylhydrazone and Oxime. By F. Tiemann (*Ber.*, **24**, 2854—2855).—Although pæonol, according to Nagai, does not form a double compound with sodium hydrogen sulphite, it readily combines with phenylhydrazine and hydroxylamine. *Pæonol phenylhydrazone*, $C_9H_{10}O_2{:}N_2HPh$, is prepared by the addition of phenylhydrazine hydrochloride and sodium acetate to an aqueous solution of pæonol, and crystallises from alcohol in pale-yellow needles, melts at 107°, is readily soluble in ether and benzene, sparingly in alcohol and light petroleum, and almost insoluble in water. *Pæonoloxime*, $C_9H_{10}O_2{.}N\cdot OH$, separates in needles when its alcoholic solution is poured into water; it is almost insoluble in cold, readily soluble in hot water, and in alcohol, ether, &c.

Pæonol itself may be readily purified by distillation in a current of steam and recrystallisation from hot water. It then melts at 48°, and not at 50°, as stated by Nagai (see preceding abstract).

H. G. C.

Acetovanillone. By F. Tiemann (*Ber.*, **24**, 2855—2862).—In the course of his researches on the members of the protocatechuic series, the author, in conjunction with Nagai (this Journal, 1877, ii,

339), showed that acetyleugenol, on oxidation and subsequent hydrolysis, gives a product from which α-homovanillic acid, vanillic acid, and vanillin, may be isolated; in addition to these, a large quantity of a resinous mass is obtained, which, on dry distillation, gives guaiacol as the sole recognisable product. Further investigation of this resin in larger quantity has shown that a crystalline compound may be obtained from it, by neutralising the free acid present with calcium or magnesium carbonate, repeatedly extracting with boiling water, and shaking the extract with ether. The ethereal solution is then treated with sodium hydrogen sulphite to remove vanillin, the ether evaporated, and the oily residue repeatedly washed with water, and distilled under a pressure of 50 mm. The distillate solidifies on cooling, and may be purified by dissolving it in aqueous soda, reprecipitating with carbonic anhydride, extracting again with ether, evaporating the latter, and recrystallising the residue from boiling water, alcohol, or benzene. The new compound then forms long prisms, melts at 115°, boils at 295—300°, and may be readily sublimed. The analysis and molecular weight determinations lead to the formula $C_9H_{10}O_3$, and it is termed *acetovanillone* for the reasons stated below.

Acetovanillone has the properties of a phenol, yields protocatechuic acid when fused with potash, and contains one methoxyl group, as found by Zeisel's method. It therefore contains the residue $:C\cdot C_6H_3(OMe)\cdot OH$. The remaining atoms, C_2H_3O, must be present as an acetyl group, for acetovanillone yields an oxime and phenylhydrazone, and is also formed, although only in small quantity, by distilling a mixture of calcium acetate and vanillate. On boiling with acetic anhydride, it yields an acetyl compound, which may be readily oxidised to acetovanillic acid and vanillic acid, showing that the hydroxyl and methoxyl groups occupy the same positions as in the last-named compound. Hence, acetovanillone has the constitution $C_6H_3Ac(OMe)\cdot OH$ [1 : 2 : 4], and stands in the same relation to vanillin as acetophenone does to benzaldehyde. Acetovanillone gives, with an excess of ferric chloride, exactly the same reaction as vanillin (Abstr., 1886, 238); the liquid assumes first a deep, bluish-violet colour, and on warming gives a precipitate of insoluble dehydrodiacetovanillone.

The presence of acetovanillone among the products of oxidation of acetyleugenol, $CH_2{:}CH\cdot CH_2\cdot C_6H_3(OMe)\cdot OAc$, is not capable of ready explanation. The simplest way of explaining it would be to suppose that it is present ready formed in the eugenol, or that it is obtained by the oxidation of an isomeride of eugenol, of the formula $CH_2{:}CMe\cdot C_6H_3(OMe)\cdot OH$, either present in the liquid or formed during the reaction; no evidence has, however, been found in favour of these views. To explain its formation from acetoeugenol, one might suppose that the latter first takes up the elements of water, forming the compound $OH\cdot CH_2\cdot CH_2\cdot CH_2\cdot C_6H_3(OMe)\cdot OAc$, and then undergoes oxidation in the ω- and β-carbon atoms of the side chain, yielding $COOH\cdot CH_2\cdot CO\cdot C_6H_3(OMe)\cdot OAc$, which loses carbonic anhydride, forming acetovanillone.

The properties of the substances obtained in this research are given in the following abstract. H. G. C.

Derivatives of Acetovanillone. By E. Neitzel (*Ber.*, **24**, 2863—2868).—Acetovanillone yields a series of phenol salts with the metals of the alkalis and alkaline earths, the former having an alkaline reaction, and all readily undergoing decomposition. The *copper* salt is a yellowish-green, amorphous powder.

By the action of an alcoholic solution of methyl iodide on an alkali salt of acetovanillone, the *methyl* ether, or *acetoveratrone*, $C_6H_3Ac(OMe)_2$, is obtained; it forms rhomboïdal crystals, melts at 48—49°, boils at 207° under 15 mm. pressure, is soluble in hot water, alcohol, ether, and benzene, and is converted by potassium permanganate into veratric acid. The corresponding *ethylacetovanillone* forms radial groups of needles, and melts at 78°. *Acetylacetovanillone*, $OMe{\cdot}C_6H_3Ac{\cdot}OAc$, prepared by boiling acetovanillone with acetic anhydride, crystallises from alcohol, on the addition of water, in long needles melting at 58°, and yields vanillic acid on oxidation. *Benzoylacetovanillone*, $OMe{\cdot}C_6H_3Ac{\cdot}OBz$, obtained from an alkaline solution of acetovanillone by the action of benzoic chloride, melts at 106°.

Acetoprotocatechone. $C_6H_3Ac(OH)_2$, is formed in small quantity by the action of hydrochloric acid on acetovanillone at 140—150°, and separates from chloroform solution, on the addition of light petroleum, in crystals which melt at 96—98°. The same compound appears to be formed by the action of zinc chloride on a mixture of catechol and acetic acid, but could not be separated from the excess of catechol.

Acetovanillonephenylhydrazone, $N_2HPh{:}CMe{\cdot}C_6H_3(OMe){\cdot}OH$, forms well-developed crystals, melts at 125°, and is soluble in alcohol and ether; the *oxime*, $OH{\cdot}N{:}CMe{\cdot}C_6H_3(OMe){\cdot}OH$, melts at 95°, is fairly soluble in water, and crystallises best from benzene. *Ethylacetovanillonoxime*, $NOH{:}CMe{\cdot}C_6H_3(OMe){\cdot}OEt$, crystallises from alcohol in lustrous prisms melting at 116—118°. As already mentioned in the preceding abstract, ferric chloride converts acetovanillone into *dehydrodiacetovanillone*, $C_{18}H_{18}O_6$, which is almost insoluble in the usual solvents, and melts above 300°.

When a mixture of calcium acetate and vanillate in molecular proportions is distilled, acetovanillone passes over in small quantity together with acetone, guaiacol, &c. These are removed by distilling in a current of steam, and the residue purified by repeatedly precipitating the benzene solution with light petroleum. H. G. C.

Synthesis of Acetovanillone from Guaiacol and Acetic Acid. By T. Otto (*Ber.*, **24**, 2869—2870).—Acetovanillone may be obtained synthetically by dissolving 60 parts of guaiacol in 120 parts of acetic acid, and gradually adding 30—40 parts of a mixture of zinc and aluminium chlorides in equal proportions; the whole is warmed on the water-bath after the frothing has moderated, and finally heated at 140—150° until hydrogen chloride is no longer evolved. The product is then poured into water, the unaltered guaiacol removed by distillation in a current of steam, the solution filtered from resinous matters, and extracted with ether; the residue from the ethereal solution is treated with soda, the aqueous solution saturated with carbonic anhydride and again extracted with ether, the latter distilled off,

the residue fractionated, and finally recrystallised from boiling water. The acetovanillone thus obtained crystallises in white needles, melts at 115°, and has all the properties ascribed to it in the previous abstracts; the yield of the pure compound is, however, very small.

H. G. C.

Aromatic Hydroxyketones. By P. Crépieux (*Chem. Centr.*, 1891, ii, 377; from *Schweiz. Wochenschr. Pharm.*, **29**, 255—256).—Applying the same method as Nencki used to produce hydroxyketones, the author has obtained from resacetophenone, a substance of the formula $C_6H_2Ac_2(OH)_2$, and from gallacetophenone, a compound,

$$C_6HAc_2(OH)_2{\cdot}OAc.$$

The latter is hydrolysed by potash, one acetyl group being eliminated, and the compound $C_6HAc_2(OH)_3$ formed. By the action of glacial acetic acid and fused sodium acetate on propionylphenol, resacetophenone, gallacetophenone, the acetyl derivatives acetylpropiophenone, monacetylresacetophenone, diacetylgallacetophenone are formed. Where more than one hydroxyl group was present, one remained intact, the others becoming acetylated.

J. W. L.

Constitutents of Paracoto Bark. By G. Ciamician and P. Silber (*Ber.*, **24**, 2977—2990).—The authors find that hydrocotoïn, to which they assigned the formula $OH{\cdot}C_6H_2(OMe)_2{\cdot}COPh$ (*Ber.*, **24**, 299; Abstr., 1891, 578), yields neither an oxime nor a hydrazone: many ketonic compounds are, however, indifferent towards hydroxylamine and phenylhydrazine (compare Hantzsch, Abstr., 1891, 36), and in the case under discussion, this behaviour is perhaps explained by the position of the methoxyl groups in the molecule. The compound is not attacked by aqueous alkalis, but when heated with alcoholic potash under pressure, benzoïc acid and a phenolic compound, apparently a mixture, are formed. When hydrocotoïn (10 grams) is intimately mixed with phosphorus pentachloride (60 grams), and the mixture slowly distilled until all the phosphorus trichloride and oxychloride have passed over, the residue and the distillate being then mixed with water, united, and steam distilled, benzotrichloride first passes over, and then very slowly a solid compound, $C_8H_7Cl_3O_2$; this crystallises from alcohol in colourless needles, melts at 174°, and is insoluble in alkalis; it yields methyl chloride when heated with hydrochloric acid at 140°, and is probably a dimethoxy-derivative. When methylhydrocotoïn (*loc. cit.*) is treated in a similar manner with phosphorus pentachloride, benzotrichloride, together with a *compound*, $C_9H_9Cl_3O_3$, probably a trimethoxy-derivative, is obtained; the latter forms delicate, white needles, and melts at 130—131°; benzoïc acid is found in the aqueous portion of the residue from the steam distillation, whilst by treating the solid portion of the latter with glacial acetic acid and adding water to the solution, a *compound*, $C_{16}H_{14}Cl_2O_4$, separates, which crystallises from alcohol in colourless prisms, melts at 81—82°, and is perhaps dichloromethylhydrocotoïn.

Protocotoïn, $C_{16}H_{14}O_6$, is another constituent of paracoto bark, and occurs as an impurity in crude hydrocotoïn, from which, by reason of its much smaller solubility in alcohol, it may be separated by fractional crystallisation from that liquid. It forms bright-yellow, monoclinic

prisms, $a : b : c = 2{\cdot}9303 : 1 : 2{\cdot}0558$; $\beta = 79° 06'$, melts at 141—142°, is soluble in most solvents, but insoluble in water; it dissolves in alkalis, and is reprecipitated by carbonic anhydride; its solution in dilute alcohol gives a reddish-brown colour with ferric chloride; whilst on treating it with dilute nitric acid, a bluish-green colour is produced, and on heating the solution a reddish-brown precipitate is formed. When its solution in alkalis is reduced with sodium amalgam and acidified, ether extracts a compound crystallising from alcohol in white, amorphous flocks, and melting at 215—220°. A determination by Zeisel's method showed that protocotoïn contains two methoxyl groups. The *acetyl derivative*, $C_{18}H_{16}O_7$, prepared by heating it with an equal weight of anhydrous sodium acetate and four times its weight of acetic anhydride in a reflux apparatus for six hours, forms colourless crystals, melts at 103°, and is insoluble in water and alkalis, but readily soluble in ether, hot alcohol, and chloroform; it dissolves in cold nitric acid to a yellow solution, which, on heating, becomes bluish-green, and finally red; its solution in dilute alcohol gives no coloration with ferric chloride; on boiling with alkalis, protocotoïn is regenerated; it contains one methoxyl group.

Methylprotocotoïn, $C_{14}H_7O_3(OMe)_3$, is obtained by heating together in a sealed tube, protocotoïn (10 grams), a little methyl alcohol, potash (3 grams), and methyl iodide (15 grams), evaporating the alcohol, washing with water, and crystallising from alcohol; it forms colourless prisms, melts at 134—135°, and is insoluble in water and in alkalis. Protocotoïn does not react with hydroxylamine.

The *hydrazone*, $C_{22}H_{20}N_2O_5$, is obtained by heating protocotoïn with an excess of phenylhydrazine, dissolving the melt in glacial acetic acid, pouring it into water, and crystallising the precipitated compound from alcohol; it forms small, colourless prisms, melts at 211°, and is sparingly soluble in alcohol and glacial acetic acid. *Dibromoprotocotoïn*, $C_{16}H_{12}Br_2O_6$, is prepared by treating protocotoïn dissolved in chloroform with an excess of bromine, evaporating the solvent, and crystallising from alcohol; it crystallises in silky scales, melts at 170°, and dissolves in alkalis, in hot dilute nitric acid, and in sulphuric acid with a yellow colour. *Bromacetylprotocotoïn*, $C_{16}H_{15}BrO_7$, is obtained in a similar manner from acetylprotocotoïn; it forms small, delicate, white needles, melts at 175°, and is insoluble in water and cold alkalis, but dissolves in hot alkalis with a yellow colour. Protocatechuic acid is produced when protocotoïn is fused with potash or heated with concentrated hydrochloric acid in a sealed tube at 130°; whilst the compound $C_8H_7Cl_3O_2$, melting at 174°, and identical with that obtained from hydrocotoïn (see above) is produced by treating protocotoïn with phosphorus pentachloride in the manner already described under hydrocotoïn. Methylprotocotoïn, treated in a similar manner, yields the compound melting at 131° identical with that obtained from methylhydrocotoïn. Taking all these facts into consideration, it is probable that protocotoïn has the constitution

$$CH_2\begin{matrix}{}^{3}O\\O\end{matrix}{}^{4}>C_6H_3{\cdot}CO{\cdot}C_6H_2(OMe)_2{\cdot}OH,$$

which is, however, given under reservation, as the presence of a methylene group has not yet been demonstrated.

When protocotoïn is oxidised in alkaline solution with potassium permanganate, an acid, which is being investigated, together with Jobst and Hesse's paracoumarhydrin (Abstr., 1880, 327), is formed; it contains a carboxyl group, as it yields a *hydrazone*, $C_{15}H_{14}N_2O_2$, melting at 114°. A. R. L.

Vanilloylcarboxylic Acid (Parahydroxymetamethoxybenzoylcarboxylic Acid). By F. Tiemann (*Ber.*, **24**, 2877—2879).—The dimethoxyphenylglyoxylic acid [1 : 3 : 4] recently obtained by Ciamician and Silber by the oxidation of methyleugenol (Abstr., 189 , 966) has already been described by the author and Matsmoto under the name veratroylcarboxylic acid (Abstr., 1878, 503). The corresponding ketonic acid of the vanillin series, or *vanilloylcarboxylic acid*, $COOH{\cdot}CO{\cdot}C_6H_3(OMe){\cdot}OH$ [1 : 3 : 4], has been found in certain vanillin preparations obtained by the oxidation of acetyleugenol, and acetylisoeugenol, and distinguished by their yellow colour. It may be separated from vanillin by shaking with water containing magnesium carbonate in suspension, the vanilloylcarboxylic acid passing into the aqueous solution as a magnesium salt. This is acidified with sulphuric acid, extracted with ether, the latter distilled off, the residue heated at 50—60° in a vacuum and crystallised from benzene. It then forms prisms containing benzene of crystallisation, which is rapidly given off on exposure to the air; after drying at 100°, it melts at 133—134°, and dissolves readily in water, alcohol, ether, and benzene, sparingly in light petroleum. When heated above its melting point, it is resolved into vanillin and carbonic anhydride. H. G. C.

Benzenesulphamides and Mixed Secondary Amines. By O. Hinsberg (*Annalen*, **265**, 178—192).—In a previous paper (Abstr., 1891, 49), it has been stated that phenylsulphonic chloride reacts very readily both with secondary and with primary amines; the compounds obtained from the primary amines are soluble in potash, yielding stable salts, which react readily with fatty and (some) aromatic halogen derivatives, being thereby converted into trisubstituted amines (or disubstituted amides). Various new compounds obtained in this manner are described below.

Benzenesulphonemethylethylamide, $SO_2Ph{\cdot}NMeEt$, is easily obtained by warming a solution of benzenesulphonemethylamide in excess of potash with a little alcohol and excess of ethyl iodide; the yield is quantitative. It is a thick oil, distils under reduced pressure (50 mm.) with only slight decomposition, and is only sparingly soluble in water, acids, and alkalis, but readily in alcohol and ether.

Ethylmethylamine, NHMeEt, is produced when the preceding compound is heated with concentrated hydrochloric acid at 150—160°; it boils at 33—34°, and has properties similar to those of its next homologues. The *hydrochloride*, C_3H_9N,HCl, separates from a mixture of chloroform and ether in colourless, hygroscopic crystals, and is very readily soluble in alcohol; all the other salts are very readily

soluble in water and alcohol, but the *platinochloride* crystallises from the former in moderately large plates.

Benzenesulphonepiperidine, $SO_2Ph{\cdot}C_5NH_{10}$, can be prepared by repeatedly adding small quantities of a mixture of phenylsulphonic chloride and concentrated potash to an aqueous solution of piperidine, and shaking vigorously until the reaction is complete. It crystallises in colourless prisms, melts at 93—94°, and is readily soluble in alcohol and ether, but only sparingly in water; it is decomposed into its components by concentrated hydrochloric acid at 150°.

Benzenesulphonebenzylamide, $SO_2Ph{\cdot}NH{\cdot}CH_2Ph$, prepared from benzylamine and phenylsulphonic chloride, crystallises from dilute alcohol in colourless needles, melts at 88°, and is readily soluble in alcohol and ether, but only sparingly in water. The *methyl* derivative, $SO_2Ph{\cdot}NMe{\cdot}CH_2Ph$, is obtained when the amide is warmed with methyl iodide and alcoholic soda; it is a colourless, crystalline compound, melts at 94°, and is decomposed into benzenesulphonic acid and methylbenzylamine by concentrated hydrochloric acid at 160—180°.

Methylbenzylamine, $CH_2Ph{\cdot}NHMe$, is a colourless liquid, boils at 184°, and has a slight amine-like odour; it is more readily soluble in cold than in hot water. The *sulphate* and the *hydrochloride* are very readily soluble in water. The *platinochloride*, $(C_9H_{11}N)_2,H_2PtCl_6$, crystallises in long, yellowish-red needles, melts at about 193°, and is moderately easily soluble in water. The *nitrosamine* is an oil.

Benzenesulphoneorthotoluidide, $SO_2Ph{\cdot}NH{\cdot}C_6H_4Me$, crystallises from dilute alcohol in colourless needles, melts at 125—126°, and is readily soluble in alcohol and ether, but only sparingly in water: it is insoluble in mineral acids, but it forms stable, readily soluble salts with alkalis.

Benzenesulphoneparaphenetidine, $SO_2Ph{\cdot}NH{\cdot}C_6H_4{\cdot}OEt$, crystallises from alcohol in colourless needles melting at 142°; its *methyl* derivative, $C_{15}H_{17}NSO_3$, crystallises from ether in large plates, and melts at 79°.

Dibenzenesulphonediphenetidine, $C_{28}H_{28}N_2S_2O_6$, can be obtained by gradually adding a concentrated solution of iodine in potassium iodide to a hot, concentrated solution of benzenesulphonephenetidine in sodium carbonate. It crystallises from alcohol in colourless needles, melts at 168°, and is more sparingly soluble in alcohol, ether, and glacial acetic acid than the simple sulphone from which it is obtained; it gives a blue coloration with hot, concentrated sulphuric acid, and forms a crystalline *potassium* derivative of the composition $C_{28}H_{27}N_2S_2O_6K$, which is only sparingly soluble in water, but more readily in alcohol. When heated with concentrated hydrochloric acid at 170°, it yields ethyl chloride, benzenesulphonic acid, and a blue substance which is soluble in alkalis; its constitution is probably expressed by the formula $SO_2Ph{\cdot}NH{\cdot}C_6H_4(OEt){\cdot}N(SO_2Ph){\cdot}C_6H_4{\cdot}OEt$. A *benzyl* derivative of the composition $C_{35}H_{34}N_2S_2O_6$ is formed when the potassium derivative just referred to is treated with benzyl chloride; it crystallises from alcohol in slender, colourless needles, and melts at 158°.

Dibenzenesulphoneparaphenylenediamine, $C_6H_4(NH{\cdot}SO_2Ph)_2$, crystal-

lises in colourless, lustrous plates, melts at 247°, and is readily soluble in alkalis, but only moderately easily in hot alcohol, and almost insoluble in water. The *diethyl* derivative, $C_{22}H_{24}N_2S_2O_4$, crystallises from dilute alcohol, in which it is moderately easily soluble, in colourless needles melting at 197°; on hydrolysis, it yields diethylphenylenediamine, the *diacetyl* derivative of which crystallises from hot water or dilute alcohol in colourless needles, melts at 186—187°, and has the composition $C_{14}H_{20}N_2O_2$.

Dibenzenesulphoneorthotoluylenediamine, $C_6H_3Me(NH\cdot SO_2Ph)_2$, crystallises from alcohol in plates, melts at 178—179°, and is readily soluble in alkalis; its solution in ammonia gives a blue, amorphous precipitate on the addition of copper sulphate. The *diethyl* derivative, $C_{23}H_{26}N_2S_2O_4$, crystallises from alcohol in colourless needles containing $\frac{1}{2}$ mol. C_2H_6O, and melting at about 117° with previous softening; it loses its alcohol at about 120°, and solidifies on cooling to a vitreous mass, which melts at 62—70°.

Diethyltoluylenediamine, $C_6H_3Me(NHEt)_2$, is obtained when the preceding compound is hydrolysed with concentrated hydrochloric acid; it is a colourless oil, boils at 265° (uncorr.), and rapidly darkens on exposure to the air. It gives a reddish-brown coloration with platinic chloride and also with ferric chloride in presence of hydrochloric acid; in its concentrated aqueous solution, potassium ferrocyanide produces a colourless precipitate. Its salts are readily soluble in water, and seem not to crystallise; when the diamine is warmed with phenanthraquinone and acetic acid, it yields a reddish-yellow solution, from which, on evaporation, only amorphous substances are obtained. F. S. K.

Synthesis of Indole from Tartaric Acid and Aniline. By H. Polikier (*Ber.*, **24**, 2954—2959).—Tartranilide (30 grams) is fused in a retort, and, after heating at 260—270° for two hours, slowly distilled over a free flame, until nothing more passes over; the product is then redistilled in a current of steam, when a mixture of aniline and indole passes over, from which the latter can be isolated as picrate, 0·74 gram being obtained; whilst a yellowish residue weighing 4·8 grams remains, which, on crystallisation from alcohol, melts at 220°, and proves to be dianilidosuccinanilide (compare this vol., p. 55). By heating tartranilide (20 grams) with an equal weight of zinc chloride at 270—280° for an hour, dianilidosuccinanilide (1·32 grams) and indole (0·22 gram) may be isolated; whilst, if a mixture of tartaric acid, aniline, and zinc chloride is heated in a sealed tube at 280°, the product extracted with alcohol, and the solution distilled, indole is obtained from the portion of the distillate passing over last, and is purified as described above.

When tartaric acid is added by degrees to boiling orthotoluidine it dissolves after a time, and, on now distilling, the temperature quickly rises to 300°, carbonic anhydride is evolved, and orthotoluidine, methylindole, and a white, crystalline compound melting at 247° pass over; the methylindole is formed in much larger quantity than is indole by the methods described above.

When dianilidosuccinanilide is heated in a sealed tube with a little

water at 200°, a resinous mass, together with aniline and traces of indole is obtained; whilst, if ethyldianilidosuccinic acid (Abstr., 1888, 951) is heated with zinc chloride, a compound melting at about 62°, and giving all the reactions of indole, is produced. It would appear, therefore, that by the action of aniline on tartranilide, dianilidosuccinanilide is initially formed, and this, by the action of water, yields indole, aniline, carbonic anhydride, and carbonic oxide. Further experiments are promised. A. R. L.

Molecular Weight of Nitrosoindole. By C. Zatti and A. Ferratini (*Gazzetta*, **21**, ii, 19—25).—The authors have already noted the comparatively high melting point of the nitrosoindole described by them (Abstr., 1890, 1293), and suggested that its empirical formula might have to be doubled to give the true molecular weight. The molecular weight could not be determined by the cryoscopic method, owing to the very sparing solubility of the substance in the cold, but by observing the elevation of the boiling point of its solution in acetone, numbers were obtained showing that the molecular formula of nitrosoindole is $C_{16}H_{12}N_4O_2$.

Nitrosodimethylindole behaves normally in its solution in acetone, the formula of the molecule being $C_{10}H_{10}N_2O$.

When nitrosoindole is treated with nitric acid, it dissolves, yielding an intensely red solution, and on pouring this into water, a flocculent, blood-red substance separates, which agrees in properties with the so-called nitrosoindole nitrate prepared by Nencki (Abstr., 1875, 1205). W. J. P.

Indazole Derivatives. By C. Paal (*Ber.*, **24**, 3058—3065; compare Abstr., 1891, 723).—Phenylindazole, $C_6H_4<\begin{matrix}N-\\ |\\ CH\end{matrix}>NPh$ [1 : 2], was dissolved in glacial acetic acid, treated with rather more than the theoretical amount of chromic acid, and boiled in a reflux apparatus until the solution acquired a pure green tint. On diluting the mass with water, *azobenzeneorthocarboxylic acid*, $N_2Ph{\cdot}C_6H_4{\cdot}COOH$, separates out, the yield being 70 per cent. of the theoretical. It dissolves easily in ether, alcohol, glacial acetic acid, ethyl acetate, and benzene, very sparingly in hot light petroleum, and not at all in water. It crystallises from alcohol slowly in large, dark-red crystals, or quickly in small needles of the colour of azobenzene. It melts at 95°, and at a higher temperature decomposes with evolution of red fumes, azobenzene being formed. The *alkali salts* and the *barium salt* are easily soluble in water; the *lead salt* forms an orange-coloured, granular, amorphous precipitate which melts in hot water; the *silver salt* forms an unstable, yellowish precipitate, which decomposes when heated, yielding azobenzene, carbonic anhydride, silver, and carbonaceous products. The acid itself is converted into *hydrazobenzeneorthocarboxylic acid*, $NHPh{\cdot}NH{\cdot}C_6H_4{\cdot}COOH$, when it is dissolved in alcohol and treated with zinc-dust and a few drops of acetic acid. The new acid separates on pouring the mixture into water. It dissolves easily in mineral acids, ether, alcohol, glacial acetic acid, and ethyl acetate, sparingly in benzene and light petroleum, scarcely at all in

water. It crystallises in yellowish, ill-defined prisms which melt at 165—166°, and, in the air, quickly darken in colour, becoming oxidised to the azo-acid. The white *sodium salt* dissolves readily in water; the *barium salt*, $(C_{13}H_{11}N_2O_2)_2Ba$, forms long, white, hair-like crystals grouped as in wavellite; it oxidises readily in the air.

Benzidinemetacarboxylic acid, $NH_2{\cdot}C_6H_4{\cdot}C_6H_3(NH_2){\cdot}COOH$, is formed to the extent of 60 per cent. of the theoretical yield, when azobenzene-orthocarboxylic acid is reduced by dissolving it in absolute alcohol, excess of tin added, and then hydrochloric acid in successive small proportions, the mixture being heated. On cooling the solution, the *dihydrochloride*, $C_{13}H_{12}N_2O_2,2HCl$, crystallises out in white, lustrous needles which melt at a very high temperature, and do not dissolve in alcohol, but do so in water, undergoing dissociation and forming the *monohydrochloride*, $C_{13}H_{12}N_2O_2,HCl$, which separates in short, dull-white needles; this melts at a very high temperature, and is only sparingly soluble even in hot water. This salt may also be obtained by boiling a hydrochloric acid solution of hydrazobenzeneorthocarboxylic acid. The acid itself is obtained by dissolving either of the hydrochlorides in aqueous ammonia and adding acetic acid. It dissolves sparingly in hot water, hardly at all in absolute alcohol; from dilute alcohol, it crystallises in crusts formed of white needles which melt at 210°, decomposing into carbonic anhydride and benzidine. The *alkali salts* are soluble in water, but insoluble in concentrated alkalis. The *barium salt* forms short, white prisms, almost insoluble in cold water. The *silver salt*, $C_{13}H_{11}N_2O_2Ag$, is a white, amorphous substance, fairly stable in the light, and almost insoluble in hot water.

Parachlorazobenzeneorthocarboxylic acid, $C_6H_4Cl{\cdot}N_2{\cdot}C_6H_4{\cdot}COOH$, is obtained by oxidising parachlorophenylindazole in acetic acid solution with chromic acid, cooling the solution, and diluting it with water. It dissolves readily in hot alcohol, glacial acetic acid, and benzene, scarcely at all in light petroleum. It forms small, orange-coloured, dendritic needles, and melts at 166°. Reduced with zinc-dust and acetic acid, it yields *parachlorhydrazobenzeneorthocarboxylic acid*, $C_6H_4Cl{\cdot}NH{\cdot}NH{\cdot}C_6H_4{\cdot}COOH$, which is precipitated in white flakes on the addition of water. The yellow *sodium salt* of the azo-acid is soluble in water, but insoluble in concentrated alkalis. The *barium salt* forms lustrous, orange-coloured needles insoluble in water. The *copper salt* forms a bright-green, amorphous, the *silver salt*, a reddish, amorphous, granular, and the *ferric salt*, a bulky, reddish, precipitate.

Parabromazobenzeneorthocarboxylic acid, $C_6H_4Br{\cdot}N_2{\cdot}C_6H_4{\cdot}COOH$, is prepared by oxidising parabromophenylindazole with chromic acid in acetic acid solution. It crystallises from alcohol in small, lustrous, orange-red needles, melts at 176°, and dissolves readily in glacial acetic acid, ethyl acetate, and benzene, but not in light petroleum. It is reduced by zinc-dust and acetic acid to *parabromhydrazobenzene-carboxylic acid*, $C_6H_4Br{\cdot}NH{\cdot}NH{\cdot}C_6H_4{\cdot}COOH$, which forms white, crystalline flakes insoluble in water. The salts of the bromazo-acid resemble those of the chlorazo-acid, except that they are redder, and that the copper and ferric salts are, respectively, bright-green and rusty coloured.

C. F. B.

Synthesis of Indigodisulphonic Acid. By B. Heymann (*Ber.*, **24**, 3066—3070).—A reply to Knietsch (Abstr., 1891, 1231). It is shown that when indigocarmine is obtained from phenylglycocine by dissolving the latter in fuming sulphuric acid (containing 80 per cent. of the anhydride) and removing the excess of anhydride by the addition of concentrated sulphuric acid, the oxygen of the air plays no oxidising part in the reaction, for in an experiment, during which air was carefully excluded, as good a yield was obtained as in other experiments. The author is of opinion that the leuco-compound at first formed has a constitution similar to $HSO_3 \cdot C_6H_3 < \begin{matrix} C(OSO_3H) \\ NH \end{matrix} > CH$, and that, when the concentrated sulphuric acid is added, this compound either splits up into indigo-carmine, sulphurous acid, and water, the sulphuric acid residue furnishing the necessary oxygen, or, as is more probable, breaks up into the sulphonic acid and the leuco-compound, which is then oxidised to indigo-carmine by sulphuric anhydride still present in the solution. C. F. B.

Diphenyltetraketone. By P. W. Abenius and H. G. Söderbaum (*Ber.*, **24**, 3033—3034).—The yellow substance melting at 170° (Abstr., 1891, 1043) obtained when the acetyl derivative of *ω*-isonitrosoacetophenone (benzoylformoxime) is dissolved in a dilute solution of sodium carbonate is shown to be in reality diphenylhydroxytriketone (phenylglyoxalbenzoïn), OH·CHBz·COBz, for it is identical with the substance obtained by treating benzoylformaldehyde, COPh·CHO, with potassium cyanide in alcoholic solution. When treated with strong nitric acid, it is oxidised to a *tetraketone*, COPh·CO·CO·COPh, a red substance which easily takes up 1 mol. of water, forming a yellow hydrate which melts at 86—88° and crystallises well.

C. F. B.

Constitution of Naphthalene. By G. Ciamician (*Gazzetta*, **21**, ii, 101—108).—The author considers Bamberger's hypothesis of the constitution of naphthalene to be erroneous, and believes that the internal structure of the molecule is better represented by employing Baeyer's conception of five double bonds of mean solidity or resistance.

The author is of opinion that the internal structure of the naphthalene molecule is well represented by considering the carbon atoms placed at the centres of the sides of two intersecting equilateral but not equiangular hexagons, the two central carbon atoms being common to both hexagons. In the orthogonal projection of such a system as this, six of the straight lines joining pairs of carbon atoms will be longer than the remaining five; these latter represent the five double bonds in Baeyer's conception of the ring, whilst the longer ones represent the single bonds. The hydrogen atoms are disposed in two planes parallel to that of the carbon atoms, the plane of the hydrogen atoms belonging to one hexagon being above, that of the other hexagon below, the carbon plane. Such a system as this is perfectly symmetrical and may be considered to explain the seeming proximity of the peri-hydrogen atoms in the naphthalene molecule.

W. J. P.

Azines of the Uric Acid Group. By O. Kühling (*Ber.*, **24**, 3029—3033; compare this vol., p. 1341).—*Dimethylnaphthalloxazine*, $C_{10}H_6<\begin{matrix}N:C\cdot NMe\cdot CO\\ |\quad\quad\quad |\\ N:C\cdot CO\cdot NMe\end{matrix}$, is prepared by the reaction of tetramethylalloxantin with α-naphthylenediamine hydrochloride in aqueous solution; it crystallises from a mixture of glacial acetic acid and alcohol in small, slender, yellow needles, melts at 285°, and is insoluble in soda or in sodium carbonate solution.

Methylalloxazine, $C_6H_4<\begin{matrix}N:C\cdot NMe\cdot CO\\ |\quad\quad\quad |\\ N:C\cdot CO\cdot NH\end{matrix}$, is obtained from orthophenylenediamine hydrochloride and dimethylalloxantin, and crystallises from a mixture of alcohol and glacial acetic acid in small, pale-yellow needles, melting at 250°. The compound is soluble in sodium carbonate solution at the ordinary temperature, and is reprecipitated unchanged by acids.

Methyltolualloxazine, $C_6H_3Me<\begin{matrix}N:C\cdot NMe\cdot CO\\ |\quad\quad\quad |\\ N:C\cdot CO\cdot NH\end{matrix}$, is formed from 1 : 3 : 4-orthotoluylenediamine hydrochloride and dimethylalloxantin; it resembles the preceding compound in properties, and blackens when heated above 250°.

Methylnaphthalloxazine, $C_{10}H_6<\begin{matrix}N:C\cdot NMe\cdot CO\\ |\quad\quad\quad |\\ N:C\cdot CO\cdot NH\end{matrix}$, is deposited on heating α-naphthylenediamine hydrochloride with dimethylalloxantin in aqueous solution; it is insoluble in water, very sparingly so in alcohol, and crystallises from glacial acetic acid in slender, yellow needles. The azine dissolves in soda or in sodium carbonate solution on gently warming, and is precipitated unchanged by acids; it is unaltered by heating at about 300°. On boiling aqueous solutions of orthodiamine hydrochlorides with parabanic acid, sparingly soluble compounds are obtained, which proved on analysis to be dihydroxyquinoxalines; these compounds are formed by the resolution of the parabanic acid into carbamide and oxalic acid, and the condensation of the latter compound with the orthodiamine. *Naphthadihydroxyquinoxaline*, $C_{10}H_6<\begin{matrix}N:C\cdot OH\\ |\quad\quad |\\ N:C\cdot OH\end{matrix}$, is prepared by heating parabanic acid with α-naphthylenediamine hydrochloride for several hours in aqueous solution; it is purified by dissolving in dilute potash and precipitating with hydrochloric acid, and forms slender, colourless needles which melt above 300°. The compound dissolves in glacial acetic acid, and sparingly in alcohol, but is insoluble in water. The *barium salt* is insoluble in water and is decomposed by acids.

The substituted parabanic acids appear to be more stable towards orthodiamines; cholestrophane is unaffected by orthotoluylenediamine hydrochloride, and allantoïn does not react at all with orthodiamines. J. B. T.

A Volatile Oil from Aristolochia reticulata. By J. C. Peacock (*Chem. Centr.*, 1891, ii, 379; from *Amer. J. Pharm.*, June, 1890).—From the rhizomes of this plant, as they are obtained com-

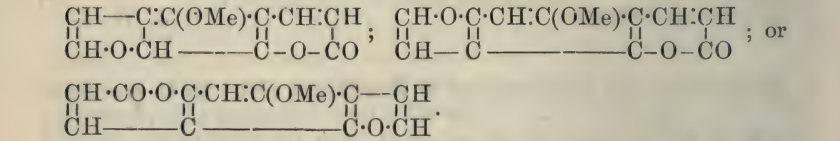
mercially, the author separated 0·61—0·94 per cent. of a golden-yellow oil. It has a camphor-like odour and taste, dries slowly when exposed to the air, does not solidify at −17°, and has a sp. gr. of 0·9745—0·9785 at 15·5°, and 0·9719—0·9758 at 20°. It is miscible with alcohol, ether, chloroform, benzene, and light petroleum; it exhibits no aldehyde reaction, and rotates the polarised ray −4° in 100-mm. tube. By fractional distillation, 10 per cent. passed over at 74—75° under a pressure of 43 mm., 60 per cent. between 122—124°, under a pressure of 43 mm., and 20 per cent. between 147—150° under a pressure of 47·7 mm.; the residue in the retort possessed a blue and green fluorescence, and contained tarry matters.

This first distillate boiled at 157° under a pressure of 769·6 mm.; its sp. gr. was 0·865 at 15·5°; its formula is $C_{10}H_{16}$, with which its vapour density corresponded; it absorbs bromine very readily, and is characterised as a member of Wallach's pinene group.

The second fraction boils at 211° under 763·6 mm. pressure; its formula is $C_{15}H_{25}O_2$, with which the vapour density corresponds. On hydrolysis with potash, a camphor, $C_{10}H_{18}O$, is produced, which is very similar to borneol; it boils at 199·5—200°. An acid is also separated of the probable formula $C_5H_9O_2$; melting point about 65°; it forms a red precipitate with ferric chloride; its odour is unpleasant.

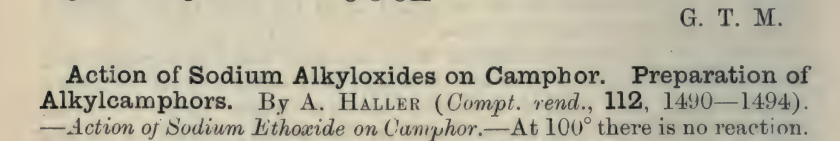
The third fraction, boiling at 239—240°, under 762·1 mm. pressure, is a greenish-yellow oil; sp. gr. 0·9888 at 15·5°; its formula is $C_{18}H_{29}O$, with which the vapour density corresponds; it is a neutral, indifferent substance. J. W. L.

Bergapten, the Stearoptene of Bergamot Oil. By C. Pomeranz (*Monatsh.*, **12**, 379—392).—This substance separates as a crystalline magma when the ethereal oil obtained from the rind of the fruit of *Citrus bergamia* is kept for some time. It may be purified by sublimation or by recrystallisation from alcohol, when it forms hard, white, silky needles, which are tasteless and odourless at ordinary temperatures, but evolve aromatic vapours when heated. It is slightly soluble in cold alcohol and in hot water; dissolves in hot alcohol, acetic acid, chloroform, benzene, and phenol, and melts at 188°, with partial sublimation. Elementary analysis and a determination of its molecular weight by observing the depression of the freezing point of a solution in phenol show that it has the molecular formula $C_{12}H_8O_4$. Aqueous and alcoholic potash, acetic anhydride, phenylhydrazine, and boiling hydrochloric acid are all without action on the compound, which, however, as shown by the action of hydriodic acid and acetic anhydride (compare Herzig, *Monatsh.*, **9**, 544), contains three methoxyl groups.



On heating bergapten with potash, methyl alcohol, and methyl iodide in a reflux apparatus for five hours, two new compounds are obtained. One of these has the formula $C_{14}H_{14}O_5$; crystallises from alcohol in microscopic prisms, which are far more soluble in alcohol, chloroform, and ether than is bergapten, and melts at 52°. The other, which the author has named *methylbergaptic acid*, contains CH less than the preceding compound, which is probably its methyl salt

since, on hydrolysis with potash, it furnishes the free acid. It crystallises from dilute alcohol in small, rhombic plates, dissolves readily in alkaline hydroxides and carbonates, and melts at 138°. When, in the above described operation, ethyl iodide is substituted for methyl iodide, *ethylbergaptic acid* is obtained; this crystallises in acute-angled prisms or in twinned or clustered needles, and melts at 142°. From its behaviour with methyl and ethyl iodides, bergapten must be regarded as the anhydride, $C_{11}H_8O_2<\begin{matrix}O\\|\\CO\end{matrix}$, and it, therefore, closely resembles coumarin in constitution.



When fused with potash, bergapten gives rise to phloroglucinol, and on treatment with two molecular proportions of bromine, the anhydride is converted into monobromobergapten dibromide, $C_{12}H_7O_4Br_3$, formed from bergapten, which has two double linkages in the side chains, by the addition of four atoms of bromine, one of which is afterwards eliminated in the form of hydrobromic acid.

On reduction with sodium amalgam, methylbergaptic acid is converted into *methylhydrobergaptic* acid, $C_{13}H_{14}O_5$, which crystallises from dilute alcohol in small, white needles, and melts at 122°. This product is analogous to the hydro-acids obtained on the reduction of methyl- and ethyl-coumaric acids.

The above-described reactions of bergapten point to its having one of the following constitutions:—

; or

.

G. T. M.

Action of Sodium Alkyloxides on Camphor. Preparation of Alkylcamphors. By A. Haller (*Compt. rend.*, **112**, 1490—1494). —*Action of Sodium Ethoxide on Camphor.*—At 100° there is no reaction. 5 grams of camphor and 30 c.c. of absolute alcohol to which 0·75 gram of sodium has been added are heated in sealed tubes for 24 hours at 200°. A great pressure is observed on opening the tubes, due to the disengagement of large quantities of hydrogen. The product is treated with water, and the separated, coloured, viscous mass dissolved in ether, from which it separates on spontaneous evaporation of the solvent. Repeatedly crystallised from a mixture of ether and light petroleum, it forms white, hexagonal crystals, melting at 208—210°. This substance is a mixture of dextro- and lævo-borneol, the proportions varying with the preparation. The rotatory powers of two preparations were $[\alpha]_D = +12·5°$ and $[\alpha]_D = +16°$.

15 grams of camphor yield 8—10 grams of pure borneol. The yield is better than with Berthelot's method; the product is not mixed with camphor, and only contains traces of camphic acid, small quantities of a liquid product insoluble in water and alkalis, and sodium acetate.

Sodium propoxide, isobutoxide, and amyloxide yield borneol, the quantity decreasing with the rise in the molecular weight of the alcohol employed. Secondary liquid products intermediate in composition between alkylcamphors and alkylborneols increase in the same ratio.

Action of Sodium Benzyloxide on Dextrocamphor. Benzylcamphor.—Dry dextrocamphor (1 mol.) is heated with sodium benzyloxide (1 mol.), dissolved in excess of benzyl alcohol, at 220—225° for 24 hours. There is no disengagement of gas. Distillation of the ethereal extract at 220—225° (H = 70 mm.) yields a syrupy, very refractive substance, which, at first, has a slight empyreumatic odour, becoming similar to the odour of benzaldehyde on exposure to the air. Boiling alcoholic potash, glacial acetic acid, or hydrochloric acid does not attack this substance. It crystallises on cooling, after the addition of a crystal of benzylcamphor, in small crystals which, when recrystallised from alcohol, yield fine, large crystals melting at 51—52°, soluble in alcohol, ether, benzene, and toluene, and insoluble in water and the alkalis. The formation of benzylcamphor is accompanied by the production of an equivalent amount of sodium benzoate and the liberation of hydrogen, which, doubtless, acts on a part of the benzylcamphor yielding reduction products which remain in the uncrystallisable oil.

Benzylcamphor may also be obtained by the action of benzyl chloride on sodiumcamphor when heated. The reaction is finished when a portion of the material, diluted with water, does not give an alkaline reaction. When distilled at 110 mm. pressure, a mixture of camphor and oily products passes over below 200°; from 215—220°, benzylborneol passes over; whilst from 220—250°, a fraction distils as a thick oil, crystallising on cooling. The crystals, purified by recrystallisation from alcohol, correspond in properties with the benzylcamphor prepared from sodium benzyloxide.

Benzalcamphor also yields benzylcamphor on reduction with sodium amalgam.

Benzylcamphoroxime, $C_8H_{14}<\begin{matrix}C{:}NOH\\ |\\ CH{\cdot}CH_2Ph\end{matrix}$, is obtained by heating for two days benzylcamphor, mixed with the theoretical amount of the double chloride of zinc and hydroxylamine and a little alcohol. The product crystallises from alcohol in long, flat prisms melting at 127—128°, soluble in ether, benzene, and light petroleum, insoluble in alkalis. The oily liquid separated from the oxime solidifies in time; it has not been examined, but is, doubtless, an isomeride.

Lævobenzylcamphor may be prepared from lævocamphor by the methods given above. The crystals melt at 50—52°. Benzylborneols are formed, together with benzylcamphors, when the camphor iodides are treated with benzyl chloride. They are separated from the benzylcamphors with some difficulty, owing to the approximation of the boiling points. They are oily liquids, having the odour of bitter almonds, and distilling at 215—216° under a pressure of 80 mm.

The oily products obtained by treating camphor at a high temperature with sodium propoxide, butoxide, and amyloxide are held to contain the propyl-, butyl-, and amyl-camphors. W. T.

Action of Sodium Benzyloxide on Ethyl Camphocarboxylate. By J. Minguin (*Compt. rend.*, **112**, 1454—1455).—20—30 c.c. of benzyl alcohol to which has been added 0·5 gram of sodium is heated with 10 grams of ethyl camphocarboxylate at 150° for 24 hours. The resulting pasty mass yields an oil on treatment with water. On evaporating the ethereal solution, the residue yields benzyl alcohol and a viscous liquid distilling at 260—290° under 10 mm. pressure. This is *benzyl hydroxycamphocarboxylate*,

$$C_7H_7O\cdot CO\cdot C_8H_{14}\cdot CH_2\cdot COOC_7H_7.$$

The yield is about 30 grams from 40 grams of ethyl camphocarboxylate. Hydrolysis with alcoholic potash in sealed tubes gives benzyl alcohol and hydroxycamphocarboxylic acid. The rotatory power in alcohol is $[\alpha]_D = +35·5°$.

The wash waters, on neutralisation with an acid, yield an oil which distils at 250—275° at a pressure of 10 mm. This acid is very viscous at the ordinary temperature. On hydrolysis, it gives benzyl alcohol and hydroxycamphocarboxylic acid. It may be considered to be benzylhydroxycamphocarboxylic acid, $COOH\cdot C_8H_{14}\cdot CH_2\cdot COOC_7H_7$. Its rotatory power in alcoholic solution is $[\alpha]_D = 52·62°$.

W. T.

New Method for Determining the Constitution of Homologues of Pyrroline. By C. U. Zanetti (*Gazzetta*, **21**, ii, 25—32).—Ciamician and Zanetti (Abstr., 1890, 1155) showed that hydroxylamine reacts with members of the pyrroline series, yielding dioximes, which are oximes either of diketones or of ketoaldehydes, according to the constitution of the pyrroline. By boiling the resulting oxime with 30 per cent. potash, the author finds that the corresponding bibasic or keto-acid is obtained. This reaction furnishes a means of determining the constitution of the pyrroline homologue employed.

Hydroxylamine and pyrroline react to form succindialdoxime; when this is boiled with 30 per cent. caustic potash there is an abundant evolution of ammonia, and succinic acid, amounting to 70 per cent. by weight of the oxime employed, may be extracted from the solution.

2 : 4-Dimethylpyrroline, on treatment with hydroxylamine, yields α-methyllevulindioxime, which, when boiled for $2\frac{1}{2}$ hours with caustic potash, gives the β-acetoisobutyric acid prepared by Bischoff (Abstr., 1881, 412). The *hydrazone* of this acid crystallises from alcohol in splendid, yellowish scales melting at 122°, with evolution of gas, to a yellow liquid; it is soluble in glacial acetic acid, alcohol, ether, benzene, and ethyl acetate, sparingly so in cold dilute alcohol, and insoluble in water or light petroleum. It dissolves in solutions of the alkaline carbonates with effervescence, and is precipitated unaltered by acids. On exposure to air and light, it is converted into a heavy, reddish-brown liquid. *Ethyl β-acetoisobutyrate* is obtained as a liquid of fruity odour on passing dry hydrogen chloride through a strongly cooled solution of the acid in absolute alcohol. Its *hydrazone*, which separates from dilute alcohol in yellowish scales, melts at 105°, and is soluble in alcohol, ether, ethyl acetate, and acetic acid, sparingly so in cold, dilute alcohol, and insoluble in water and alkaline

carbonates. Like the hydrazone of the free acid, it liquefies on exposure to air and light. W. J. P.

Methyldipyridyls. By A. Heuser and C. Stoehr (*J. pr. Chem.* [2], **44**, 404—410).—$\alpha\alpha$-Dimethyldipyridyl (Abstr., 1891, 80) is better isolated by extracting the base, which separates from the aqueous solution of the reaction mass, with ether, drying the ethereal solution over potassium hydroxide, distilling off the ether, re-dissolving in absolute alcohol, and converting the base into hydrochloride by a stream of dry hydrogen chloride.

When $\alpha\alpha$-dimethyldipyridyl is oxidised with permanganate, three acids are obtained, namely, α-methyldipyridyl-α-carboxylic acid, dipyridyl-$\alpha\alpha$-dicarboxylic acid, and lutidinic acid, in the proportion of 10, 2, and 2 grams respectively, from 20 grams of the base. Five grams of the base are introduced into a solution of 12 grams of potassium permanganate in 1200 grams of water, and the solution is kept at 40° for about 14 days. The manganese dioxide is then filtered off, the filtrate evaporated in a stream of carbonic anhydride, and neutralised with nitric acid. By evaporation with alcohol, most of the potassium nitrate is separated, and the acids are then precipitated with silver nitrate; the silver salts are decomposed by hydrogen sulphide, when a yellow precipitate separates as the hot filtrate cools; this contains the mono- and di-carboxylic acids, which can be separated by the greater solubility of the former in hot water; the lutidinic acid is extracted from the filtrate from the yellow precipitate by evaporation with ammonia and extraction with ether.

α-Methyldipyridyl-α-carboxylic acid has been already described (Abstr., 1891, 81). When heated with glacial acetic acid at 180°, it is converted into methyldipyridyl with evolution of carbonic anhydride.

Dipyridyl-$\alpha\alpha$-dicarboxylic acid, $C_{10}H_6N_2(COOH)_2 + H_2O$, crystallises in colourless needles, melts at 247·5°, decomposes at a slightly higher temperature, and dissolves sparingly in water and glacial acetic acid. It is coloured reddish-yellow by ferrous sulphate when in aqueous solution, and violet when crystalline. The *silver* and *barium* salts were obtained, and also an easily soluble *platinochloride*. When this acid is heated with glacial acetic acid in a sealed tube at 180°, it yields $\gamma\gamma$-dipyridyl, which melts at 111—112° (Weidel gives 114°, Abstr., 1883, 483); the *platinochloride* of this base was obtained, and it is noted that potassium ferrocyanide gives a red-brown solution with the base, from which transparent, six-sided tables gradually separate (compare Abstr., 1891, 80).

Lutidinic acid, $C_5H_3N(COOH)_2 + H_2O$ [$(COOH)_2 = \alpha : \gamma$], crystallises in aggregates of colourless needles, melts at 232—233° with rapid evolution of gas, and dissolves easily in hot water.

A. G. B.

Preparation of α- and β- Pyridyllactic Acid from α-Picoline. By A. Einhorn (*Annalen*, **265**, 208—238).—Pyridyl-ω-trichloro-α-hydroxypropane (Abstr., 1887, 845) is best prepared by heating a solution of α-picoline (50 c.c.) and chloral (45 c.c.) in amyl acetate (175 c.c.) for 10 to 12 hours at 140—150°; the product is extracted

from the solution by shaking with dilute hydrochloric acid. The yield of the hydrochloride is at least 125 grams from 100 grams of picoline; this salt crystallises from alcohol in long, prismatic needles, and melts at 201—202°. The free base crystallises from dilute alcohol in hexagonal plates melting at 86—87°. The *hydrobromide*, $C_8H_9NOCl_3,HBr$, forms well-defined crystals, and melts at 207—208°.

Pyridyl-ω-trichloropropylene, $C_5NH_4{\cdot}CH{:}CH{\cdot}CCl_3$, can be obtained by gradually adding phosphorus pentachloride to a boiling mixture of pyridyltrichlorohydroxypropane hydrochloride and chloroform, and decomposing the salt thus produced with sodium carbonate; it crystallises from alcohol in prismatic needles, melts at 97°, and gradually decomposes on keeping.

α-Pyridyllactic acid, $C_5NH_4{\cdot}CH_2{\cdot}CH(OH){\cdot}COOH$, is formed when an aqueous solution of pyridyltrichlorohydroxypropane hydrochloride is gradually added to boiling sodium carbonate, and the heating continued until the reaction is at an end; it is isolated by means of its basic copper salt. It crystallises from alcohol in transparent, seemingly monoclinic prisms, melts at 124—125°, and is only sparingly soluble in ethyl acetate, but more readily in chloroform. The basic *copper* salt, $(C_8H_8NO_3)_2Cu,CuO$, crystallises from hot water and ammonia in slender, green needles. The *silver* salt, $C_8H_8NO_3Ag$, crystallises from dilute ammonia in colourless needles. The *hydrochloride*, $C_8H_9NO_3,HCl$, separates from alcohol in crystalline aggregates, and melts at 85—86°. The *hydrobromide*, $C_8H_9NO_3,HBr$, crystallises from glacial acetic acid and alcohol in large, well-defined needles melting at 125—126°. The *platinochloride*, $(C_8H_9NO_3)_2,H_2PtCl_6$, is moderately easily soluble, and melts at 202—204°. The *aurochloride* forms compact, yellow prisms, and melts at 177°. When pyridyllactic acid is heated at 130—140° under reduced pressure, it is converted into pyridylacrylic acid with elimination of 1 mol. H_2O; on oxidation with excess of very dilute potassium permanganate, it yields picolinic acid.

Benzoyl-α-pyridyllactic acid, $C_5NH_4{\cdot}CH_2{\cdot}CH(OBz){\cdot}COOH$, is best prepared by gradually adding benzoic anhydride (4 grams) in small portions at a time to a solution of α-pyridyllactic acid (2 grams) in water (4 grams), heated at a temperature just below 90°; it crystallises from hot water in lustrous needles, and melts at 145° with decomposition. The *platinochloride*, $(C_{15}H_{13}NO_4)_2,H_2PtCl_6$, crystallises from water or dilute alcohol in yellow, transparent, prismatic needles melting at 179° with decomposition. The *barium* salt is a colourless, crystalline compound, readily soluble in water and alcohol; the *silver* salt crystallises in colourless needles. The *methyl* salt, prepared by treating the silver salt with methyl iodide, is an oil, but its platinochloride, $(C_{16}H_{15}NO_4)_2,H_2PtCl_6$, crystallises from hot water and dilute alcohol in yellow needles melting at 193° with decomposition.

Methyl α-pyridyllactate, $C_5NH_4{\cdot}CH_2{\cdot}CH(OH){\cdot}COOMe$, prepared by treating a methyl alcoholic solution of the acid with hydrogen chloride, is a colourless, crystalline compound melting at about 34°; its *aurochloride*, $C_9H_{11}NO_3,HAuCl_4$, separates from water in crystals, and melts at about 119°; its *benzoyl* derivative crystallises in transparent needles, melts at 41°, and is identical with the methyl benzoylpyridyl-α lactate

just described (as an oil), as was proved by converting it into the crystalline platinochloride (m. p. 193—194°).

Pyridylacrylic acid, $C_5NH_4{\cdot}CH{:}CH{\cdot}COOH$ (*loc. cit.*), is best prepared by adding pyridyltrichloropropane hydrochloride (60 grams), in small portions (3 to 4 grams) at a time, to a boiling solution of potassium hydroxide (132 grams) in alcohol (400 grams), air being excluded as much as possible. After boiling for six hours, the filtered solution is evaporated with hydrochloric acid, the residue extracted with alcohol, the extract decolorised with animal charcoal and concentrated; on cooling, pyridylacrylic acid hydrochloride is deposited in crystals, and the mother liquors contain pyridyllactic acid hydrochloride, which can be isolated by means of its copper salt; the yield of the former is 20 grams, and of the copper salt, 5 grams. Pyridylacrylic acid crystallises from boiling water in small, transparent needles, melts at 202—203° with decomposition, and is almost insoluble in cold water, but readily soluble in alcohol. The hydrochloride crystallises from alcohol in colourless needles melting at 220° with decomposition. The *hydrobromide*, $C_8H_7NO_2,HBr$, forms spear-shaped crystals, and melts at 222—223°. The *aurochloride*, $C_8H_7NO_2,HAuCl_4$, crystallises from hot water in small, light-yellow needles, and melts at 194—195°. The *platinochloride*, $(C_8H_7NO_2)_2,H_2PtCl_6$, is moderately easily soluble in water, from which it crystallises in reddish-yellow prisms melting at 209—210°. The barium salt and the salts of the alkalis do not crystallise, but the *calcium* salt, $(C_8H_6NO_2)_2Ca$, separates from dilute alcohol in slender needles; the *silver* salt, $C_8H_6NO_2Ag$, is also crystalline. The *methyl* salt, prepared by treating the acid with hydrogen chloride in methyl alcoholic solution, is a solid, very hygroscopic substance; its *hydrochloride*, $C_9H_9NO_2,HCl$, separates from methyl alcohol in small, colourless crystals melting at 185—186°. The *ethyl* salt crystallises in long, transparent needles. The *methiodide*, $C_8H_7NO_2,MeI$, separates from dilute alcohol in amber-yellow, prismatic needles, and melts at 219—220° with decomposition. The *methobromide*, $C_8H_7NO_2,MeBr$, separates from water in colourless crystals, melts at 242° with decomposition, and is almost insoluble in alcohol, and only sparingly soluble in glacial acetic acid.

Pyridyldibromopropionic acid, $C_5NH_4{\cdot}CHBr{\cdot}CHBr{\cdot}COOH$, prepared by warming pyridylacrylic acid (1 part) with a glacial acetic acid solution of bromine (1·3 parts), separates from water in yellowish crystals melting at 127°, and from glacial acetic acid in grey crystals, which retain some of the solvent, and melt at 146·5°.

β-Pyridylbromopropionic acid hydrobromide,

$$C_5NH_4{\cdot}CHBr{\cdot}CH_2{\cdot}COOH,HBr,$$

is formed when pyridylacrylic acid is heated at 100° with a solution of hydrogen bromide in glacial acetic acid, saturated at 0°; it crystallises in colourless needles or plates, and melts at 163—164°.

Pyridylethylene is produced, together with pyridylacrylic acid and β-pyridyllactic acid, when an aqueous solution of the preceding compound is warmed with a slight excess of sodium carbonate; it is a colourless oil, boils at 159—160° with partial decomposition, and is identical with Ladenburg's vinylpyridine. The *platinochloride*,

$(C_7H_7N)_2,H_2PtCl_6$, separates from water in crystals, and melts at 174° with decomposition. The *aurochloride*, $C_7H_7N,AuCl_3$, crystallises in yellow needles, and melts at 144°.

β-Pyridyllactic acid, $C_5NH_4{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$, is isolated from the red solution which remains after distilling the pyridylethylene with steam, by first acidifying with dilute hydrochloric acid to precipitate the pyridylacrylic acid, and then adding an ammoniacal solution of copper sulphate to the filtrate; after a time, the basic *copper* salt, $(C_8H_8NO_3)_2Cu.CuO$, is deposited in blue crystals, and can be purified by recrystallisation from dilute ammonia. The free acid is a crystalline compound melting at 86°. The *hydrochloride*, $C_8H_9NO_3,HCl$, crystallises from alcohol in colourless prisms, and melts at 147°. The *platinochloride*, $(C_8H_9NO_3)_2,H_2PtCl_6$, separates from dilute alcohol in small, yellow crystals melting at 191°. The *methyl* salt, prepared by treating a methyl alcoholic solution of the acid with hydrogen chloride, is a light, yellow oil; its *platinochloride*, $(C_9H_{11}NO_3)_2,H_2PtCl_6$, crystallises from dilute alcohol in lustrous, yellow plates, and melts at 178·5°. The *ethyl* salt is also a pale-yellow oil, but its *hydrochloride* crystallises from alcoholic ether in lustrous plates.

Benzoyl-β-pyridyllactic acid, $C_{15}H_{13}NO_4$, is formed when ethyl β-pyridyllactate is warmed with benzoic chloride on the water-bath; the benzoic acid is separated in the usual way, the product then dissolved in hydrochloric acid, the solution kept for some days, and the crystalline hydrochloride thus obtained decomposed with water: the free acid crystallises from hot water in lustrous prisms, and melts at 135·5°. The *silver* salt is a colourless, crystalline compound. The *methyl* salt, $C_{16}H_{15}NO_4$, prepared from the silver salt, crystallises in transparent prisms, and melts at 79°.

The relationship between some of the compounds described above and certain derivatives of cocaïne is shown with the aid of graphic formulæ. F. S. K.

Synthesis of Quinoline Derivatives by means of Alkyl Acetoacetates. By M. Conrad and L. Limpach (*Ber.*, **24**, 2990—2992).—An extension of the method previously described by the authors (Abstr., 1888, 593) to the synthesis of other quinoline derivatives.

Methyl phenylamidomethylcrotonate is obtained by mixing methyl methylacetoacetate and aniline in equivalent proportions, and allowing the mixture to remain for some days, or by dissolving methyl phenylamidocrotonate in benzene, and treating it first with sodium and then with methyl iodide.

Dimethylhydroxyquinoline, $C_9NH_4Me_2{\cdot}OH$ [$Me_2 : OH = 2' : 3' : 4'$], is obtained by quickly heating methyl phenylamidomethylcrotonate (30 grams) to 240°, withdrawing the source of heat as soon as the temperature reaches 260°, dissolving in dilute hydrochloric acid, treating the solution with animal charcoal, and rendering it faintly alkaline with ammonia or soda, when it separates as a white, crystalline mass; the yield is 10 grams. It crystallises from boiling water in lustrous prisms containing 1 mol. H_2O, sublimes at 300°, melts above 305°, and is only slightly soluble in alcohol; it has not a bitter

taste. The *platinochloride*, $(C_{11}H_{11}NO)_2,H_2PtCl_6 + 2H_2O$, forms long, orange-yellow needles.

Methylethylhydroxyquinoline, $C_9NH_4MeEt{\cdot}OH$, is produced in a similar manner to the dimethyl derivative, by heating methyl phenylamidoethylcrotonate; it melts at 290°, and is only sparingly soluble in boiling water and alcohol. A. R. L.

Action of Hydroxylamine on Ketonic Nitriles. By HANRIOT (*Bull. Soc. Chim.* [3], **5**, 773—779).—When ethyl α-cyanethyl ketone, COEt·CHMe·CN (Abstr., 1889, 841) (100 grams) is dissolved in concentrated potash (200 c.c.), a *potassium* compound is formed, which may be crystallised in brilliant plates; but if the solution is heated on the water-bath for half an hour with a solution of hydroxylamine hydrochloride (100 grams) in the minimum quantity of water, *amidomethylethylisoxazole*, $\begin{matrix}CMe{:}C(NH_2)\\ |\\ CEt{=\!=\!=}N\end{matrix}\!\!>O$, separates as an oily liquid, which, on purification, becomes crystalline. It forms highly refractive prisms, melts at 44°, and boils at 180° under a pressure of 20 mm.; at a higher temperature, it changes into an isomeric substance melting at 280°. It is soluble in the usual menstrua, with the exception of petroleum, and is not affected by alkalis. The *hydrochloride*, $C_6H_{10}N_2O,HCl$, crystallises in long needles, and is soluble in water and alcohol, but insoluble in ether. The *acetyl* derivative, $C_6H_9N_2OAc$, crystallises in colourless plates, melts at 161°, and is soluble in alcohol and acetone, sparingly soluble in water, and insoluble in ether.

When an ethereal solution of the isoxazole is saturated with bromine, a yellow, viscous mass is obtained, which is decomposed by water into ammonium chloride and *methylethylbromazolone*,

$$\begin{matrix}CMeBr{\cdot}CO\\ |\\ CEt{=\!=}N\end{matrix}\!\!>O,$$

a crystalline substance which melts at 41°, and dissolves in the usual menstrua. If, however, the bromination is effected in chloroform solution, a substance melting at 92° is obtained.

When the isoxazole is oxidised with nitrous acid (sodium nitrite and hydrochloric acid), yellow crystals of the corresponding azoxy-compound are obtained. *Azoxymethylethylisoxazole*,

$$\begin{matrix}CEt{\cdot}CMe & O & CMe{\cdot}CEt\\ \|\ \ \| & /\!\backslash & \|\ \ \|\\ N{\cdot}O{\cdot}C{-\!-}N & -N & -\!-C{\cdot}O{\cdot}N\end{matrix},$$

melts at 65—66°, and explodes at a somewhat higher temperature. It is soluble in alcohol, ether, and alkalis; the alkaline solution is red, and is decolorised by acids, the compound being reprecipitated. It does not unite with bromine.

When hydrogen sulphide is passed through an ammoniacal alcoholic solution of the azoxy-compound, the colour disappears, and on evaporation crystals of *hydrazomethylethylisoxyazole*,

$$\begin{matrix}CEt{\cdot}CMe & & CMe{\cdot}CEt\\ \|\ \ \| & & \|\ \ \|\\ N{\cdot}O{\cdot}C{-\!-}NH & -NH & -\!-C{\cdot}O{\cdot}N\end{matrix},$$

are deposited. When pure, it forms felted needles, melts at 150°, and dissolves in the usual menstrua. It is easily oxidised to the azoxy-compound, and forms an oily compound with bromine.

When ethyl α-cyanisopropyl ketone, $COEt\cdot CMe_2\cdot CN$ (*loc. cit.*), is treated with hydroxylamine hydrochloride, the ring condensation can no longer take place, as the hydrogen previously available for that purpose is replaced by methyl. Consequently, *ethyl α-cyan-isopropyl ketoxime*, $OH\cdot N{:}CEt\cdot CMe_2\cdot CN$, is obtained, instead of an isoxazole. It crystallises in plates, melts at 61—62°, and is soluble in the usual menstrua with the exception of petroleum. It differs from the isoxazole in that it forms a crystalline potassium derivative when treated with potash, that it does not unite with bromine, and that it is not oxidised with nitrous acid. Jn. W.

Methylphenyldihydroquinazoline and its Derivatives. By C. Paal and F. Krecke (*Ber.*, **24**, 3049—3058; compare Abstr., 1890, 1443).—After orthonitrobenzylacetanilide,

$$NO_2\cdot C_6H_4\cdot CH_2\cdot NPhAc\ (1:2),$$

has been reduced with tin and hydrochloric acid, and the stannochloride of methylphenyldihydroquinazoline, $C_6H_4<\begin{matrix}N=CMe\\ CH_2\cdot NPh\end{matrix}$, has been removed by crystallisation, there remains in the mother liquor a varying quantity, never exceeding one-third of the theoretical, of *orthamidobenzylacetanilide*, $NH_2\cdot C_6H_4\cdot NPhAc$. This substance is not formed when the reduction is carried out with zinc-dust and acetic acid. It can be obtained from the mother liquor by removing the tin with sulphuretted hydrogen, and extracting the filtered solution with ether, after previously making it alkaline. It crystallises from alcohol or water in lustrous, white prisms melting at 126—127°, and dissolving easily in alcohol, benzene, carbon bisulphide, ethyl acetate, and glacial acetic acid, moderately in ether, and sparingly in light petroleum and hot water. When oxidised with alkaline permanganate at 100°, it yields, besides a small quantity of azobenzene, a substance of undetermined constitution which crystallises from water in broad, yellowish needles melting at 178°, and from ethyl acetate in crossed crystals; this dissolves sparingly in benzene, easily in alcohol, ethyl acetate, glacial acetic acid, concentrated hydrochloric acid, alkalis, and alkaline carbonates.

Orthamidobenzylacetanilide hydrochloride, $C_{15}H_{16}N_2O,HCl$, is best obtained by adding a little concentrated sulphuric acid and ether to an alcoholic solution of the base. It crystallises in white needles, melts at 170°, and is readily soluble in water and alcohol. The *stannochloride*, $C_{15}H_{16}N_2O,HSnCl_3$, does not crystallise readily; it melts between 110—115°, and dissolves easily in water and alcohol. The *acid sulphate*, $C_{15}H_{16}N_2O,H_2SO_4$, crystallises in stellate groups of colourless needles, which become green on the surface when kept, melts at 163°, and dissolves readily in water. The *oxalate* and the *picrate* are both easily soluble in water and alcohol.

When the base is boiled for a short time with excess of acetic anhydride, and the product treated with a dilute solution of sodium

carbonate, *orthacetamidobenzylacetanilide*, $NHAc{\cdot}C_6H_4NPhAc$, separates. It crystallises from alcohol in four-sided plates, melts at 121°, and dissolves readily in most organic solvents and in dilute mineral acids, but very sparingly in water.

Methylphenyldihydroquinazoline, previously obtained by reducing orthonitrobenzylacetanilide with tin and hydrochloric acid, is better obtained by using zinc-dust and acetic acid, the solution being kept cool. The solution is then filtered from excess of zinc, and treated with excess of soda; the base is extracted with ether, and converted into the sparingly soluble hydrochloride, which is purified by crystallisation from water. It may also be obtained by distilling orthamidobenzylacetanilide, which loses water and gives almost a quantitative yield of methylphenyldihydroquinazoline. The *acid sulphate* $C_{15}H_{14}N_2,H_2SO_4 + H_2O$, obtained by adding sulphuric acid in slight excess and then some ether to an alcoholic solution of the base, crystallises from water in colourless, interwoven needles. It melts at 78°; when anhydrous, at 201°. When methylphenyldihydroquinazoline is oxidised with alkaline permanganate, the filtered solution contains *phenylketodihydroquinazolinecarboxylic acid*,

$$C_6H_4<\begin{matrix}N:C{\cdot}COOH\\ CO{\cdot}NPh\end{matrix}.$$

This can be separated as a crystalline precipitate by adding hydrochloric acid to the solution; when fresh, it is soluble in hydrochloric acid, alkalis, and alkaline carbonates, but it readily loses carbonic anhydride, yielding *phenylketodihydroquinazoline*, $C_6H_4<\begin{matrix}N:CH\\ CO{\cdot}NPh\end{matrix}$. The manganese precipitate contains *methylphenylketodihydroquinazoline*, $C_6H_4<\begin{matrix}N:CMe\\ CO{\cdot}NPh\end{matrix}$, which may be extracted with alcohol; it crystallises from that solvent in long, yellowish prisms, melts at 143°, and dissolves readily in ether, alcohol, benzene, and light petroleum, very sparingly in hot water. The *hydrochloride* forms bunches of white needles, melts at a very high temperature, and dissociates in water.

Methylphenyltetrahydroquinazoline, $C_6H_4<\begin{matrix}NH{\cdot}CHMe\\ CH_2{\cdot}NPh\end{matrix}$, was obtained by reducing a hot concentrated alcoholic solution of the dihydrocompound with sodium in large excess, and then diluting the mixture with water. It crystallises from dilute alcohol in broad needles, melts at 94—95°, and dissolves easily in most organic solvents and in mineral acids, but not in water. The *hydrochloride* and *oxalate* were prepared. When heated with acetic anhydride, it yields *acetylmethylphenyltetrahydroquinazoline*, $C_6H_4<\begin{matrix}NAc{\cdot}CHMe\\ CH_2{\cdot}NPh\end{matrix}$, which crystallises from dilute alcohol in colourless, rhomboidal plates, melts at 120·5°, and dissolves readily in the usual organic solvents. C. F. B.

Action of Hydriodic Acid on Quinine. Isoquinine. By E. Lippmann and F. Fleissner (*Monatsh.*, **12**, 327—337; compare Zorn,

Annalen, **8**, 201; Skraup, *J. pr. Chem.* [2], **8**: and Comstock and Koenigs, Abstr., 1887, 1122, and 1888, 71).—*Hydriodoquinine hydriodide*, $HIC_{20}H_{24}N_2O_2,2HI$, is obtained as a heavy, yellow, crystalline powder on warming quinine with hydriodic acid of sp. gr. 1·7—1·8. It is sparingly soluble in cold water; dissolves in hot water with partial decomposition; crystallises from hot alcohol in bright-yellow prisms, melts at 215—230° with decomposition, and, on treatment with dilute ammonia, gives the compound *hydriodoquinine*,

$$C_{20}H_{24}N_2O_2,HI.$$

This substance crystallises in slender needles, softens at 95°, and commences to melt at a higher temperature; gives silver iodide on heating with silver nitrate solution; is insoluble in water, dissolves in alcohol and in ether, and forms soluble salts with acids. *Hydriodoquinine platinochloride*, $HI,C_{20}H_{24}N_2O_2,H_2PtCl_6 + 2H_2O$, is obtained as a light-brown, crystalline precipitate on adding platinum chloride to a cold solution of hydriodoquinine hydriodide in hydrochloric acid.

Hydriodo-apoquinine is prepared by heating hydriodoquinine hydriodide with a solution of hydriodic acid, saturated at 0° for several hours under pressure at 100°. Methyl iodide is evolved, and, on cooling, the new compound, $HIC_{19}H_{22}N_2O_2,2HI$, separates as a yellow, crystalline mass, which, after recrystallisation from alcohol, commences to darken in colour at 120°, and melts with decomposition at 237°. On the addition of ammonia, 2 mols. of hydriodic acid are removed with formation of hydriodo-apoquinine, of which the platinochloride, $C_{19}H_{22}N_2O_2,HI,H_2PtCl_6 + H_2O$, is a heavy, brown, crystalline powder.

Iso-apoquinine, $C_{19}H_{22}N_2O_2$, is formed on warming hydriodo-apoquinine in alcoholic solution with potash. It melts at 176° (Hesse states that the compound decomposes at 160°), and dissolves readily in dilute potash; the *platinochloride*, $C_{19}H_{22}N_2O_2,H_2PtCl_6 + H_2O$, is a crystalline powder, only sparingly soluble in water.

Isoquinine.—This base is obtained when hydriodoquinine is boiled with alcoholic potash. After repeated crystallisations from ether and dilute alcohol, it melts at 186° (uncorr.). Hesse and Lenz have given the melting point as 174·4—175° and 170·4—174·4° respectively. The base is levorotatory, $[\alpha]_D = -186·75°$ being the rotation of an alcoholic solution containing 0·9644 gram in 100 c.c., and $[\alpha]_D = -180·8°$ for a solution containing 3·9936 grams in 100 c.c. Isoquinine crystallises in small needles containing 2 mols. H_2O; the *sulphate*, $[C_{20}H_{24}N_2O_2]_2,H_2SO_4 + 10H_2O$, forms characteristic groups of slender needles readily soluble in water, giving a ready means of distinguishing between the base and quinine. The *normal hydrochloride*, $C_{20}H_{24}N_2O_2,HCl + 2H_2O$, crystallises in needles, and is readily soluble in water; the *acid hydrochloride*, $C_{20}H_{24}N_2O_2,2HCl$, is not so easily soluble; the platinochloride may be obtained as a crystalline, yellow precipitate; and the compound with silver nitrate, $C_{20}H_{24}N_2O_2,AgNO_3$, is precipitated as a gelatinous mass on adding an alcoholic solution of the base to a solution of silver nitrate. G. T. M.

Compounds of the Cinchona Alkaloïds with Hydriodic Acid. By Z. H. Skraup (*Monatsh.*, **12**, 431—434).—Quinine, quinidine, cinchonidine, and cinchonine are all dissolved slowly by cold, and more quickly by warm, hydriodic acid, with the formation of yellow or orange-red coloured compounds, which contain 1 mol. of the base to 3 mols. of the acid; the quinine and quinidine solutions, if kept, further exchange methyl for hydrogen, giving compounds of the formula $C_{19}H_{22}N_2O_2(HI)_3$, which are readily soluble in caustic potash. All these substances crystallise well; they are almost insoluble in water, slightly soluble in absolute alcohol, and dissolve to a moderate extent in dilute alcohol, from which, with care, they may be recrystallised (compare Lippmann and Fleissner, preceding abstract). The compounds from isomeric alkaloïds differ in appearance, solubility, and melting point, and are analogous in composition to the corresponding compounds with hydrochloric and hydrobromic acids (compare Comstock and Koenigs, Abstr., 1887, 1122; and Zorn, *Annalen*, **8**, 20).

When the compounds $C_{20}H_{24}N_2O_2$,3HI and $C_{19}H_{22}N_2O$,3HI which are formed from quinine and cinchonidine respectively, are gently warmed with caustic alkalis, they lose 2 mols. of hydrogen iodide, and furnish the compounds $C_{20}H_{25}N_2O_2I$ and $C_{19}H_{23}N_2OI$ respectively. These are analogous in composition to the compounds with hydrochloric acid, which are obtained in a similar way (Comstock and Koenigs, *loc. cit.*). The compounds $C_{20}H_{24}N_2O_2$,3HI and $C_{19}H_{22}N_2O$,3HI, formed from quinidine and cinchonine respectively, lose only 1 mol. of hydrogen iodide when treated with excess of alkali, the bases $C_{20}H_{26}N_2O_2I_2$ and $C_{19}H_{24}N_2OI_2$, respectively, being produced. The mono- and di-iodine compounds are almost colourless, and must not be regarded as periodides, the hydrogen iodide evidently being held within the molecule. The compounds of the formula $C_{19}H_{22}N_2O_2$,3HI, obtained from quinine and quinidine, and which are soluble in potash, behave in a precisely similar way when treated with alkalis, the compound from the former base losing 2 mols. of hydriodic acid, whilst that from the latter loses only 1 mol. This different behaviour of the products of the action of hydriodic acid with potash forms a convenient means of distinguishing between the isomeric cinchona alkaloïds; and it is also remarkable that those alkaloïds which are decomposed in the same way have a similar effect on circularly polarised light.

Attempts to displace the iodine of the mono- and di-iodine compounds with alkyl groups or other radicles by heating with sodium ethoxide, potash, silver nitrate, &c., invariably led to the elimination of hydrogen iodide. The base $C_{19}H_{24}N_2OI_2$, obtained from cinchonine, however, gave, with sodium ethoxide, in addition to cinchonine, a small quantity of a base which was readily soluble in ether, refused to crystallise, and was probably isocinchonine. The quinidine compound $C_{20}H_{26}N_2O_2I_2$, on similar treatment, did not give the original base, but an isomeride, which is only slightly soluble, and gives salts which crystallise badly. The isomeric quinine compound behaves in an analogous way, but also gives some quinine; whilst the quinine

compound that is soluble in potash does not give rise to cupreïne, but forms an isomeride.

The compounds with hydriodic acid are easily reduced with zinc-dust, and the products appear to be different from those obtained by the reduction of the cinchona alkaloïds. They are semi-liquid, volatile in steam, and very rich in hydrogen.

Quinoline, paramethoxyquinoline, chitenine, and cinchotenine do not combine with hydriodic acid. The author therefore supposes that it is the $C_{10}H_{15}NO$ portion of the quinine molecule that attaches the hydriodic acid, but cannot explain the absorption of 2 mols. of hydrogen iodide, as, even if the oxygen were originally held to a carbon atom by a double bond, only one of the two molecules is accounted for. To explain the addition by assuming a molecular rearrangement of the quinoline nucleus is unsatisfactory, as the hydriodic acid is taken up at ordinary temperatures.

Full particulars of the compounds of the cinchona alkaloïds with hydriodic acid will be given in a future paper. G. T. M.

A new Alkaloïd from Chrysanthemum Flowers. By F. Marino Zuco (*Gazzetta*, **21**, 516—554).—The author has previously extracted from chrysanthemum flowers a new cholesterol (Abstr., 1890, 757), a glucoside, and an alkaloïd (*Rend. Acad. Lincei*, **6**, ii, 572; **7**, i, 121). The latter is prepared in quantity by boiling about 10 kilos. of the flowers in distilled water (3 parts) for 2 or 3 hours, filtering through cloth, pressing the residue, and treating it again in the same manner. The extracts are evaporated down to 30 litres, treated with neutral lead acetate and basic acetate of lead, neutralised with soda, filtered, and the excess of lead removed by passing sulphuretted hydrogen. After filtration, the liquid is concentrated to about 2 litres, boiled for some time with dilute sulphuric acid, filtered, and again boiled until no more resinous matters are formed. The liquid is then decolorised with animal black and an excess of the double iodide of potassium and bismuth added, when a heavy, bright-red, crystalline powder containing the whole of the alkaloïd is deposited.

The pure alkaloïd *chrysanthemine*, $C_{14}H_{28}N_2O_3$, is a colourless syrup which, when kept in a vacuum, partially crystallises in tufts of silky needles, and may be heated without decomposition to 100°, but not beyond that temperature. It dissolves in water forming alkaline solutions which absorb carbonic anhydride from the air; it is also soluble in ethyl and methyl alcohols, but not in ether, chloroform, or benzene. Salts of chrysanthemine yield, with the double iodide of potassium and bismuth, orange-red, flocculent precipitates which become crystalline and bright-red on agitation; with the double iodide of mercury and potassium, a yellowish-white precipitate; with the iodide of platinum and sodium, a brown precipitate; with auric trichloride, a yellow, crystalline precipitate which dissolves on heating and is redeposited on cooling; no precipitate is formed with platinic chloride, picric acid, tannin, or mercuric chloride. The base is optically inactive and physiologically innocuous. Its salts are for the most part soluble in water and even deliquescent; the aurochloride and the double iodide of bismuth and chrysanthemine are insoluble. It is a

biacid base, but in dilute solutions it behaves towards acids as if it were monacid. Both the *hydrochlorides* crystallise in small, colourless, deliquescent needles, very readily soluble in water and alcohol, but only moderately in hot water. The *aurochloride*,

$$C_{14}H_{30}N_2O_3Au_2Cl_8,$$

crystallises in minute, golden-yellow prisms very readily soluble in hot water and in absolute alcohol; when pure, it is not much affected by light. The *platinochloride*, $C_{14}H_{28}N_2O_3,H_2PtCl_6$, crystallises in orange-coloured prisms, and is extremely soluble in water.

On heating chrysanthemine with an excess of methyl iodide for two days at 100°, two methyl groups are taken up, and it is partly converted into a new base in which both nitrogen atoms are combined with hydrogen. The two bases can be separated by taking advantage of the great difference in the solubility of their platinochlorides in water. The *platinochloride* of the new base, $C_{16}H_{32}N_2O_3,H_2PtCl_6$, crystallises in small, orange-coloured needles, dissolves very sparingly in water, but moderately in hot water slightly acidified with hydrochloric acid; it is insoluble in absolute alcohol. The *hydrochloride* is a deliquescent compound which crystallises in a vacuum in tufts of small needles. It is freely soluble in water and in hot absolute alcohol. The free base is a syrupy liquid which becomes partially crystalline after being kept for a long time in a vacuum.

Oxychrysanthemine, $C_{14}H_{26}N_2O_4$, prepared by oxidising chrysanthemine with sodium hypobromite, yields a double iodide with bismuth, crystallising in orange-coloured needles readily soluble in hot water. The alkaloid is a syrupy liquid which, if kept in a vacuum, is slowly converted into a very deliquescent, crystalline mass. It has an acid reaction, but combines with both acids and alkalis. It forms two hydrochlorides: the *dihydrochloride* is a deliquescent, crystalline mass very soluble in absolute alcohol; the *monohydrochloride* is a colourless, crystalline mass composed of very slender, brilliant needles very soluble in water, but only sparingly in absolute alcohol. The *aurochloride*, $C_{14}H_{28}N_2O_4Au_2Cl_8$, crystallises in brilliant, golden-yellow, hexagonal laminæ freely soluble in hot water. Chrysanthemine strongly resists the action of oxidising agents; on heating a sulphuric acid solution of the base with potassium dichromate and sulphuric acid, it is almost quantitatively converted into oxychrysanthemine; a solution of potassium permanganate, on the other hand, only partially converts it into oxychrysanthemine, carbonic anhydride, ammonia, and traces of trimethylamine being evolved, whilst a portion of the base is completely broken up. Oxychrysanthemine is completely disintegrated by a hot solution of potassium permanganate. Dilute solutions of alkalis have no action on chrysanthemine even after prolonged boiling: very concentrated solutions decompose it into trimethylamine, γ-hydroxybutyric acid, and hexahydropiperidinecarboxylic acid with evolution of hydrogen according to the equation $C_{14}H_{28}N_2O_3 + 4KOH + H_2O = C_6H_{10}NO_2K + C_4H_7O_3K + NMe_3 + K_2CO_3 + 4H_2$. The hexahydropiperidinecarboxylic acid obtained in this way yields a very stable *aurochloride*, crystallising in golden-yellow scales very soluble in hot water, but only very sparingly in cold. It

melts at 150—151° without decomposition. The *hydrochloride* crystallises in plates, and melts at 184—185°. The acid corresponds, therefore, neither with Ost's pipecolinic acid (Abstr., 1883, 791) nor with Ladenburg's nipecotinic acid (Abstr., 1891, 735) but is probably a γ-piperidinecarboxylic acid (hexahydroisonicotinic acid). If chrysanthemine is treated with a moderately concentrated solution of potash, the decomposition takes place more slowly and a small quantity of a product intermediate between chrysanthemine and hexahydropyridinecarboxylic acid is obtained. This compound yields an *aurochloride*, $C_{11}H_{21}O_4NAuCl_3$, crystallising in tufts of reddish-yellow needles. Oxychrysanthemine is decomposed by very concentrated solutions of potash into hexahydropyridinecarboxylic and succinic acids, carbonic anhydride, trimethylamine, and hydrogen. Fuming hydrochloric acid has no action on chrysanthemine even after prolonged heating; concentrated sulphuric acid merely resinifies a very small proportion on boiling. A glacial acetic acid solution of chrysanthemine (1 mol.) dissolves iodine (10 atoms), and on distilling off the solvent in a vacuum, a brown oil is left which does not lose iodine on heating at 150°. Chrysanthemine may be boiled with water for days without change; if, however, a solution of the base in an equal weight of water is fractionally distilled, water alone passes over until the temperature exceeds 150°; trimethylamine then begins to come off, and continues to do so until the temperature reaches 200°, when an oily product accompanies it. If the apparatus is now exhausted, the residue distils over between 200° and 230°, the distillate consisting of a mixture of aqueous solutions of hexahydropyridinecarboxylic acid, amyl glycol, dihydroxyamylpiperidine, trimethylamine, and traces of pyridine bases. The amyl glycol is separated from the mixture in the form of *benzoate*, $C_5H_{10}(OBz)_2$, a colourless, crystalline powder melting at 40°; the hexahydropyridinecarboxylic acid is then removed as aurochloride, and the residue contains *dihydroxyamylpiperidine aurochloride*, $C_{10}H_{21}O_2NAuCl_3$, a yellow, crystalline salt which readily loses a molecule of hydrogen chloride and decomposes at 100°.

From a consideration of all the above reactions, the author arrives at the conclusion that the structure of chrysanthemine is best represented by the formula $\begin{matrix} NMe_3\cdot CH_2\cdot CMe\cdot CH_2\cdot CH_2\cdot OH \\ | \qquad\qquad\quad | \\ O-CO-C_5NH_9 \end{matrix}$.

A new Albumin from Protoplasm. By W. Demme (*Chem. Centr.*, 1891, ii, 257; from *Centr. med. Wiss.*, 1891, 483).—*Cytoglobin*, obtained from the lymphatics, liver, spleen, &c., by pressing, extracting the deposit with alcohol, dissolving the residue in water, and reprecipitating with absolute alcohol, is readily soluble in water, is reprecipitated without coagulation from this solution by absolute alcohol, and may be again dissolved in water. It decomposes hydrogen peroxide. Addition of a mineral acid to the aqueous solution converts it into an albumin, *præglobulin*, which is insoluble in water, and into a substance soluble in water; the same change being effected by heating to boiling. Cytoglobin and præglobulin are but

little soluble in the gastric juice, and still less so in the pancreatic juice. Cytoglobin contains: carbon, 52·4; hydrogen, 6·9; nitrogen, 16·7; sulphur, 3·5; and phosphorus, 4·5 per cent.; præglobulin: carbon, 51·4; hydrogen, 7·6; nitrogen, 23·9; sulphur, 3·4; phosphorus, 3·7 per cent. J. W. L.

Physiological Chemistry.

Influence of Wine on Peptic Digestion. By L. Hugounenq (*Bull. Soc. Chim.* [3], 5, 849—855).—Fibrin was digested with dilute hydrochloric acid in the presence of various colouring matters and wines. It was found that peptic digestion is considerably hindered by colouring matters, whether occurring naturally in the wine, or added fraudulently, and in the latter case, whether artificial, such as magenta, azoflavine, and methylene blue, or natural, such as the colouring matters of elder and mallow. Plastered wine was found to exercise a less injurious influence than wine containing the full amount of tartrates. Jn. W.

Coagulation of the Blood. By C. A. Pekelharing (*Virchow's Festschrift*, 1891, Bd. 1).—Recently, a number of observations on the importance of calcium salts in the process of blood coagulation have been published.

Brücke first showed that the ash of fibrin always contains calcium. In 1875, Hammarsten found that calcium chloride can take the place of serum globulin in fibrin formation. In 1887, Green (Abstr., 1888, 306) found that in magnesium sulphate plasma, and also in other forms of plasma, coagulation is hastened if small quantities of calcium sulphate is added in addition to fibrin ferment. Later, Ringer and Sainsbury (Abstr., 1890, 1176) found that this result can be brought about by other calcium salts, such as the chloride, and also, but not so readily, by means of soluble strontium and barium salts. Freund (*Med. Jahrb.*, 1888, 259) who also noted the hastening of coagulation by calcium salts, considered that the blood corpuscles, as soon as the blood is shed, yield alkaline phosphates to the plasma; meeting with the calcium salts there, tricalcium phosphate is precipitated, and herein lies the cause of fibrin formation. Latschenberger (*Med. Jahrb.*, 1888, 479), and von Strauch (*Dissert. Dorpat*, 1889) showed certain fallacies in this hypothesis; thus the addition of alkaline phosphates and calcium salts resulting in the precipitation of tricalcium phosphate does not always lead to the formation of fibrin in fibrinogenous liquids; also the first portions of fibrin formed were found to contain calcium, but no phosphoric acid, and further, in the present research, it is shown that injection of disodium phosphate into the circulation of a living animal is not followed by thrombosis.

Arthus and Pagès (*Arch. de Physiol.*, 1890, No. 4) found that blood coagulation may be entirely prevented if, immediately on being shed, the blood is mixed with small quantities of substances, like oxalates

or fluorides, which precipitate calcium salts as very insoluble compounds. On adding to the plasma obtained from this blood a slight excess of calcium chloride, coagulation immediately ensues. Fibrin ferment is, however, essential for the process; and the action of this agent is considered to be the bringing together of fibrinogen and the calcium compound, and thus the formation of fibrin. In this, they draw a close analogy between fibrin formation and the formation of caseïn in milk under the influence of the rennet ferment. Green attempted to answer the question, Does the fibrin ferment exist as zymogen in the plasma, and is such zymogen converted into the ferment by the action of the calcium salt? He was unable to find a positive answer; and therefore considered that the calcium acts in assisting the ferment much as hydrochloric acid in the gastric juice favours the activity of pepsin. This question is again taken up in the present investigation, and it was found possible to prepare from plasma (such as oxalate plasma which contains no ferment) a globulin which has no fibrinoplastic properties, which, however, after contact with calcium chloride, is converted into the ferment. The zymogen yields an ash containing little or no calcium, whilst the ferment is rich in calcium. The material in question arises from the formed elements of the blood, and is identical with what is called cell-globulin by Halliburton (Abstr., 1888, 974).

Fibrin, moreover, is a calcium compound, and the main action of the ferment appears to be to transfer the calcium to the fibrinogen.

Granting this hypothesis, it is possible to explain several facts hitherto but little understood in connection with blood coagulation, and to reconcile certain conflicting theories. The action of oxalates in hindering coagulation is explained on the supposition that the precipitate of calcium oxalate, on account of its insolubility, is not available for the conversion of zymogen into ferment. The action of neutral salts in restraining clotting is explained on the assumption that the ferment is a globulin, and, although the amount of salt added is not sufficient to precipitate the globulin, yet it is sufficient to lessen those intramolecular movements which, in the end, produce its specific action.

The action of peptone in hindering coagulation can be explained by the affinity between peptone and calcium compounds. It thus prevents these from converting the zymogen into the ferment. This view is supported by the fact that other substances, like soaps, which combine with calcium compounds, produce similar symptoms to those set up by peptone (Munk). Thus, there is loss of coagulability of the blood, low blood pressure, suppression of secretions, and even death. The toxic effects appear to be due to the removal of calcium salts, which are necessary, as Ringer has shown, for all vital processes. A further support to the theory is obtained from the fact that injection into the circulation of calcium chloride simultaneously with the peptone, or after the peptone, obviates the poisonous effects of the latter; peptone is then no longer capable of rendering the blood uncoagulable. Peptone also restrains coagulation in intravascular plasma (or solutions of Hammarsten's fibrinogen), provided that it is added so rapidly that the zymogen has not had time to combine with

the calcium to form the ferment. After the ferment has been once formed in the plasma, or added to the solution of fibrinogen, peptone has no longer any hindering influence on coagulation.

Wooldridge's tissue fibrinogens appear to consist of proteïd, nucleïn, and lecithin. They contain no fibrin ferment until they have been digested for some time with a little calcium chloride; it is, therefore, considered that they contain the zymogen of fibrin ferment, and their action in producing intravascular coagulation is explicable on the theory that, in the blood, they come into contact with calcium compounds, so that the zymogen is then converted into the ferment.

W. D. H.

Hematic Glycolysis. Estimation of Glycogen in the Blood. By R. Lépine and Barral (*Compt. rend.*, **112**, 1414—1416).—The sugar present in the blood of a starving dog was estimated after destroying the glycolytic ferment at 90°. Four portions of the same blood were maintained at 39° for 15, 30, 45, and 60 minutes respectively.

Taking the initial sugar at 100, the sugar present at each interval would be represented by 88, 81, 76, and 72, indicating losses for each successive 15 minutes of 12, 7, 5, and 4 respectively. Treating the blood of a well-nourished dog in the same manner, the loss of sugar for the first 15 minutes was hardly measurable. There is frequently an augmentation of the quantity of sugar present after the first 15 minutes; this is more frequently the case with serum. The glycolytic ferment is contained in the white corpuscles and not in the serum. Sugar is doubtless produced at the expense of the glycogenic matter. To estimate the amount thus formed, blood is raised to 58° to destroy the glycolytic ferment and the sugar titrated as above, yielding for successive periods of 15 minutes, a gain of 18, 2, 0, and 0 respectively. The addition of saliva to the blood did not increase the gain.

The glycolytic power of the blood of a starving dog is given by deducting the quantity of sugar obtained after an hour at 39° from the initial quantity, the apparent power only is given for the blood of a well-fed dog; to obtain the real power in the latter case, it is necessary to add the quantity of sugar produced during the same time to the apparent glycolytic power. At 58°, the transformation of glycogen into sugar is rapid; after an hour at this temperature, the whole of the glycogen of the blood may be estimated as sugar.

W. T.

Mechanism of the Production of Urea in the Animal Organism. By Popoff (*Bull. Soc. Chem.* [3], **5**, 551—554).—To determine whether the transformation of ammonium salts into urea is effected by an unorganised ferment, or by the living cell, portions of liver, spleen, and kidney, removed from recently-killed dogs and guinea-pigs, were digested, with antiseptic precautions, for many hours with warm, dilute (0·5—1·0 per cent.), sterilised solutions of various ammonium salts. In no case was any trace of urea formed. The author concludes, therefore, that the formation of urea from

ammonium salts is due to the direct action of the living cells of the various organs, and not to that of soluble ferments secreted by them.

Jn. W.

The Action of Azoimide on Living Organisms. By O. Loew (*Ber.*, **24**, 2947—2953).—Experiments were made to test the action of azoimide (N_3H) on living plants and animals. Sodium azoimide was found to be a powerful poison in all cases; seedlings died in about three days if attempts were made to grow them in a nutritive fluid containing 0·1 per cent. of the poison. Algæ were not affected so readily, but did not grow. Bacteria were killed, and thus the material in question acts as an antiseptic. Experiments with yeast, penicillium, and other fungi were entirely confirmatory of the above. To animal life, as tested on infusiorians, various invertebrates, and mammals (mice and rabbits) this substance is equally inimical. There is, first, loss of movement, preceded in mammals by muscular twitchings and finally death.

The imide is thus not available as a nitrogenous food; and the cause of its toxicity is considered to be its sudden decomposition when it comes into relation with the cells and the aldehyde containing radicles of proteïd within them. This, occurring within the nerve cells, produces first, stimulation, hence the spasmodic movements, and then kills them. Probably the decomposition that occurs, may be represented thus, $N_3H + H_2O = N_2O + NH_3$. It certainly yields ammonia when acted on by platinum black. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

A Bacterium which Ferments Starch and Produces Amyl Alcohol. By L. Perdrix (*Chem. Centr.*, 1891, ii, 252—253; from *Ann. Inst. Pasteur*, 1891, No. 5).—The author has separated from Paris water a bacillus, *B. amylozymicus*, which ferments starch, with production of amyl alcohol. It is separated by cultivation on potatoes, and finally on gelatin. The bacillus is 2—3 μ long, and 0·5 μ thick; the rods are joined in pairs and chains, and in the absence of oxygen are motile, like *Vibrio butyricus*, Pasteur. The rods are readily stained; the spores are set free through the dissolution of the walls of the mother cell. The bacillus flourishes only in the absence of oxygen, readily, however, either in a vacuum or in hydrogen, nitrogen, or carbonic anhydride. The optimum temperature is 35°; it grows quite well at 20—25°; at 16—17°, fermentation commences at the end of four days. Its "maximum" temperature is 42—43°. It will grow in all the usual cultivating media, ferments the sugars and starch, but does not attack cellulose or calcium lactate, differing in this respect from *Vibrio butyricus*, Pasteur. Acids are produced during the fermentations which it causes, and the presence of acidity, equivalent to 0·055 gram sulphuric anhydride, or of

alkali equivalent to 0·08—0·11 gram in 100 c.c., is sufficient to arrest the process; the addition of calcium carbonate to the liquid enables the fermentation to become perfect. Glucose ferments to hydrogen, carbonic anhydride, acetic and butyric acids during the first three days; from the third to the ninth day, no acetic acid is formed. From saccharose and lactose, acetic acid is formed during the first five days. The greater the amount of oxygen present, the more acetic acid is produced; it was also observed that at the time of the butyric acid formation, all the cells contained spores. From the fermentation of starch a distillate was obtained, of which one-third was amyl alcohol, and from 100 grams of potatoes, 2·3—2·5 c.c. of alcohols were separated. The sugar obtained from starch is very similar to glucose, but has a less rotatory action, and its phenylglucosazone melts 10° lower than that from glucose; 94 per cent. of the starch is converted into sugar, carbonic anhydride, ethyl and amyl alcohols, acetic and butyric acids, and 6 per cent. is converted into dextrin. The sugar formed by the bacillus from starch may be fermented perfectly with beer-yeast, either after sterilisation, or in the presence of the bacillus. If either the sugar obtained by fermentation of starch with this bacillus, or a sterilised mash, be fermented with a pure cultivation of yeast, no fusel oil is formed, and the author concludes that the fusel oil found in commercially prepared alcohol, is formed by the action of bacteria. The *B. amylozymicus* remains uninjured for 10 days at 50—55°. J. W. L.

Action of the Bacillus of Malignant Œdema on Carbohydrates, and on Lactic Acid. By R. Kerry and S. Fraenkel (*Monatsh.*, **12**, 350—355; compare Abstr., 1890, 1454).—When lactic acid, in the form of its calcium salt, is dissolved in bouillon containing peptone and Kemmerich's meat extract, and the solution, placed in an atmosphere of hydrogen, is inoculated with the bacillus of malignant œdema, fermentation occurs. After remaining 8—10 days, the solution contains propyl alcohol and formic and butyric acids, but no ethyl alcohol.

Milk sugar, cane sugar, and starch, in presence of substances containing the materials necessary for building up the organism, are all fermentable by the bacillus, and yield variable quantities of butyric, formic, and inactive lactic acids, and ethyl alcohol. The formation of the last-named product on long-continued anaërobic fermentation of the carbohydrates is most probably to be ascribed to a further change induced in the propyl alcohol derived from the lactic acid.

The authors have succeeded in fermenting the wood pulp obtained from fir, and have recognised the presence of volatile alcohols and fixed acids in the product; all attempts to induce decomposition in pure cellulose have, however, led to negative results. G. T. M.

Influence of Carbohydrates on the Accumulation of Asparagine in Plants. By Monteverde (*Ann. Agron.*, **17**, 376—377).—Branches of lilac, plunged in distilled water, and in 4 per cent. solution of glycerol, and kept in the dark, contained abundance of asparagine at the end of 15 days, but neither starch nor mannitol. Branches of

the same plant kept in solutions of glucose, cane sugar, or mannitol formed no asparagine in a month, but contained much starch and mannitol. Peas, vetches, and monkshood, which do not stand the dark well, were kept in the light in an atmosphere deprived of carbonic anhydride; when plunged in solutions of glucose or cane sugar, they were completely deprived of asparagine in 10 days.

J. M. H. M.

Diastase. By G. Krabbe (*Ann. Agron.*, **17**, 381).—The author believes that diastase attacks the starch of malt, not by gradual percolation through the entire mass, but by local action. Diastase is not dialysable, and the author considers its particles to consist of groups of molecules, and chains of groups too large to pass from one cell to another; it will not even traverse biscuit ware. J. M. H. M.

Quantity of Starch in the Tubercles of the Radish. By P. Lesage (*Compt. rend.*, **113**, 373—375).—The radish contains little or no starch, even when examined in different degrees of development. If watered with solutions of sodium chloride containing 1 to 20 grams per litre, starch appears in the endoderm, and also in some cases in the cortical parenchyma. The results were as follows:—No starch with pure water or water containing 1, 2, or 20 grams of salt per litre; very little starch with 3 and 5 grams per litre; a little starch with 10 grams per litre; a considerable quantity with 4 grams per litre; 20 grams of salt per litre kills the plant. In other cases the maximum amount of starch was found with proportions of salt amounting to 5 grams and 10 grams per litre. C. H. B.

Oil of Lime Seed. By C. Mueller (*Ann. Agron.*, **17**, 431—432).—The seeds of *Tilia phatyphylla*, or *grandifolia*; *T. ulmifolia*, or *parvifolia*; and *T. intermedia*, contain little starch, and about 58 per cent. of oil. It is a yellow, bland oil, resembling the best olive oil, not bitter or aromatic, and non-drying. It does not become rancid, or resinify on exposure to air. Mixed with sulphuric acid, the liquid becomes deep brown-red, and the rise in temperature is considerable. The oil solidifies under the action of nitric acid and mercury. Its soda soap crystallises from alcohol in long, yellow needles. The oil does not solidify at −21·5°. J. M. H. M.

Earth-nut Meal. By A. Emmerling (*Bied. Centr.*, **20**, 606—607).—The author has already called attention to the adulteration of food with the husks of earth-nuts. Attempts are now being made to introduce the latter, in the form of meal, as a food. The commercial product is a dirty-yellow powder with a slightly bitter taste, and contains sand. It is prepared from the outer covering of the earth-nut, but contains portions of the skin of the seeds. The analysis of six samples gave the following results:—

	Water.	Ash.	Crude proteïn.	Crude fibre.	Carbohydrates.	Crude fat.
Minimum..	7·26	3·83	7 64	48·87	15·88	3·46
Average ..	7·95	10·15	8·23	53·66	16·33	4·11
Maximum .	8·58	14·31	8·97	58·96	16 85	5·65

The digestibility of the proteïds was determined in two samples :—

Total proteïds, per cent.	Digestibility, per cent.	Coefficient of digestibility, per cent.
7·87	4·20	53·3
8·66	4·01	46·3

The name given to the meal is misleading, as it denotes the skin of the seed, whereas it is prepared mainly from the outer covering, the nutritive value and digestibility of which is less than that of the skin. N. H. M.

Behaviour of Strontium Tartrate with Plastered Wines. By M. Spica (*Gazzetta*, **21**, ii, 12—19).—When a wine is plastered or treated with plaster of Paris in order to preserve it, a certain amount of potassium sulphate goes into solution and may be deleterious to the health of the consumer.

Dreyfus (*Mon. vinicole*, 1890, 66) has described a method for the removal of the potassium sulphate, which consists in treating the wine with strontium tartrate. The author gives complete analyses of three samples of wines both before and after treatment with strontium tartrate, which show that the quantity of potassium sulphate is not sufficiently reduced, as from a third to a half of the salt originally present remains in the wine. The quantity of hydrogen potassium tartrate in solution is increased from less than 1 gram to between 2 and 3 grams per litre. The amount of free tartaric acid is considerably diminished, but the total acidity notably increases and the weight of ash is diminished to about one-half, whilst a quantity of strontium hydrogen tartrate varying from half a gram to more than 1 gram per litre goes into solution and may be injurious to health. The wine is also rendered somewhat insipid by the treatment.

W. J. P.

Presence of Boric Acid in Products of the Soil. By A. Gassend (*Ann. Agron.*, **17**, 352—354).—Having had his attention directed to certain samples of wine by the Custom House authorities, the author has examined a great number of samples of French, Greek, Italian, Spanish, Algerian, and Corsican wines, and finds boric acid to be a normal constituent of them all, in the proportion of 5—10 milligrams per litre. In this proportion the ash of 10 c.c. of wine will not give the green flame with alcohol and sulphuric acid, but the boric acid is easily recognised by the turmeric paper test and by the spectroscope. When the spectroscope is employed, the ash should be moistened with 10 drops of pure hydrofluosilicic acid. The author finds similar traces of boric acid in grapes, apples, potatoes, radishes, lettuce, and in some pears, not in all. He does not find it in tea, saffron, or cow's milk. Hotter also has found boric acid in some plants. J. M. H. M.

Action of Lime as a Manure, with special regard to Paddy Fields. By O. Kellner, H. Sakano, D. Sato, and S. Shinjo (*Imp.*

Univ. Coll. Agric. Tokyo Bull., **9**, 1891, 1—25).—The excessive amount of lime (11360 kilos. per hectare) applied to rice in the paddy fields in many districts of Japan causes injury to the soil and crops. The mineral constituents of the soil are liable to become cemented together, either at the surface or a few feet below, rendering the treatment and cultivation of the soil difficult for this reason, as well as owing to the consequent stagnation of water on it. Potash and ammonia are, moreover, liberated from the soil and are liable to be washed away by the irrigating water; in fact, complete infertility from over-liming has occurred in several parts. Besides the injurious effect on the soil, both physically and from loss of valuable constituents, the crop itself suffers, the stems becoming more fragile and the grain acquiring an inferior taste and lustre, and becoming lighter. An examination of several samples of hulled rice (all exceedingly brittle) from different soils showed no great difference in composition from ordinary hulled rice, grown without lime; but it proved to be somewhat poor in crude proteïds. This result was unexpected, as it was thought that something in the composition of the seed, as in the amount of carbohydrates, would throw some light on the action of lime. Lower percentage of proteïds has already been thought to be the reason of the glassy condition of barley and wheat, but this has never been known to arise from over-liming. Experiments made to ascertain the relation of the hardness of the grain to the percentage of crude proteïn in the dry matter showed that the proportion of nitrogenous compounds plays an important part in the resistibility of rice grains to pressure or impact. The brittleness caused by over-liming, is due to the destruction of nitrogenous matter in the soil by the lime. The mealy condition of the rice may be diminished by early cutting. The liming of over-limed fields should be stopped and large amounts of nitrogenous manure applied for the first year to compensate for the loss of nitrogen; and the manures should be thoroughly fermented before being mixed with the soil. Paddy rice prefers ammonia as nitrogenous food, and does not thrive well, as long as it is irrigated, if supplied with nitrates alone.

In order to investigate the action of lime on soils, experiments were made in which several kilograms of dry and paddy earth, after being dried and mixed, were treated with slaked lime and kept in closed bottles. The dry land soil (containing 200 grams of dry matter) was previously mixed with air-dry soy beans (containing 10 grams of dry matter) and 50 c.c. of water. The paddy soil was similarly treated, but had 300 c.c. of water. The amount of lime added corresponded with 10 grams of CaO. The results, which are given in tables, show that lime accelerates the decomposition of organic matter in both dry-land and irrigated soils, and that the action is much greater in dry land than in irrigated land. Thus, whilst the dry-land soil lost, in six weeks, 13·58 per cent. of its organic matter, the paddy soil lost only 5·85 per cent.; the same soils, but without the addition of lime, lost respectively 3·24 and 2·21 per cent. of their organic matter.

Experiments are next described which were made on the formation of nitric acid and ammonia from nitrogenous manures in dry-land and

paddy soils. The percentage composition of the partly dried soils was as follows :—

	Hygroscopic water.	Humus and combined water.	Total nitrogen.	Nitric acid.	Ammonia.	Organic nitrogen.
Dry-land soil..	41·12	14·06	0·231	0·098	0·009	0·198
Paddy soil	42·12	21·61	0·455	0·048	0·024	0·418

Glass jars were filled with the soils (1400—1600 grams), which were only so far dried as not to destroy the micro-organisms contained in them. The soils were manured with ammonium sulphate, fish manure, and in some cases with calcium carbonate, and the jars then taken to the respective fields, where they were let into the ground; the paddy soil was watered with distilled water, the level of which was kept about 2 cm. above the surface of the soil. It was found that in dry-land soil the nitrogenous manures were quickly converted into nitric acid, whilst nitrification did not take place in the irrigated paddy soil, in which ammonia seems to be among the principal products of the decomposition of the nitrogenous organic manure. The application of lime distinctly favours, on the one hand, nitrification in the dry land, and, on the other hand, the formation of ammonia in the paddy soil. The fact that nitrification does not take place in paddy soils was observed by Kellner and Sawano in 1882 (Abstr., 1884, 674; compare Baumann, Abstr., 1887, 82, and Muntz, Abstr., 1890, 1183). Many organic and inorganic constituents of soils have the power of retaining ammonia, and protect it very well from being washed away, but lime (as oxide or hydroxide) will disperse the ammonia, and may thus give rise to considerable loss of nitrogen.

The action of lime on the phosphates in the two soils was next investigated. The first soil was taken from the surface of the paddy field; the other was from the subsoil of a dry-land field. Bottles were filled with the soils (10 grams each) containing 0·0, 0 25, 0·5, 1·0, 2·5, and 5·0 per cent. of quicklime. Each bottle received 20 c.c. of water, and two weeks later a solution of potassium dihydrogen phosphate (containing 0·05 gram of phosphoric acid) was added to each bottle. The first set of soils examined one month after the application of the phosphate showed that in the paddy soil only 12·7 per cent. of the phosphoric acid remained in the soluble form, and that the addition of lime was decidedly beneficial, the maximum effect being obtained with an application of 1 to 2·5 per cent., the amount of soluble phosphate being in both these cases 22·6 per cent. of the total phosphate added. After two months, there was still more soluble phosphate (27·2 per cent.) in the soil which had 2·5 per cent. of lime. This slight after-effect is attributed to the action of calcium hydrogen carbonate on ferric phosphate, converting a part of it into free ferric hydroxide and calcium phosphate. This view is verified by direct experiments with ferric phosphate and lime-water saturated with carbonic anhydride.

The beneficial effect of lime was not observed in the case of the dry-field subsoil, and inasmuch as the two soils have the same geological origin there is no doubt that the humus of the paddy soil

played an important part in bringing about the action of lime on superphosphates.

With regard to the frequent application of large amounts of lime it is shown that the exhaustive action of lime is not confined to nitrogen and potash but also favours the consumption of the phosphatic ingredients of the soil by the crops. N. H. M.

The Value of Animal Débris as Nitrogenous Dressing. By A. Müntz and A. C. Girard (*Compt. rend.*, **112**, 1458—1460).—Nitrogenous materials require that their nitrogen be transformed into the state of nitrate before plants can avail themselves of them as aliment. Hence the aptitude of organic manures to undergo nitrification under the influence of organisms present in the soil may be taken as a measure of their activity as dressings. No practical value can be assigned to the ordinary laboratory methods of comparing the relative values of animal manures.

A number of substances have been compared by the authors by ascertaining the proportion of nitrate formed in a given time by introducing quantities of the substances containing an equivalent amount of nitrogen into a nitrifying soil and maintaining the same conditions in each case.

Commercial manures may be divided into three classes: the first, undergoing nitrification rapidly, comprises dried blood, dried flesh, horn refuse, and guano; these substances are nearly as active, and have nearly the same effect on the crop, as the mineral manures. sodium nitrate and ammonium sulphate; the second comprises burnt leather. woollen waste, and dried night soil, of which the nitrification is slower; these consequently do not give their whole effect in one season. but have some influence on the following crop; the third includes unburnt leather waste, the nitrification of which is so slow that the yield of the crop is not sensibly augmented.

This classification has been confirmed by careful practical agricultural experiments. With manures of the first class, 60 per cent. of the nitrogen has been utilised in two years; with those of the second class, 40 per cent.; and with that in the third class, 20 per cent. only. The unburnt leather refuse should only be used in compost heaps, as its nitrification proceeds too slowly for it to be directly available for the crops.

The unit of weight of nitrogen often costs more when purchased as organic manure than when obtained as saline manures; it would be more logical to pay the higher price for it in the latter case, as it could then be immediately utilised, and its application regulated according to the needs of the crops. W. T.

Analytical Chemistry.

Estimation of Hydrochloric Acid in the Gastric Juice. By J. Boas (*Chem. Centr.*, 1891, ii, 357; from *Centr. med. Wiss.*, 1891, 509).—The author has adopted Bourget's method (evaporation and incineration with barium carbonate, extraction with water, and precipitation of the barium chloride formed by sodium carbonate), with the slight modification that, after dissolving the precipitate in decinormal acid, the liquid is boiled until all carbonic anhydride is expelled, and the excess of acid is then neutralised with decinormal alkali; the indicator is phenolphthaleïn. J. W. L.

Estimation of Free Oxygen by means of Nitric Oxide. By L. L. de Koninck (*Zeit. ang. Chem.*, 1891, 78—80).—The author's attention was drawn to an article by Wanklyn and Cooper on the estimation of oxygen by means of nitric oxide. These chemists consider that this process, which was originated by Priestley, but which now only possesses an historical interest, is not only very accurate but even one of the best methods known, and they communicated a few satisfactory test analyses. The author some time ago had occasion to try the process, but his experience agreed with the results obtained by Berthelot, Lunge, and Winkler, which were very irregular and unsatisfactory. He therefore thought it advisable to once more thoroughly investigate the matter.

The *modus operandi* was practically identical with that employed by Wanklyn and Cooper, except, perhaps, as regards the preparation of the nitric oxide, which was obtained by the action of nitric acid (sp. gr. 1·1) on a spiral of sheet-copper contained in an old-fashioned Hempel's hydrogen pipette. On account of its simplicity and easy execution, the following plan was adopted :—The gas (oxygen or air) was introduced into a Winkler-Hempel burette, the nitric oxide introduced into a like apparatus, and thoroughly shaken with the water to saturate this with the gas, and also to remove traces of nitric peroxide. After a few minutes rest, the two volumes of gas were respectively recorded, and after connecting the two burettes with a capillary tube filled with water, the oxygen mixture was forced into the nitric oxide (not the reverse way), and the burettes were now disconnected. After thoroughly shaking to facilitate the absorption, and waiting for twelve or fifteen minutes, the volume of the gas was read off with the usual precautions, and the contraction noted. The results obtained once more proved the process to be absolutely useless, as the quantity of oxygen found varied between 77·5 and 122·5 per cent. of the amount operated on. From a scientific point of view, however, the results were not uninteresting.

The ratio between the volume of the oxygen and the contraction after the action of the nitric oxide may theoretically vary between 1 : 2·33 and 1 : 5, as shown by the following equations :—

$4NO + 3O_2 + 2H_2O = 4HNO$; ratio, 1 : 2·33,
$2NO + O_2 + H_2O = HNO_2 + HON_3$; „ 1 : 3,
$4NO + 2O_2 + H_2O = 4HNO$ „ 1 : 5.

A good deal depends on the celerity with which the gases have been mixed and shaken with the water. As a rule, a large excess of nitric oxide or admixture with an inert gas, such as nitrogen, seems to favour the formation of nitrous acid. L. DE K.

Estimation of Free Oxygen dissolved in Water. By W. KISCH (*Zeit. ang. Chem.*, 1891, 105—108).—The author compared the various processes in use for the estimation of free oxygen in water. (*a.*) Bunsen-Tiemann's process.—The water is boiled, and the gases collected over hot solution of caustic potash. The oxygen is then estimated by explosion with hydrogen or by absorption with alkaline pyrogallol. (*b.*) Mohr's process.—The sample is mixed with an acid solution of ferrous sulphate of known strength, then with aqueous soda to throw down the ferrous hydroxide. After remaining for a few hours (air, of course, being rigidly excluded), the precipitate is redissolved in sulphuric acid, and the ferrous sulphate titrated with permanganate. (*c.*) The Schützenberger-Risler process.—The water is allowed to act on a solution of sodium hydrindigotindisulphonate, which then passes into the blue compound. Standard solution of sodium hyposulphite is then run in till the liquid is again decolorised. (*d.*) Winkler's process.—The water is mixed with a solution of manganous chloride, and then with potassium iodide and potassium hydroxide. The precipitated manganous hydroxide rapidly absorbs the oxygen, and passes into a higher oxidised state. On adding hydrochloric acid, iodine is liberated, which is then estimated by a solution of sodium thiosulphate. On applying these processes to the same sample of water, the results obtained by Bunsen-Tiemann's process were decidedly lower than those obtained by Winkler's process, whilst those obtained by both Mohr's and the Schützenberger-Risler methods corresponded very well with Winkler's figures. The author, however, strongly recommends the latter process as being the safest, most trustworthy, and the easiest in manipulation. L. DE K.

Schützenberger's Process for the Estimation of Free Oxygen. By T. KÖNIG (*Zeit. ang. Chem.*, 1891, **108**, 110).—The author, not always getting satisfactory results with this process, investigated the cause. Success depends in a great measure on the quality of the indigo solution employed. If the sample is poor in quality, it does not absorb the oxygen rapidly enough, and a portion of this is swept away by the current of hydrogen. Indigo-carmine is obtained by precipitating a solution of purified indigo in sulphuric acid with salt. If simply collected, a pasty mass is obtained which forms the commercial indigo-carmine; but, if well washed and dried, solid sodium indigodisulphonate is obtained. These preparations vary, however, considerably in strength, sometimes from 79·08 to 91·58 per cent. in the so-called crystallised and sublimed product, whilst other

samples varied in strength from 9·41 to 72·42 per cent. It is no use to increase the quantity of indigo solution when dealing with poor samples. The colour will generally be very dirty, and it will be almost impossible to notice the change from blue to a yellow or pale yellow. Analysts wishing to use the process must, therefore, get the best quality of indigo-carmine. L. DE K.

Analysis of Phosphates. By R. JONES (*Zeit. ang. Chem.*, 1891, 3—4).—The author is very satisfied with Glaser's alcohol process, but thinks it may be much improved by lessening the amount of sulphuric acid. Glaser recommends 45 grams of the strongest acid; but even if the sample consisted solely of calcium oxide, 2 grams would be quite sufficient. The author also thinks that the quantity of the sample actually used for the analysis (0·4 gram) is far too small, and that at least 1 gram should be taken. He finally recommends the following process:—

10 grams of the sample, which must be free from organic matter, is dissolved in nitro-hydrochloric acid, and diluted to 500 c.c. 50 c.c. of the solution (= 1 gram of the sample) is evaporated to 25 c.c. and, while still hot, mixed with 10 c.c. of dilute sulphuric acid (1 : 5). After adding 150 c.c. of alcohol, the mixture is allowed to remain for at least three hours (Glaser thought half an hour sufficient). The calcium sulphate is collected and washed with alcohol until the washings, after being diluted with water, do not show the faintest acidity with methyl-orange. If it is desired to estimate the amount of calcium (the process is really devised for the accurate estimation of the iron and aluminium), the filter is put into a platinum dish, the alcohol burnt off, and the calcium sulphate finally ignited and weighed. The alcoholic filtrate is distilled, the residue rinsed into a beaker, and a slight excess of ammonia added, but it must again be completely boiled off. This is of particular importance when the phosphate contains magnesia; the precipitate at first always contains magnesia, but this is redissolved on boiling. In order to get a clear filtrate, it is as well to wash the precipitate, consisting of ferric and aluminic phosphates, with water containing a little ammonium nitrate. If it is preferred to weigh the iron and aluminium as pure oxides, the precipitate may be treated according to Stutzer's plan, namely, removal of the phosphoric acid by ammonium molybdate and precipitation of the filtrate with ammonia. L. DE K.

Physiological Detection of Carbonic Oxide in a Medium containing only 1 part in 10,000. By N. GRÉHANT (*Compt. rend.*, **113**, 289—290).—When air containing only 1 part of carbonic oxide in 10,000 is passed for half an hour through 50 c.c. of defibrinated, filtered dog's blood, the respiratory power falls from 23·7 to 23·0. Under a pressure of 5 atmospheres, with the same gas and the same blood, the respiratory power falls to 17·2. This fact may be utilised for the detection of minute quantities of carbonic oxide. It is clear that the absorption of carbonic oxide by the blood is not determined by the percentage of this gas by volume, but by the mass of the gas present in a given volume. C. H. B.

Separation of Barium from Calcium. By R. Fresenius (*Zeit. anal. Chem.*, **30**, 583—595).—*Methods based on the Differential Action of Alkaline Carbonates on the mixed Sulphates.*—Boiling the freshly-precipitated sulphates with a mixture of potassium carbonate and sulphate, and subsequent treatment with hydrochloric acid, gives fairly accurate results, the comparatively small errors compensating one another. The errors are much larger when cold ammonium carbonate solution is used for the decomposition of the calcium sulphate, the barium sulphate being also attacked to a considerable extent, whilst weighable amounts of calcium are left undissolved. Fleischer's method gives results sufficiently accurate for most purposes. The solution is precipitated by a mixture of 3 parts of potassium sulphate and 1 part of potassium carbonate. Since this at once throws down the calcium as carbonate, there is no tendency for the barium sulphate to retain calcium sulphate. After 12 hours' digestion, the precipitate is washed with ammonium carbonate, then dried, weighed (burning the filter and treating the ash with ammonium carbonate), and treated with a measured excess of standard hydrochloric acid, the excess being titrated with alkali. To complete the action of the acid on the calcium carbonate, prolonged digestion is necessary. Sidersky's process likewise affords serviceable results. The solution is precipitated by a mixture of ammonium sulphate and oxalate (200 grams of the former and 30 grams of the latter in a litre). The washed precipitate, consisting of barium sulphate and calcium oxalate, is dissolved in dilute hydrochloric acid, and the oxalic acid titrated by permanganate. The barium sulphate can then be collected (after partially neutralising the acid by ammonia), or the joint amount of the two metals may be found in a separate portion. Rose's proposal to separate calcium sulphate from strontium sulphate by digestion with concentrated solution of ammonium sulphate, appeared likely to succeed with a mixture of barium and calcium sulphates, but prolonged digestion leaves much of the calcium undissolved, whilst the portion dissolved cannot be accurately estimated by ammonium oxalate, since the ammonium sulphate solution (whether concentrated or dilute) is capable of dissolving a very notable amount of calcium oxalate. M. J. S.

Combination of Wet and Dry Methods in Chemical Analysis. By W. E. Adeney and T. A. Shegog (*Chem. News*, **64**, 174—175, 185—187, and 192—193).—The problems which the authors wished to solve by direct experiments were: 1. Whether, when fused in the reducing flame on charcoal with borax and sodium carbonate, the metals antimony, tin, lead, arsenic, silver, bismuth, copper, nickel, and zinc could be completely reduced from their salts containing either volatile or non-volatile acids. 2. Whether, when similarly treated, aluminium, chromium, manganese, cobalt, and iron are wholly non-reducible from their compounds; the cobalt and iron more especially from their arsenates and phosphates. 3. Whether, when a mixture of salts is similarly treated, the constituent metals thereof respectively behave as in simple compounds, or whether their behaviour is modified in any way. In their present paper, the authors mainly deal with the

problems Nos. 1 and 2. The details of manipulation are as follows :—

The Charcoal Support.—The pieces should be about 15 inches in length, and about $1\frac{3}{4}$ inches in diameter, and should be tolerably free from fissures. The cavity into which the substance is to be introduced should be bored conical, the sides being slightly curved. The size, of course, varies with the quantities of the materials used in the experiment; but, in the authors' assays, the diameter was $1\frac{1}{2}$ inches, and the greatest depth $1\frac{1}{2}$ inches. *The Source of Heat.*—Although an ordinary paraffin oil lamp, or one burning solid paraffin, may be advantageously used, still, when coal gas is procurable, it is by far the most convenient source of heat, as it can be burnt at the end of a flattened tube; and, if this be pivoted so that it can rotate in a vertical plane, it will be found of advantage in dealing with readily oxidisable metallic beads. *The blowpipe* used was an ordinary mouth-blowpipe, furnished with a platinum jet, and fixed in a clip on a retort-stand. An india-rubber hand-blower was used for obtaining the blast. *The borax* used was fused in a platinum dish, powdered, and kept in a dry and well-stoppered bottle. *The silver* was at first used in the form of nitrate, but, this not answering well, it was replaced by a mixture of argentic chloride and borax. In some cases it was used in the form of wire, or a button, after the substance and the fluxes had been first fused in the oxidising flame. *The sodium carbonate*, which the authors now only employ in the analysis of silicates, was the ordinary dried and powdered commercial article. *Quantities.*—The most convenient quantities to work on generally are 0·3 gram of substance and 1·2 grams of borax; but, when dealing with ores rich in nickel or zinc, not more than 0·1 gram should be taken. While the fusion is proceeding, the charge must be worked round and round the cavity, the metallic bead being made to run round the glass and pick up the metals as reduced. To prevent oxidation, a stream of coal gas is directed into the cavity while the melt is cooling.

As regards the first problem, the authors found that when fusing oxygenated compounds of antimony, tin, lead, arsenic, bismuth, and copper, or nickel chloride (mixed with metallic arsenic), with a mixture of borax, sodium carbonate, and argentic chloride, the reduction of the metals was practically complete, the glass bead being free from metal. Zinc, however, was found in both beads, showing the incompleteness of the reduction. Another series of experiments was now made. The ores and fluxes were fused together in a shallow cavity in charcoal with the aid of the oxidising flame. After cooling, the beads were transferred to a cavity of the usual shape and size, and, after the addition of a button of metallic silver, heated in the reducing flame. Satisfactory results were obtained with antimony, lead, arsenic, copper, and nickel; but in the case of tin and bismuth the reduction was incomplete.

As regards the difficultly reducible metallic oxides, the authors operated as follows:—0·3 gram of the substance was fused with 1·2 grams of borax or charcoal in the oxidising flame, 0·9 gram of silver button (1·2 grams when dealing with cobalt) was added, and the fusion

repeated in the oxidation flame. The results were qualitatively satisfactory with cobalt, aluminium, chromium, and manganese; of iron, only a mere trace passed into the silver button.

The investigation as regards mixed metallic compounds will be carried on by one of the authors. L. DE K.

Assay of Commercial Aluminium. By F. REGELSBERGER (*Zeit. ang. Chem.*, 1891, 20, 52).—Klemp has proposed to measure the volume of hydrogen which is evolved by dissolving the metal in potash-ley; but as commercial aluminium invariably contains silicon, which also evolves hydrogen, his process cannot give the exact amount of pure metal. A sample submitted to the author contained 98 per cent. of aluminium, but as it also contained 1·5 per cent. of silicon, it showed 99·9 per cent. of metal by Klemp's process. The author thinks it by far the best plan to carefully estimate the percentage of impurities in the sample and take the aluminium by difference; but if a direct estimation of the metal is desired, he proceeds as follows:—

Two grams of the sample is dissolved in a platinum basin, in water containing 15 grams of potassium hydroxide, and the whole is finally made up to 200 c.c. 50 c.c. of the alkaline solution (= 0·5 gram of the sample) is now boiled with a slight excess of neutral ammonium nitrate which throws down the alumina with more or less silica. After washing, igniting, and weighing, any silica must be estimated in the usual way by fusion with potassium hydrogen sulphate, and if there is any reason to believe that the reagents used contain alumina or silica, the usual check must be made. L. DE K.

Direct Estimation of Aluminium in Iron and Steel. By T. M. DROWN and A. G. MCKENNA (*Chem. News*, **64**, 194—196).—The alumina obtained during a quantitative analysis often contains ferric oxide and phosphoric acid. As the direct estimation of the alumina is as yet very unsatisfactory, the analyst, as a rule, contents himself with estimating the iron and phosphoric acid, and taking the alumina by difference. This is a very good plan when the iron and phosphorus are present in relatively small quantities, but when, as in the modern alloys of aluminium and iron, the aluminium may be present only to the extent of a fraction of 1 per cent., nothing short of the isolation of the alumina can satisfactorily prove its presence. The authors, after many experiments, finally adopted the following electrolytic process:—About 5 to 10 grams of the iron or steel is dissolved in sulphuric acid, and the solution heated until white fumes of sulphuric anhydride begin to come off. Boiling water is added to dissolve the iron salt, and the liquid filtered off from the silica and carbon, which are washed with acidified water. The filtrate is nearly neutralised with ammonia, and, if necessary, diluted to 300—500 c.c. The beaker in which the electrolysis is to be made contains from 500 to 1000 grams of mercury, which constitutes the cathode. It is connected with the battery or dynamo current in such a manner that about 2 ampères may pass through the

solution over night, which is best accomplished by using three lamps of 32-candle power, arranged in parallel on an Edison circuit. After, as far as possible, neutralising the acid which has been set free, the electrolysis is continued until the liquid gives no reaction for iron. It generally turns reddish from the formation of permanganic acid. When all the iron has amalgamated, the liquid is removed by means of a pipette while the current is still passing, and the mercury is repeatedly washed. The platinum anode, which will generally be slightly coated with manganese dioxide, is now taken out, and the mercury again washed with water until the last traces of solution have been removed from it. After filtering to remove any suspended manganese dioxide, excess of sodium phosphate is added, and also 10 grams of sodium acetate. After boiling for at least 40 minutes, the aluminium phosphate is collected, washed, ignited, and weighed. The formula is not, as generally believed, $Al_2P_2O_8$, but $7Al_2O_3,6P_2O_5$. It should, of course, have a pure white colour, but it must be remembered that the presence of even 4 per cent. of ferric oxide will give a decidedly reddish product. In case of doubt, it may be fused with potassium hydrogen sulphate, and the solution once more submitted to electrolysis, but the authors have always found this to be superfluous.

The test analyses are satisfactory. L. DE K.

Separation of Iron from Cobalt, Nickel, and Manganese. By A. C. CAMPBELL (*Zeit. anal. Chem.*, **30**, 616—617; from *J. anal. Chem.*, **2**, 291).—Ferric salts are precipitated by lead carbonate, whilst those of cobalt, nickel, manganese, and ferrous iron are not decomposed. Some lead chloride should be present to neutralise any traces of alkali. Warming promotes the reaction, and as oxidation of the cobaltous, manganous, and ferrous salts must be prevented, nitrates should be absent. The washed precipitate is treated with sulphuric acid, whereby the iron is redissolved and separated from the lead. To test the iron precipitate for cobalt and nickel, it is dissolved in hydrochloric acid and the concentrated solution reduced by tin foil. Traces of cobalt or nickel can then be recognised by the colour they communicate to the colourless ferrous chloride solution.

M. J. S.

New Methods of Quantitative Analysis. Part I. By A. BAUMANN (*Zeit. ang. Chem.*, 1891, 135—142).—When chromic acid is dissolved in dilute sulphuric acid and mixed with hydrogen peroxide, oxygen is evolved. According to some investigators, the reaction is not quantitative, but the author's experiments prove that 1 mol. of chromic acid liberates exactly 2 mols. of oxygen and 1 mol. of potassium dichromate 4 mols. of that gas. The most suitable apparatus is a Wagner's azotometer, or a Knop's apparatus connected with a Wagner's gas flask, which is an ordinary flask into which a small glass cylinder has been sealed.

Estimation of Chromic Acid.—The liquid, which must not be too concentrated and not exceed 50 c.c. in bulk, is mixed with 10 c.c. of dilute sulphuric acid (1 : 5) in the outer chamber of the flask. The

little glass cylinder is filled with 5 to 10 c.c. of commercial hydrogen peroxide. After allowing the hydrogen peroxide to run into the chromate, the liquid will at first assume a fine blue colour, and then gradually evolve oxygen. The bulk of this gas will be given off in a few minutes, but the remainder will be only expelled after five minutes' brisk agitation. When shaking, the operator must open the stopcock about every half minute to let the oxygen gradually escape into the measuring tube. The liquid in the non-graduated tube ought to stand a little lower during the evolution of the gas. When no more gas is given off, the apparatus is put, for about 15 minutes, into water of the temperature of the room; the water in the tubes is levelled, and the volume of the gas is read off; 1 c.c. of oxygen at normal temperature and pressure = 0·002246 gram of chromic acid (CrO_3). It is not advisable to work with hydrochloric instead of sulphuric acid, as there is always a risk of chlorine being evolved. Traces of free nitric acid do not interfere, but when the liquid contains more than 0·2 gram the oxygen found will be somewhat too low. Acetic and succinic acids do not affect the results, but other organic acids or organic substances decidedly interfere. In standardising a solution of potassium dichromate, it must be remembered that only three-eighths of the oxygen evolved is derived from the chromic acid.

Estimation of Chromic Oxide.—This is very readily converted into a chromate by treating its alkaline solution with hydrogen peroxide, the excess of which may be driven off by boiling. After neutralising the solution with sulphuric acid, the chromic acid is determined as directed, and calculated to Cr_2O_3. In the assay of chrome-iron ore by this process, the use of nitre as an oxidising flux must be avoided, and 0·3 gram of the finely powdered mineral must be fused with a mixture of 3 grams of sodium carbonate and 3 grams of barium peroxide for half an hour. The mass must afterwards be decomposed with sulphuric instead of hydrochloric acid.

Estimation of Combined Sulphuric Acid.—The liquid, which should contain no excess of hydrochloric acid and but traces of nitric acid or nitrates, is put into a 100 c.c. measuring flask, and precipitated in the cold with a solution of pure barium chromate in hydrochloric acid. As the commercial salt often contains alkali chromate, it must before use be thoroughly washed with water until the filtrate is practically colourless. The residue is then dissolved in an insufficiency of hydrochloric acid containing 3 per cent. HCl, and, after filtering, preserved for use.

After diluting with water to about 90 c.c., the liquid is rendered faintly alkaline with ammonia, made up to the mark, and filtered. An aliquot part of the filtrate, say 25 or 60 c.c., is then treated in the apparatus with sulphuric acid and hydrogen peroxide. 1 c.c. of oxygen = 0·001787636 gram of sulphuric anhydride.

The various test analyses are very satisfactory. L. DE K.

General and Physical Chemistry.

Apparent Variability of the Electro-chemical Equivalent of Copper. By J. Vanni (*Ann. Phys. Chem.* [2], **44**, 214—221).—Gray (*Phil. Mag.* [5], **22**, 389; **25**, 179), in his researches on the electro-chemical equivalent of copper, found that this magnitude at 12° varied from 0·0003287 with a current density of 20 milliampères per square centimetre at the cathode, to 0·0003278 with a density of 3·3 milli-ampères; and at 35° sank so low as 0·0003245. He advances as a probable explanation of this variability the fact, observed by Gore, that the solution of copper sulphate dissolves up a quantity of copper varying with different conditions. The object of the present investigation was to test the validity of this explanation, and to determine the true electro-chemical equivalent.

Two copper voltameters with plates of different surface (4 : 1) were placed in the same circuit; and it was found, for instance, that with a solution of copper sulphate containing 1 per cent. of free sulphuric acid, 0·1903 gram of copper was deposited on the larger cathode, while 0·1960 gram was deposited on the smaller cathode, in the course of three hours. After interruption of the current, the cathodes were allowed to remain three hours longer in the solutions, when it was observed that the larger cathode had lost weight to the extent of 9·2 milligrams, and the smaller cathode only 3·2 milli-grams. These weights, added to the former pair, give 0·1995 gram and 0·1992 gram respectively—results sufficiently close.

The author found that when the copper sulphate solution em-ployed contained merely a trace of sulphuric acid (about 5 milligrams per litre), there was no perceptible quantity of copper dissolved in two hours. With such solutions, the electro-chemical equivalents of copper and of silver were compared; and, taking that of silver as equal to 0·001118, the author gives, as a mean value of 12 concordant ex-periments, the electro-chemical equivalent of copper in cupric salts as equal to 0·0003284. J. W.

New Method of Measuring Electromotive Forces and Electrical Resistances. By S. Pagliani (*Gazzetta*, **21**, 449—454). —A standard wire of known resistance is joined in circuit with the current generator whose electromotive force is to be measured. A branch circuit containing a voltameter is also established, having one terminal fixed to one end of the standard wire and the other fixed to a key which slides along the standard wire. The voltameter consists of a glass tube, closed by two taps, containing a 25 per cent. solution of potassium iodide to which has been added a little starch solution. Platinum and copper wires are used for the cathode and anode respectively. The width of the tube is 10 mm.; the distance between the electrodes 120 mm. The resistance of the standard wires must be so great as to render negligible the internal resistance of the

current generator. At the commencement of the determination, the branch circuit is so arranged that the difference of potential at its terminals is insufficient for the electrolysis of the potassium iodide solution: the key is now moved along the standard wire until it reaches a point at which a violet coloration is observable at the surface of the platinum wire. The position of the key is then noted, and the electromotive force of the current generator can be calculated in terms of the electromotive force necessary to decompose the potassium iodide solution (0·610 volt).

Electrical resistances may be measured by employing a current generator of known electromotive force, and inserting the unknown resistance in either the main or the branch circuit.

The author states that this method gives very concordant results.

Characteristic Difference between the Substituted Alcohol Radicles directly united with Carbon or with Nitrogen. By C. Matignon (*Compt. rend.*, **113**, 550—551).—In the course of a thermochemical study of the ureides, the author has arrived at the law, "The substitution of an alcohol radicle directly united with nitrogen increases the heat of combustion more than when the same radicle is directly united with carbon." The publication of a paper by Stohmann and Langbein (this vol., p. 4), enunciating the same law, rendered necessary the immediate production of the author's results.

Caffeïne, theobromine, cholestrophane, and ethylcarbamide were purified and analysed; their heats of combustion at constant pressure, together with those of parabanic acid and carbamide, are given below.

		cal.	cal.
Caffeïne(methyltheobromine)	$C_7O_2N_4H_7Me$,	1016·0	170·1.
Theobromine	$C_7O_2N_4H_8$	845·9	
Ethylcarbamide	CON_2H_3Et,	472·2	320·7
Carbamide	CON_2H_4,	151·5	(=155+165·7).
Cholestrophane	$C_3O_3N_2Me_2$,	538·6	326
Parabanic acid	$C_3O_3N_2H_2$,	212·6	(=163 × 2).

The introduction of a methyl group united with carbon never increases the heat of combustion of the substance by more than 157 cal.; in the above cases, this number is exceeded by an amount far beyond the limits of experimental error. Ethylcarbamide is considered as derived from urea by two successive methyl substitutions; taking 155 cal. as the mean for a substitution of methyl united with carbon, 165·7 cal. is the increase caused by the introduction of a methyl group combined with nitrogen.

The application of this law confirms the suggestion of Grimaux, that pyruvile is a methyl derivative of allantoïn, and that it is a true homologue of that substance; the increase in heat of combustion in this case is 153 cal.

W. T.

Expansion of Water. By W. Marek (*Ann. Phys. Chem.* [2], **44**, 171—172).—This paper contains a table of the densities of water con-

taining air for every tenth of a degree from 0° to 31°. Details of the experimental method will be given in a subsequent communication.

H. C.

Molecular Weights of Liquids as evinced by their Boiling Points. By H. M. Vernon (*Chem. News*, **64**, 54—58).—The author endeavours to show that from the boiling point of liquids some indication as to the probable value of their molecular weights may be obtained. Hydrogen iodide boils at −25°, hydrogen bromide at −73°, and hydrogen chloride at −100°, from which a boiling point of about −120° might be predicted for hydrogen fluoride. But since hydrogen fluoride actually boils at 19·4°, we must assume a more complex molecule for this substance in the liquid state than that represented by the formula HF. This result agrees with Thorpe and Hambly's conclusion that at the boiling point the hydrogen fluoride molecule is probably H_4F_4. In like manner, comparing the boiling point of water with those of the similar compounds SH_2, SeH_2, and TeH_2, which are gaseous at temperatures far below 0°, we should have to assign to liquid water a molecular weight not smaller than that corresponding with the formula $(H_2O)_4$. The following table illustrates the striking regularity in increase of boiling point which is always observed on the substitution of bromine for chlorine :—

Chloride.	B. p.	Bromide.	B. p.	Increase for each atom of Br.
PCl_3	76·0°	PBr_3	175·0°	33·0°
$POCl_3$	107·2	$POBr_3$	195·0	29·3
$AsCl_3$	134·0	$AsBr_3$	220·0	28·7
BCl_3	18·2	BBr_3	90·5	24·1
$SiCl_4$	59·6	$SiBr_4$	154·0	23·6
$CHCl_3$	61·0	$CHBr_3$	151·0	30·0
CCl_4	76·5	CBr_4	189·0	28·1
CH_3Cl	−22·0	CH_3Br	4·5	26·5
$TiCl_4$	136·1	$TiBr_4$	230·0	23·5

Other cases are discussed, and the author argues, from a study of the boiling points, that in all probability all compounds, both organic and inorganic, containing one or more hydroxyl groups, have in the liquid state molecular weights double those expressed by their ordinarily received formulæ.

H. C.

Solubility of Gases in Water. By C. Bohr and J. Bock (*Ann. Phys. Chem.* [2], **44**, 318—343).—The authors have made fresh determinations of the solubility of oxygen, hydrogen, and nitrogen in water, partly by means of a Bohr's absorptiometer, and partly by means of two new instruments—a differential absorptiometer and a pumping-out apparatus—which are fully described and figured in the paper. The differential absorptiometer was used for temperatures from 0° to 60°; from 60° to 100° the other apparatus was employed.

The mean coefficient of absorption of oxygen in water was found to

be 0·03497 at 15°; at 100° it is 0·01679. The agreement with the values obtained by Dittmar and Winckler is good. For nitrogen, the absorption coefficient is 0·01667 at 19°, and 0·01046 at 100°. The coefficient remains practically constant between 60° and 100°. The authors' numbers agree well with those of Petterson and Sondén, Dittmar, and Hamberg, but diverge considerably from those of Bunsen and of Hüfner.

In the case of hydrogen, the author finds that the coefficient of absorption is not independent of the temperature, as Bunsen stated, but falls to a minimum at about 60°, after which it rises until at the boiling point it becomes equal to the coefficient of absorption of oxygen at the same temperature. The numerical values are—

$$\alpha_{0°} = 0{\cdot}0203,\ \alpha_{15°} = 0{\cdot}0183,\ \alpha_{60°} = 0{\cdot}0144,\ \alpha_{100°} = 0{\cdot}0166.$$

The authors further made two determinations of the solubility of carbonic anhydride, and found α for 37·29° to be 0·5629, and for 100° to be 0·2438. J. W.

Nature of Solution. By J. A. Wanklyn and W. Johnstone (*Chem. News*, **64**, 39, 51, and 146; compare Abstr., 1891, 1412).—When a solid is dissolved, the volume of the solution is not, as a rule, equal to the sum of the volumes of the solid and solvent. The authors have determined the amount of the change for a considerable number of substances which dissolve in water.

The alteration, which is usually that of contraction, is expressed in terms of a quantity, which they name the *condensate*, and obtain by subtracting the mass of solvent displaced by unit mass of dissolved substance from the ratio of the excess of the density of the solution over that of the solvent to the solution-density of the dissolved substance:—

$$c = i - i_1,$$

where $i = \dfrac{\text{Density of solution} - \text{density of solvent}}{\text{No. of grams of dissolved substance per c.c. of solution}}$,

and $i_1 = 1 - \dfrac{1}{\text{Density of dissolved substance}}$.

The condensate, which, it is stated, may be regarded as the amount of solvent which enters into combination with, or is condensed by, the dissolved substance, appears in several cases to bear a simple molecular ratio to the amount of the latter. Thus, with potassium nitrate, the number is 0·058, whilst the ratio $H_2O : 3KNO_3$ is 0·059, and with barium hydroxide the number is 0·320, whilst the ratio $3H_2O : Ba(OH)_2$ is 0·316. In other cases, however, the agreement is not so close, and the numbers can only be expressed by more complex ratios.

With cane sugar, the condensate is zero, whilst with certain ammonium salts it appears to be negative. Jn. W.

Strong Solutions and the Dissociation Hypothesis. By S. U. Pickering (*Ber.*, **24**, 3317—3327).—The author states that the fact

established by him (Abstr., 1891, 972), that weak solutions of sulphuric acid and other substances contain less, instead of more, acting units than the acid and water separately, cannot be brought into harmony with the dissociation hypothesis, as Arrhenius considers (Abstr., 1891, 1148), by admitting that complex aggregates of similar molecules exist in pure liquids and strong solutions. After answering some recent criticisms of Arrhenius, he gives a preliminary statement of numerous results obtained in a study of the freezing points of strong solutions. Very weak solutions of electrolytes, as is well known, exhibit an abnormally large molecular depression; this decreases as the strength is increased up to a certain point, but afterwards it again increases, and often attains values which are abnormally large in a very high degree. Non-electrolytes appear to behave in the opposite manner; in every case investigated, the molecular depression decreases with the strength of the solution, although in a few cases this abnormally small depression is preceded by a comparatively slight and temporary increase. Although so-called dissociation may offer some explanation of the behaviour of very weak solutions, it appears to be incapable of explaining that of stronger solutions, for here the molecular depression increases, while the amount of dissociation, as measured by the electric conductivity, diminishes. The abnormally high values obtained by Perkin for the magnetic rotation of many salts, &c., in strong solution, and by Gladstone for their refractive indices, is probably due to the same causes as those owing to which these solutions exhibit an abnormally large depression. A table is given in which the rotation values are compared with the amount of dissociation existing, and there appears to be no connection whatever between the two.

S. U. P.

The Cryoscopy of Cane Sugar Solutions. By S. U. Pickering (*Ber.*, **24**, 3328—3341).—Numerous determinations, both with very weak solutions, and with solutions up to 64·5 per cent., are quoted, and the results examined in detail, partially by the bent-lath method and partially by the application of parabolas deduced from the experimental values. In all the instances where both methods were applied to the same series of results, they have led to precisely the same conclusions respecting the nature of the figure formed, that is, whether it is a continuous curve or whether it contains changes of curvature. With very weak solutions—0 to 1·2 mols. to $100H_2O$, with an actual depression extending up to 1·4°—the molecular depression increases from 1·050° to 1·105° at a strength of 0·1 mol., then diminishes to 1·102 at 0·3 mol., and finally increases again till it reaches 1·156° at 1·2 mols. From 0·06 to 1·2 mols. can be represented by two curves meeting at about 0·6 mol., so as to give the apparent error of the points very nearly the same value as the known experimental error, whereas when the same portion is drawn as one continuous curve the apparent error is twice the experimental error, and there is such a bad arrangement of error of like signs, that such a drawing could not be accepted as a legitimate representation of the results. Hence the author concludes that a "break" exists at about 0·6 mol. to $100H_2O$. There appears to be some further irregularity in

the region of much weaker solutions, but the position of a break here cannot well be determined.

With the freezing points of stronger solutions, the figure is sensibly a straight line as far as about 2·5 mols.; it then bends downwards as far as 5·5 mols., when it begins to bend in the opposite direction. The molecular depression for the strongest solution, 9·5 mols., is 1·445, the maximum molecular depression being reached at 8 mols., where it amounts to 1·455. The author considers that there is a change of curvature at 2·5 or 2 mols., but not at 5·5 mols., where the inflection of the figure occurs: a representation, either by bent-lath curves or by parabolas, which shows a break at the former point, gives a mean apparent error for the points agreeing very closely with the experimental error, whereas a one-curve representation, which makes no break at this point, gives an apparent error 2·4 times larger than the known experimental error, or taking into account indications of error other than the mean error—such as arrangement of like signs into groups, and the occurrence of errors of improbable magnitude—the total apparent error, and, therefore, the improbability, of the one-curve drawing, is estimated by the author to be 100 times greater than that of the two-curve drawing. Representing the figure by three curves, instead of two, produces no appreciable diminution in the apparent error of the points. S. U. P.

Existence of Acid or Basic Salts of Monobasic Acids in very Dilute Solutions. By D. Berthelot (*Compt. rend.*, **113**, 641—643).—If a dilute solution of an alkali is added, in gradually increasing proportion, to an equivalent solution of a monobasic acid, the phenomena can be represented in a very simple manner by means of a curve, the abscissæ being the electrical conductivity of the mixture, and the ordinates the proportion of one of the constituents. The curve consists mainly of two right lines (one corresponding with excess of acid, and the other with excess of base), inclined at an acute angle, and connected by a short curved portion, part of which represents the effect of a slight excess of acid, whilst the remainder represents the influence of a slight excess of base. A slight excess of base has a greater effect than an equivalent excess of acid, but the effect disappears rapidly as the quantity of acid or base in excess is increased. These results are very distinctly shown by solutions of barium chloride, hydrochloric acid, and barium hydroxide, and they indicate that acid or basic salts are not completely decomposed by dilution, but exist in minute quantities even in very dilute solutions. C. H. B.

Catalytic Influence of Acids on the Velocity of the Reaction between Hydrogen Peroxide and Hydriodic Acid. By G. Magnanini (*Gazzetta*, **21**, 476—490).—The author has studied the effect of hydrochloric, nitric, nitro-hydrochloric, sulphuric, hydriodic, oxalic, acetic, monochloracetic, and phosphoric acids on the velocity of the reaction between hydrogen peroxide and hydriodic acid, in a similar manner to that employed in his study of the reaction between bromic and hydriodic acids (Abstr., 1891, 144). As in the case of the latter reaction, the velocity of the action is acceler-

ated by the addition of acid. When hydrochloric or sulphuric acid is employed, the accelerations are not rigorously proportional to the amount of acid added, the ratio of the acceleration to the quantity of foreign acid present decreasing slightly, but sensibly, as the amount of acid is increased; this constitutes a marked difference from the case of bromic and hydriodic acids, in which this ratio increases rapidly with increase of acid.

The quantity of iodine set free when nitric acid is used is practically the same as with hydrochloric acid. The accelerating effect of hydriodic acid is very great. W. J. P.

Optical Proof of the Existence of Suspended Matter in Flames. By G. G. Stokes (*Chem. News*, **64**, 167—168; compare G. J. Burch, Abstr., 1885, 466).—When a beam of sunlight, condensed by a lens, is passed through a candle-flame, the area of intersection of the double cone of light with the luminous envelope is marked by two brighter patches of light of inappreciable thickness, which exhibit the polarisation of light scattered by fine particles —that is to say, when viewed in a direction perpendicular to the incident light, it was polarised in a plane passing through the beam and the line of sight. They can be made more conspicuous by viewing the whole through a cell containing copper ammonium sulphate solution, or through cobalt glass. The same phenomenon is shown by a luminous gas or ether flame, but not by the blue base of a candle flame, or by a Bunsen flame, even when rendered luminous with sodium chloride, or by an alcohol flame, or by an ether flame, just expiring for want of air.

The separation of carbon, or carbon associated with hydrogen, thus rendered evident by its polarising effect on light, is due to the action on the volatile carbon compounds, in the absence of a sufficient supply of oxygen to effect complete combustion, of the heat evolved by the more complete combustion at the base of the flame. In the case of the dying ether flame, the heat is probably distributed over too large a mass of inert gases to effect the decomposition.

The thinness of the stratum of glowing carbon is probably due to the combined attack of oxygen on the outside, and carbonic anhydride on the inside (compare Smithells, Proc., 1891, 159). Jn. W.

Inorganic Chemistry.

Sulphur Tetroxide. By D. Carnegie (*Chem. News*, **64**, 158—159).—A criticism of Traube's work on the electrolysis of 40 per cent. aqueous sulphuric acid (Abstr., 1891, 978). The author, whilst admitting that the substance formed cannot be a heptoxide of sulphur, comments on the absence of direct evidence in favour of the existence of a tetroxide. The ratio 1 : 5 of active oxygen to sulphuric anhydride, which Traube considers to prove the existence of the tetroxide SO_4 in the electrolysed solution, would be equally well

explained on the hypothesis of the existence of a substance having the composition S_2O_7,H_2O_2,xH_2O. The existence of such a substance would not only accord with Berthelot's results (Abstr., 1878, 469), but would harmonise with the known existence of tungsten and molybdenum heptoxides, and with the tendency of peroxides of the type M_2O_7 to form stable compounds with hydrogen peroxide. Moissan's perchromic acid (Abstr., 1884, 20; compare Berthelot, Abstr., 1889, 350) might then be regarded as a compound, Cr_2O_7,H_2O_2,H_2O, of the same type.

With regard to the low amount of active oxygen shown by the iodometric method, the author points out that this cannot be accounted for by the presence of sodium hydrogen carbonate, since the latter has practically no action on iodine, but that it can be accounted for by the presence of free alkali in the potassium iodide, and that this supposition accords with the higher results which were obtained on working with acid instead of neutral solutions.

Jn. W.

Azoimide. By T. Curtius (*Ber.*, **24**, 3341—3349; compare Abstr., 1891, 56).—Ethereal salts of benzoic acid react with hydrazine hydrate according to the equation $Ph{\cdot}COOR + N_2H_4,H_2O = COPh{\cdot}NH{\cdot}NH_2 + ROH + H_2O$. The benzoylhydrazine, when treated with nitrous acid, yields benzoylazoimide, and on digesting this with sodium ethoxide it is decomposed quantitatively into sodium nitride, NaN_3, and ethyl benzoate.

The salts of azoimide may also be prepared from hippurylhydrazine, by the action of nitrous acid; in this case, a compound is formed which was previously termed nitrosohippurylhydrazine; it is, however, a diazo-compound with the formula $COPh{\cdot}NH{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}N{:}N{\cdot}OH$ (see below); it cannot be converted into hippurylazoimide by elimination of water, but on treatment with ammonia in alcoholic solution, it is decomposed into hippuramide and ammonium nitride; the hippuramide combines with hydrazine hydrate to form hippurylhydrazine.

Argentic nitride, AgN_3, has been previously described; it is soluble in ammonia, from which it crystallises in long, colourless needles; it is exceedingly explosive.

Mercurous nitride, HgN_3, is precipitated in microscopic needles which are insoluble in water; it is more stable than either the silver or lead salts, becomes yellow on exposure to light, and yields a black, insoluble compound with aqueous ammonia.

Plumbic nitride, PbN_6, is prepared by adding plumbic acetate to a solution of the sodium or ammonium salts; it is soluble in excess of the precipitant, but insoluble in water in the cold, and more sparingly soluble in boiling water than plumbic chloride, which it closely resembles. It crystallises from water in long, colourless, lustrous needles, which explode violently on gently warming and decompose gradually when heated with water or acetic acid.

Sodium nitride is most readily prepared in the manner described above, but may also be obtained by adding soda to solution of the free acid or of the ammonium salt; it is readily soluble in water, insoluble in alcohol or ether, has a slight alkaline reaction and a

saline taste. The compound is neither volatile nor hygroscopic; its solution may be evaporated to dryness without undergoing any change, and it only explodes when heated to a comparatively high temperature.

Ammonium nitride, N_4H_4, obtained as above, is readily purified by adding ether to the alcoholic solution, or it may be crystallised from alcohol, from which it is deposited in plates closely resembling ammonium chloride, but not belonging to the regular system. It is excessively volatile, and explodes violently when heated in a combustion tube with cupric oxide in a current of air; it may, however, be sublimed by cautiously heating at a little above 100°, although violent explosions occur if it is rapidly heated.

Hydrazine nitride, N_5H_5, is prepared by adding hydrazine hydrate to ammonium nitride or to the free acid; it crystallises in long, lustrous prisms, or in plates, and is sparingly soluble in alcohol. By detonation, or on rapidly heating, the compound explodes violently, but it will burn quietly with a smoky, slightly yellow flame; if the combustion takes place on a metallic surface, every trace of oxide on it will be reduced and the metal will appear bright and polished.

The formation of diazohippuramide, $COPh{\cdot}NH{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}N{:}OH$, has already been described; it combines with ammonia, aniline, hydrazine, and similar compounds with elimination of azoimide, whilst the action of water, alcohol, aldehydes, or acidyl hydrazines causes nitrogen to be evolved; for example, the action of aniline on diazohippurylamide gives rise to hippurylanilide, aniline nitride, and water; the reaction with alcohol is represented by the equation,

$$NHBz{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}N_2{\cdot}OH + EtOH = N_2 + NHBz{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}OEt + H_2O.$$

On treating diazohippurylamide with benzoylhydrazine, nitrogen and water are eliminated, and a compound is formed which has the formula $NHBz{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}NH{\cdot}NHBz$; this is exceedingly stable towards acids and alkalis, and attempts to hydrolyse it have hitherto been unsuccessful; its properties and mode of formation prove it to be a derivative of *triamide*, $NH_2{\cdot}NH{\cdot}NH_2$, which has not as yet been obtained in the free state. J. B. T.

The Colour of Nitric Acid. By L. Marchlewski (*Ber.*, **24**, 3271—3276).—It is well known that as water is added to red fuming nitric acid, the colour changes through green to blue and finally disappears. In explanation of this, it has always been assumed that the red acid is a solution of nitrogen peroxide, N_2O_4, in nitric acid, and that the water added decomposes the peroxide with formation of nitric and nitrous acids. The solution of nitrous acid in nitric acid is blue, and this, with the red solution of still undecomposed peroxide, gives a green colour. As more water is added, this excess of peroxide is decomposed, and nothing is then left but a blue solution of nitrous acid.

The author has investigated the matter experimentally in the following manner:—The gases contained in the coloured acid were expelled by means of carbonic anhydride and collected in concentrated sulphuric acid, with which nitrous acid forms nitrosyl hydrogen sulphate,

but with nitrogen peroxide forms a mixture of nitrosyl hydrogen sulphate with nitric acid in molecular proportion. The total nitrogen was determined with the nitrometer, and the reducing power by titration with permanganate. Both results were calculated to trioxide, and from the ratio of the second to the first a conclusion could be drawn as to the constitution of the mixture of gases absorbed. If the gas were pure trioxide, the ratio would of course be 1; if it were pure peroxide, 0·5, since the reducing power of the peroxide is only half that of the trioxide. The results obtained were astonishing, for although they showed that the blue acid contained pure trioxide, yet they also showed that the green acid did not contain more than at most mere traces of the peroxide. The author was consequently led to suspect that his results were vitiated by the presence of nitric oxide, NO, in the coloured acids examined; and in fact when the experiments were repeated, the gases that escaped absorption in the strong sulphuric acid being passed through a strongly acid permanganate solution, the permanganate was perceptibly reduced. The reduction was, of course, due to nitric oxide, and a great deal of this gas must have been present originally, for had only a small quantity been there, it would have formed nitrosyl hydrogen sulphate with the peroxide also present and the concentrated sulphuric acid, and would thus have been absorbed.

The solutions investigated were made by passing the gaseous oxide into pure nitric acid. Solutions obtained by mixing pure liquid peroxide with nitric acid of different strengths are now being investigated. C. F. B.

Boron Phosphoiodides. By H. Moissan (*Compt. rend.*, **113**, 624—627).—Melted phosphorus acts with great energy on boron triiodide, and if red phosphorus is heated in the vapour of the iodide, decomposition takes place with incandescence. If, however, a solution of the iodide in carbon bisulphide is mixed with a similar solution of phosphorus, great care being taken to avoid the presence of moisture, the reaction takes place more slowly. The mixture is sealed up in a flask and kept at the ordinary temperature of the laboratory; it is at first clear, but has a red colour. In a few minutes a brown precipitate begins to separate, and the reaction is complete in about three hours. The product is filtered through glass wool, washed with carbon bisulphide, and dried in a vacuum, the apparatus being filled with carbonic anhydride until the latter is removed by the pump.

The product is *boron phosphodiiodide*, BPI_2, an amorphous, homogeneous, deep-red powder. When heated in a vacuum, it melts at 190—200°, and will remain in superfusion at the ordinary temperature for a long time; in a vacuum, it begins to volatilise at 170—200°, and condenses on the cold part of the tube in distinct red crystals. It is only very slightly soluble in carbon bisulphide, and seems to be completely insoluble in benzene, phosphorus trichloride, and carbon tetrachloride. It is extremely hygroscopic, and decomposes very rapidly in moist air. In presence of a large excess of water, it becomes yellow, without apparent development of heat, and hydriodic, phosphorous, and boric acids are formed, a small quantity of phosphine

being evolved, and a small quantity of a yellow substance with an odour of phosphorus being deposited. With a very small quantity of water, the yellow precipitate is produced in larger quantity, and a distinct quantity of phosphonium iodide is formed.

Boron phosphodiiodide, when heated in hydrogen sulphide, yields boron sulphide, phosphorus sulphide, and hydrogen iodide without any free iodine. Dilute nitric acid yields phosphoric acid and boric acid, whilst strong nitric acid produces the same result, but with incandescence. Sulphuric acid (even Nordhausen) has no action in the cold, but, on heating, free iodine, hydrogen iodide, and sulphurous anhydride are evolved. Phosphorous trichloride and carbon tetrachloride have no action even in sealed tubes at 100°. Chlorine produces incandescence, with formation of boron chloride, iodine chloride, and phosphorus pentachloride. When heated in oxygen, the compound burns and yields iodine, boric anhydride, and phosphoric anhydride. Sodium has no action in the cold, but decomposition takes place at the melting point of the metal. Powdered magnesium reacts with incandescence. When thrown into mercury vapour, the phosphodiiodide takes fire at once. In presence of carbon bisulphide the behaviour of metals is different; magnesium or sodium at the ordinary temperature produces a red compound, PBI, whilst silver or mercury in the cold, or more rapidly at 100°, yields a maroon-coloured compound with the properties of boron phosphide, BP.

Boron phosphoiodide, BPI, is obtained by heating the preceding compound in hydrogen, and is an amorphous, red powder, somewhat less hygroscopic than the diiodide. It volatilises in a vacuum at 210—250° without previous fusion, and condenses in orange-yellow crystals. Strong nitric acid decomposes it with development of heat and without incandescence, iodine being liberated. Concentrated sulphuric acid has no action in the cold, but, on heating, iodine, sulphurous anhydride, and boric acid are formed. When heated out of contact with air, it decomposes at a temperature below dull redness with evolution of vapours of iodine and boron phosphide. Mercury in excess, in presence of dry carbon bisulphide, yields mercuric iodide and boron phosphide at the ordinary temperature.

Boron phosphide, BP, resembles the phosphoiodide BPI in its general properties. It can be obtained by heating the phosphoiodide in hydrogen, and if the heating is continued, a residue of the composition B_5P_3 is left. C. H. B.

Reducing Action of Graphitoïdal Silicon. By H. N. Warren (*Chem. News*, **64**, 75).—When the oxides of easily reducible metals, such as lead, copper, and silver, are heated to dull redness with powdered graphitoïdal silicon, they are reduced to the metal, and if the silicon is in excess, a metallic silicide is formed. The oxides of chromium, tungsten, and molybdenum may also be reduced in this way. In some cases, the reduction takes place with explosive violence; when, for instance, a small quantity of a mixture of equal parts of finely-divided silicon, aluminium, and litharge was melted before the blowpipe, the explosion was so violent as to indent the supporting brick. Jn. W.

Solubility of Sodium Carbonate and Sodium Hydrogen Carbonate in Solutions of Sodium Chloride. By K. Reich (*Monatsh.*, **12**, 464—473).—The solubility of sodium carbonate at 15° in a solution of sodium chloride of gradually increasing concentration at first diminishes and then increases. The solubility y as a function of the quantity x of sodium chloride in 100 parts of water is expressed by the formula

$$y = 61{\cdot}406 - 2{\cdot}091077x + 0{\cdot}055493x^2 - 0{\cdot}000297357x^3.$$

Accordingly, the minimum lies near $x = 23{\cdot}15$ where $y = 39{\cdot}05$. On passing carbonic anhydride through the saturated solution, the amount of bicarbonate precipitated increases with the quantity of sodium chloride in solution; but a maximum cannot be recognised.

G. T. M.

Allotropic Silver. By M. C. Lea (*Phil. Mag.* [5], **32**, 337—342).—The blue form of allotropic silver is capable of change into an intermediate yellow form which seems to be identical with that into which the gold-coloured form passes under the influence of various causes (Abstr., 1891, 803). The change takes place at about 180°, both with lumps of the blue silver and with films. By the action of sulphuric acid, however, blue silver can be converted into yellow silver at the ordinary temperature, and consequently with retention of all its active properties.

40 grams of sodium hydroxide and 40 grams of yellow or brown dextrin are dissolved in 2000 c.c. of water, and 28 grams of silver nitrate is added in successive very small quantities, with frequent agitation. The solution is slightly turbid, and is deep-green by reflected light, red by transmitted light. The precipitate that forms spontaneously or is produced by the addition of acetic acid, dilute nitric acid, and many neutral substances, consists of blue silver, but if sulphuric acid is added, the precipitate, when dried in films, is blue, green, yellowish-green, or yellow, according to the proportion of acid used. When the silver solution is mixed with an equal volume of a mixture of 7·5 c.c. of sulphuric acid and 92·5 c.c. of water, the precipitate consists wholly of yellow silver, but with higher proportions of acid the product dries with a coppery shade. The lustre of the product diminishes as the proportion of acid used for precipitation is increased.

Conversely, a solution which would yield yellow silver under ordinary circumstances can be made to yield blue silver by the addition of an alkali, and it is immaterial whether the alkali is added to the ferrous tartrate or the silver mixture or to a mixture of the two. There is, therefore, a tendency for acids to produce the yellow product and alkalis the blue product, but it is a tendency only, and both forms can be obtained from neutral solutions; for instance, ferrous tartrate and silver tartrate yield gold-coloured silver, but ferrous citrate and silver citrate produce the blue variety.

When sodium hypophosphite is added to silver nitrate, there is no reduction, but if phosphoric acid is added so that hypophosphorous acid is liberated, a transient red colour appears, and red and blue

stains are formed on the side of the vessel. Phosphorous acid gives similar though somewhat less distinct results.

The blue silver obtained by adding the soda-dextrin silver solution to an equal volume of water containing 4 per cent. of sulphuric acid is not only constant in character but is one of the forms most sensitive to light. When this form is exposed to light, it first becomes more distinctly blue, then yellowish-brown, and finally is converted into the golden-yellow intermediate or crystalline form, with great brilliancy and lustre.

It is noteworthy that the action of light on this blue variety at first increases its sensitiveness to reagents such as potassium ferricyanide, and afterwards reduces it. This is well shown if one part of a film is covered with an opaque substance, another part with a translucent substance, whilst the third is left uncovered, and the three are exposed simultaneously to bright sunlight for about five hours and afterwards treated with dilute ferricyanide solution. The author regards this phenomenon as analogous to the reversing action observed with gelatinobromide plates.

The production of reduced silver is *direct* when an ordinary silver compound is converted into metal without formation of a sub-salt, and *indirect* when the silver compound is first reduced to a sub-salt, and the latter is afterwards reduced to the metal. It would seem that only under the latter conditions is there any formation of allotropic silver. If, in any of the three principal methods of producing allotropic silver, the action is interrupted by the addition of hydrochloric acid, a dark, chestnut-brown or purple-brown mixture of the subchloride with the photochloride is obtained, and from it beautiful rose-red photochloride can be obtained by treatment with cold dilute nitric acid after complete removal of the hydrochloric acid. This result is only obtained by interrupting the reaction before it is complete, and if the hydrochloric acid is added after complete reduction, only grey, normal silver is precipitated. In every case examined, silver subchloride is obtained as one of the products when a reaction resulting in the formation of allotropic silver is interrupted by the addition of hydrochloric acid before reduction is complete.

The rich and varied colour of silver sub-salts would seem to indicate that in these compounds the metal exists in an allotropic form, but, on the other hand, the greater activity of allotropic silver and its lower sp. gr. would tend to show that the allotropic form has a simpler molecular structure than the normal metal. C. H. B.

Colloïdal Silver. By E. A. Schneider (*Ber.*, **24**, 3370—3373).—Colloïdal silver prepared according to Carey Lea's method, by the reduction of silver nitrate with ferrous citrate, cannot be purified by dialysis alone; the better plan is to separate the solid colloïd from the mother liquor as completely as possible by filtration, then to dissolve the silver in a little water and allow this solution to dialyse. On adding hydrochloric acid to aqueous colloïdal silver solutions, silver and argentic chloride are precipitated, the proportion of the latter being greater with increasing quantities of hydrochloric acid; the mixed precipitate is extracted with ammonia, the argentic chloride

precipitated by acidification with nitric acid, and hydrochloric acid added to the filtrate; if the quantity of hydrochloric acid originally employed was small, a further precipitate is produced, showing the presence of a silver subchloride. The mixed precipitate of silver and argentic chloride was always rose-red.

Nitric and sulphuric acids react with colloïdal silver solutions in a similar manner. No evolution of hydrogen could be detected even when sufficient hydrochloric acid was added to the silver solution to produce a considerable precipitate of argentic chloride; this may indicate the presence of argentous oxide: neither was oxygen evolved when, in consequence of the small quantity of hydrochloric acid employed, the precipitate consisted of almost pure silver.

J. B. T.

Direct Combination of Chlorine and Bromine with Metals. By H. Gautier and G. Charpy (*Compt. rend.*, **113**, 597—600).—Well cleaned wires of various metals, 2 mm. in diameter, were kept in the dark in contact with dry bromine for a definite length of time at 15° and 100°. The percentage loss of weight in each case is given in the following table:—

	At 15° in 8 days.	At 15° in 4 months.	At 100° in 8 days.
Magnesium	0·0	0·0	0·19
Zinc	0·289	0·487	0·63
Iron	0·210	0·440	23·27
Copper	0·371	1·740	6·62
Silver	0·003	0·540	—

Aluminium under similar conditions combines energetically with bromine and becomes incandescent, a burning fragment running about on the surface of the bromine like potassium on water. With liquid chlorine in sealed tubes at the ordinary temperature, the results are similar, the percentage losses being: magnesium, 0·0; zinc, 0·0; iron, 0·740; copper, 3·241; silver, 0·673. Potassium, sodium, and aluminium seem to be unaffected by liquid chlorine at its boiling point, but at −20° aluminium combines with the halogen with incandescence.

In presence of water, the results are very different. Magnesium and aluminium, when placed in bromine-water, produce a regular evolution of hydrogen, and, after some time, an oxybromide separates, the reactions being analogous to the decomposition of water by iodine in presence of aluminium. With zinc, iron, and copper, there is no evolution of gas, and a wire 2 mm. in diameter and 50 mm. in length disappears in seven to eight hours in excess of bromine-water. It seems probable that in these cases the decomposition of water by the halogen is accelerated by the presence of the metal, the latter being converted into an oxide which is attacked by the hydracid formed.

C. H. B.

Lithium Copper Chloride. By A. Chassevant (*Compt. rend.*, **113**, 646—648).—When a concentrated solution of lithium chloride is

added to a concentrated solution of an equivalent quantity of cupric chloride, a magma of crystals of the latter salt is formed, but if the mixture is evaporated in a vacuum over phosphoric acid or on a water-bath at 100°, the crystals dissolve, the liquid acquires a brownish-red colour and deposits transparent, garnet-red crystals of the double chloride $2CuCl_2,2LiCl,5H_2O$. When exposed to the air, they decompose, and become opaque, crystals of cupric chloride separating, whilst the lithium chloride deliquesces. If heated rapidly to 130°, they melt in their water of crystallisation and form a deep-brown, almost black, solution. At a higher temperature, the salt, like lithium chloride under similar conditions, decomposes and evolves chlorine. When heated slowly in an oven, or in a current of dry air, the crystals become anhydrous at 100—120°, but some hydrochloric acid is likewise given off, and, on treatment with water, a residue of cupric oxychloride is left. The double salt can be obtained as an anhydrous, chamois-coloured powder by heating it at 120° in a current of dry air mixed with dry hydrogen chloride. It is decomposed by water, but can be recrystallised from a concentrated solution of lithium chloride. C. H. B.

Formation of Saline Hydrates at High Temperatures. By G. Rousseau (*Compt. rend.*, **113**, 643—646).—When the hydrated sodium ferrite obtained at 800°, and previously described, is allowed to remain in contact with glycerol for several days, and is washed first with this liquid and afterwards with absolute alcohol, the dried residue contains only 9·68 per cent. of water, instead of the 14·5 per cent. that it contains when water is used for washing. The ferrite, $14Fe_2O_3,13H_2O,Na_2O$, when treated with glycerol in a similar manner, loses 2·79 per cent. of water. If either of these compounds is heated at 100° with glycerol, its colour rapidly becomes darker, and if digestion is prolonged, the whole of the water and alkali is removed, and anhydrous ferric oxide remains.

The sodium manganites, such as $12MnO_2,4H_2O,Na_2O$, are not affected in a similar way by glycerol.

The author considers that these results establish his previous conclusions and support the view that the alkaline oxide replaces part of the water. C. H. B.

Crystallised Ferric Oxychlorides. By G. Rousseau (*Compt. rend.*, **113**, 542—544).—Very concentrated solutions of ferric chloride, containing about 80 per cent. of Fe_2Cl_6, maintained at a temperature of 160—220° for some time, yield a crystallised ferric oxychloride, $2Fe_2O_3,Fe_2Cl_6 + 3H_2O$. By prolonged boiling with water, this compound is gradually converted into a ferric hydroxide, $(Fe_2O_3 + H_2O)_3$, which retains the same crystalline form as the oxychloride.

Solutions containing 85 to 90 per cent. of the anhydrous ferric chloride have been heated in sealed tubes, together with a fragment of marble or giobertite. Between 225° and 280°, red-brown lamellæ of the oxychloride $2Fe_2O_3,Fe_2Cl_6$ are obtained. Between 300° and 340°, large plates of a brownish-black oxychloride $3Fe_2O_3,Fe_2Cl_6$ are formed.

The author has been unable to study the reaction at higher temperatures, but believes that a series of oxychlorides of the type $(Fe_2O_3)_n,Fe_2Cl_6$ would be formed, in which the proportion of Fe_2O_3 would increase with the temperature.

The anhydrous oxychlorides are very sparingly soluble in dilute mineral acids. When boiled with water in presence of marble for 150—200 hours, they lose all their chlorine as hydrochloric acid, ferric oxide of a fine brownish-red colour remaining.

The optical properties of these oxychlorides have been determined by Fouqué. They occur in prisms giving longitudinal extinction. The plane of their optic axes is transverse, and the bisectrix is positive.

It would be interesting to observe whether the rhombic oxychlorides retain their form during the concentration of ferric oxide in the molecule, or whether they assume, at a temperature near a red heat, the hexagonal form characteristic of ferric oxide. On the latter hypothesis, the hydrolysis of the hexagonal oxychloride, by boiling with water, should give a new method for the synthesis of hæmatite, allowing the determination of the degree of polymerisation of this mineral oxide. W. T.

Action of Water on Glass. By E. Pfeiffer (*Ann. Phys. Chem.* [2], **44**, 239—264).—The author has taken advantage of electrolytic conductivity for the purpose of determining the amount of substance dissolved from glass by water at low temperatures. Ordinary chemical methods give very uncertain numerical results, on account of the difficulty in determining the exact magnitude of the large surface which must be exposed to the action of water, and even these results are obtained under conditions diverging considerably from those of laboratory practice.

Water first of all dissolves practically pure alkali (potassium or sodium hydroxide) out of the glass, and this afterwards exerts its own influence by dissolving silica. The author estimates the amount of alkali dissolved by determining the electrical conductivity of the solution, to which it is proportional. As the molecular conductivities of potassium hydroxide and sodium hydroxide lie close together (220×10^{-7} and 200×10^{-7}, according to Kohlrausch), no great error is committed in estimating the total amount dissolved on the assumption that each alkali dissolves proportionately to the extent to which it is contained in the glass. When silicates are formed in the solution, the conductivity falls.

The experiments were made by exposing cylinders of good Thuringian glass with known surface to the action of water contained in glazed porcelain vessels; the temperature in the three series of observations made being 10°, 20°, and 30°. For one sort of glass at a given temperature, it was found that $\Delta_0 = \Delta\omega/o$ is a constant, Δ being the increase in conductivity per hour, ω the volume of water, and o the surface of the cylinder. When the glass has been exposed for some time to the action of water at a temperature of 60°, the value of Δ_0 for 20° falls considerably. $\Delta_0^{(20)}$ for the first day is much

greater than $\Delta_0^{(20)}$ afterwards. With the specimen of glass examined, it was found that at 20° one to two millionths of a milligram were dissolved out by 1 c.c. of water per square centimeter in an hour. No silica is dissolved at 10° or 20°. At 30°, however, a considerable falling off of Δ_0 with the time is observed, due in all probability to this cause. The values of Δ_0 (reduced to 20°) for the various temperatures are as follows:—

	10°.	20°.	30°.
Δ_0.....	25	100	673

Prolonged treatment of the glass at a low temperature does not appreciably affect its solubility at a higher temperature. J. W.

Stannibromides. By Leteur (*Compt. rend.*, **113**, 540—542).—The stannibromides of the alkali metals and magnesium are yellow, well-crystallised substances. Concentrated solutions have the same colour, but at a certain state of dilution, the colour disappears. The anhydrous stannibromides of potassium and ammonium only suffer change in very moist air; others are very deliquescent. Concentrated solutions may be heated without decomposition; on dilution, decomposition occurs with the formation of hydrobromic acid and the deposition of hydrated tin dioxide. Alcohol decomposes these compounds, slowly in the cold, more rapidly on heating; benzene has no action on them.

The general method for the preparation of the stannibromides consists in mixing concentrated solutions of the two bromides and evaporating the mixture in a vacuum or in dry air.

The ammonium salt, $(NH_4)_2SnBr_6$, forms sulphur-yellow octahedra belonging to the cubic system; it decrepitates when heated, and volatilises with partial decomposition.

The sodium salt, $Na_2SnBr_6 + 6H_2O$, forms yellow prisms of the monoclinic system, having a position of extinction in polarised light at 15° to the longer axis. It is very deliquescent, but effloresces rapidly over sulphuric acid or in a vacuum. It decomposes, when heated, with evolution of water and stannic bromide.

The lithium salt is probably $Li_2SnBr_6 + 6H_2O$, but the water cannot be accurately determined owing to the extreme deliquescence of the compound. It forms small, yellow, prismatic needles which act on polarised light, and appear to belong to the monoclinic system. Over sulphuric acid, these crystals effloresce, giving a citron-yellow, crystalline powder tending towards the composition $Li_2SnBr_6 + 5H_2O$.

The magnesium salt, $MgSnBr_6 + 10H_2O$, gives small, sulphur-yellow, monoclinic crystals. The ordinary form is a prism showing the faces g_1 and h_1 with modifications on the angle a. Macles are frequent. Extinction occurs at an angle of 60°.

The study of the alkaline earthy stannibromides is being now carried on. W. T.

Dissolution of Bismuth Chloride in a Saturated Solution of Sodium Chloride: Basic Bismuth Salicylate. By H. Causse (*Compt. rend.*, **113**, 547—549).—Sodium chloride, like ammonium chloride, may be employed instead of free acid to prevent the dissociation of bismuth salts by water. Hence, in presence of sodium chloride, hydrochloric acid may be completely neutralised by bismuth carbonate or oxide. 100 c.c. of hydrochloric acid solution containing 3·0775 grams HCl is left in contact with 3 grams of bismuth oxide until no further solution takes place; the remaining oxide is collected and weighed. 1·50 grams of the oxide are dissolved, requiring 0·4775 gram of the acid to form $BiCl_3$; the remaining 2·60 grams of the hydrochloric acid are required to maintain the equilibrium in the solution.

With 100 c.c. of acid containing 6·155 grams HCl, 6·00 grams of oxide are dissolved, and 3·117 grams of free acid remain. With 100 c.c. of acid containing 9·2325 grams HCl, 10 grams of oxide are dissolved, and 4·557 grams of acid remain. Each of these solutions is saturated with common salt, and then treated with bismuth oxide. The quantities of bismuth oxide dissolved as compared with the quantities required to neutralise the hydrochloric acid present with production of bismuth trichloride are respectively 6·80 : 6·584, 13·25 : 13·160, and 20·25 : 19·70.

The numbers given above do not show that any definite relation exists between the free acid and the amount of bismuth chloride formed. To ascertain whether such a relation exists at the experimental limit, the author treats 50 grams of oxide with 50 c.c. of saturated hydrochloric acid containing 22·80 grams of acid. 47·50 grams of oxide are dissolved, and 5·18 grams of free acid remain. 5·40 grams of acid would be uncombined if the reaction were as follows: $Bi_2O_3 + 8HCl = 2(BiCl_3,HCl) + 3H_2O$; hence the author concludes that under these circumstances a definite salt is formed.

To obtain basic bismuth salicylate, 40 c.c. of concentrated hydrochloric acid is saturated with bismuth oxide in presence of 500 c.c. of saturated sodium chloride solution; to another 500 c.c. of brine are added 9 grams of soda and 22 grams of sodium salicylate, the two solutions are mixed, and the precipitate formed is washed with water containing a few drops of nitric acid. The basic salicylate, $C_7H_5BiO_4,H_2O$, obtained, forms microscopic prisms, and has properties similar to those of the normal salicylate previously described. It is decomposed by heat with loss of the whole of its salicylic acid, which may also be completely eliminated by boiling concentrated alcohol. The constitution of this salt may be represented by the formula $OH\cdot C_6H_4\cdot COO\cdot Bi(OH)_2$, which accounts for its ready hydrolysis. W. T.

Mineralogical Chemistry.

Boléite, a New Mineral. By MALLARD and E. CUMENGE (*Compt. rend.*, **113**, 519—524).—This mineral occurs in cubical crystals of a fine indigo-blue colour in an argillaceous matrix, termed *jaboncillo*, next above the true copper-bearing bed of Boleo, near Santa Rosalia, Lower California. The crystals are accompanied by anglesite, phosgenite, cerussite, and atacamite. They are not decomposed by water; they melt in a candle flame, and, when heated in a closed tube, decompose with evolution of water.

Two analyses of clean samples yield the numbers :—

	I.	II.	Calculated.
Silver	8·85	8·70	8·50
Copper	13·95	14·50	15·00
Lead	48·45	49·75	48·90
Chlorine	19·98	19·00	19·55
Water	4·77	4·00	4·28
Oxygen (by diff.)	4·00	4·05	3·77

The calculated percentages correspond with the formula $3[PbCl\cdot OH,CuCl\cdot OH] + AgCl$. Metallic copper is obtained by reduction in a current of dry hydrogen without the liberation of hydrochloric acid; this would seem to indicate that the chlorine is not combined with the copper, but, in reality, the hydrochloric acid formed immediately reacts on the lead oxychloride, producing lead chloride and water. The formula given best shows the relationships of this mineral to laurionite, $PbCl\cdot OH$, and atacamite,

$$CuCl\cdot OH,Cu(OH)_2.$$

Brooke's percylite, from Sonora, may possibly be the same mineral, although its imperfect analyses do not indicate the presence of silver.

In hardness, the mineral is a little superior to calcite, and its density is 5·08. The common form is the cube without modifying faces. Some crystals show very sharp and brilliant octahedral faces; more rarely, dodecahedral faces are met with. Some small crystals have been observed with the edges replaced by re-entering angles formed by faces of the hexakistetrahedron. The cleavage is distinct and easy, parallel to the faces of the cube, the octahedral cleavage being less distinct. The observed optical properties are those of very birefringent, negative, uniaxial crystals; the index of refraction could not be accurately determined; for a prism formed by the cubical and dodecahedral faces, its approximate value is 2·07. Boléite belongs to the tetragonal system, though pseudo-cubic in habit.

Along with the cubical crystals, octahedral crystals occur in peculiar groupings, showing the octahedral faces brilliant, but generally formed of three facettes, composing a low pyramid.

The angular measurements are difficult, and only yield approximately the values for the parameters, $a : c = 1 : 1{\cdot}645$. The composition of the octahedral crystals is the same as that of the cubical crystals:—

	Cubic cryst.	Octahedral cryst.	Calculated.
Silver.....	9·2	9·4	8·5
Copper.....	14·8	15·0	15·0
Lead.....	50·2	50·7	48·9
Chlorine.....	19·4	19·7	19·5

Their densities appear to be about the same, a small specimen of the octahedral crystals giving 5·0. W. T.

Polydymite, Ullmannite, and Wolfsbergite. By H. Laspeyres (*Zeit. Kryst. Min.*, **19**, 417—436).—1. *Polydymite.*—The author brings forward fresh evidence in support of the formula Ni_4S_5 he propounded 15 years ago for polydymite and nickel-bismuth glance, minerals which he regards as identical. The accuracy of this formula is confirmed by the analysis of the polydymite from Sudbury, in Canada, as well as by the examination of some excellent crystals of this mineral from the Grüneau mine, in the Siegen district.

2. *Ullmannite.*—The author describes some crystals of ullmannite, from the Landeskrone mine, near Siegen. Although this mineral is of frequent occurrence in the Siegen mines, it has never before been found in crystals.

3. *Wolfsbergite.*—Of the crystalline form of the copper-antimony glance (Wolfsbergite), from Wolfsberg, in the Harz, all that is known is the brief account given by G. Rose in 1835. A discovery of a well-crystallised specimen in the Bonn Museum has enabled the author to give a detailed description of the crystallography of this mineral. The forms he has observed are:—0P, $\frac{3}{2}\bar{P}\infty$, $\bar{P}\infty$, $2\bar{P}\infty$, $\breve{P}\infty$, $\frac{7}{4}\breve{P}2$, $\frac{5}{3}\bar{P}\frac{5}{3}$, $\frac{7}{6}\breve{P}3$. The axial ratio is $a : b : c = 0{\cdot}52830 : 1 : 1{\cdot}62339$. B. H. B.

Some New Chilian Minerals: Darapskite, Lautarite, Iodochromate. By A. Dietze (*Zeit. Kryst. Min.*, **19**, 445—451).—1. *Darapskite.*—This is the name given by the author to a new double salt of the composition represented by the formula $NaNO_3 + Na_2SO_4 + H_2O$. It is colourless, transparent, and occurs in square tablets bevelled by tetragonal pyramids. The new mineral is found at the Pampa del Toro, and is named after Dr. L. Darapsky, the well-known mineralogist, of Santiago.

2. *Lautarite.*—Although it has long been known that the iodine contained in the *caliche* or raw nitrate is due to the presence of iodates, no iodate has hitherto been found as a distinct mineral species. The new mineral described by the author is calcium iodate, the analytical results being in accord with the formula $Ca(IO_3)_2$. It occurs at the "Pampa del Pique III," in the form of large, monoclinic prisms, having the sp. gr. of 4·59. It is transparent, and of a yellowish colour. It is very slightly soluble in water.

3. *Iodochromate.*—Near the chief locality of lauterite, small, yellow

crystals occur in the caliche. These prove on analysis to be a double iodate and chromate of calcium, of the formula $7Ca(IO_3)_2,8CaCrO_4$. The accuracy of this formula is shown by the results of seven analyses. B. H. B.

Formula of Axinite. By A. Kenngott (*Jahrb. f. Min.*, 1891, ii, Mem. 335—336).—In a recent paper (Abstr., 1891, 1168), the author published a formula for axinite calculated from two analyses given by Whitefield. This result he now compares with three analyses given by F. A. Genth (*Amer. J. Sci.*, **41**, 394). These analyses refer to axinite from Franklin, New Jersey, in crystals and in lamellæ, and from Guadalcazar, in Mexico. The analyses of axinite from Franklin give results closely approaching those obtained from Whitefield's analyses. The axinite from Guadalcazar, however, was apparently admixed with white felspar partially converted into kaolin, and, consequently, cannot be considered sufficiently pure to serve as the basis for the calculation of a formula. B. H. B.

Constitution of certain Micas, Vermiculites, and Chlorites. By F. W. Clarke and E. A. Schneider (*Amer. J. Sci.*, **42**, 242—251). —In a previous paper (Abstr., 1891, 529), the authors considered the constitution of the mica and chlorite groups. The present paper is a continuation of the same research. Throughout the investigation the fundamental hypothesis that the minerals studied are substitution derivatives of normal salts has been amply justified.

Of the so-called vermiculites, two only, jefferisite and kerrite, were considered in the former paper, and these were shown to be trihydrated micas in which the original alkalis had been replaced by hydrogen. The examination of other varieties shows that kerrite is essentially a trihydrated hydrophlogopite. Protovermiculite, from Magnet Cove, Arkansas, is the same substance mixed with an equal proportion of trihydrated hydroclintonite. Jefferisite is a similar mixture of hydrobiotite and hydroclintonite, also trihydrated. An altered biotite, from Henderson Co., North Carolina, is found to be essentially a biotite, about half way changed into a vermiculite, and is interesting as a transition product. All the vermiculites are not so simple as the above-named minerals. In some members of the group, there seems to be a small admixture of chloritic molecules, and it is even probable that many intermediate stages between mica and chlorite may exist. As bearing on this question, the authors give analyses of the hallite from Nottingham, Chester Co., Pennsylvania, and of the vermiculites from Lennie, Delaware Co., Pennsylvania. They also give the results of their examination of vermiculites from Newlin, Chester Co., and from Middletown, Delaware Co., in both of which Tschermak's view, that some of the vermiculites are probably chlorites, is partly sustained. A very interesting example of the way in which the chloritic vermiculites approach the serpentines in composition has been furnished by a specimen found at Old Wolf Quarry, Chestnut Hill, Easton, Pennsylvania, an analysis of which is given by the authors. Lastly, there is one other mineral examined during this investigation, a pale, yellowish-green mica, from

Auburn, Maine, where it occurs in direct contact with ordinary muscovite. Analysis shows that it has the composition of muscovite. The case is interesting as showing a secondary growth of muscovite on muscovite, with a marked difference in outward appearance between the two formations. B. H. B.

Genesis of Iron Ores by Replacement of Limestone. By J. P. Kimball (*Amer. J. Sci.*, **42**, 231—241).—The object of this memoir is to show that the well-recognised products of epigenesis, like siderite and ferrocalcite, are, as a rule, also products of direct pseudomorphous replacement of isomorphous calcium carbonate. From this it follows that secondary or indirect replacement of calcium carbonate by ferric hydroxide is wrought through alteration of pseudomorphous siderite or ferrocalcite, and also, through progressive alteration, by ferric oxide and even by magnetic oxide. As the result of his investigations, the author advances the proposition that deposits of concentrated iron ores occur far more extensively as pseudomorphous replacements than has hitherto been made to appear, and far more extensively than by original sedimentation of ferric hydroxide. B. H. B.

The Basalt of the Stempel, near Marburg. By M. Bauer (*Jahrb. f. Min.*, 1891, ii, Mem. 231—271).—This is the concluding instalment of an elaborate monograph (compare Abstr., 1891, 1440) on the basalt occurring at the hill known as the Stempel, which rises above the sandstone of the Lahn plateau. This section deals with the inclusions met with in the rock. These inclusions consist of limestone, quartz, apatite, nepheline, felspar, amphibolite, titanite, and zircon. B. H. B.

Organic Chemistry.

Preparation of Bromoform from Acetone and Sodium Hypobromite. By G. Denigès (*J. Pharm.* [5], **24**, 243—247).—A litre flask is charged with 100 c.c. of soda lye, 200 c.c. of water, and then 20 c.c. of bromine. After gentle shaking from time to time, the liquid becomes uniformly yellow, when sufficient acetone (about 10 c.c.) is added to decolorise the solution. There is quickly formed an almost colourless layer of bromoform. The product is washed repeatedly with water, from which it can be easily separated by filtration, and the compound is usually pure enough for immediate employment. The reaction takes place in two stages: sodium hypobromite and sodium bromide are first formed; then the hypobromite and acetone react, forming bromoform, sodium acetate, and sodium hydroxide. The yield is 60—70 per cent. of that theoretically possible. The bromoform should be removed from contact with hypobromite as soon as possible, otherwise carbon tetrabromide is

produced. A pure sample of bromoform boiling at 150 (768 mm.) had a density of 2·906 at 12° and 2·897 at 18°, or say 2·90 at about 15°, confirming Cahours' previous determination of 2·90 at 12°.

J. T.

Monobromobutylenes. By E. Reboul (*Compt. rend.*, **113**, 589—592).—When the bromide CHMeBr·CHMeBr, boiling at 150°, and obtained by the action of bromine on symmetrical dimethylene, CHMe:CHMe, is treated with alcoholic potash, it yields a mixture of the two bromobutylenes, CHMe:CMeBr and CHMeBr·CH:CH_2.

A new brombutylene, $CH_2Me{\cdot}CBr{:}CH_2$, is obtained by the removal of HBr from ethylethylene bromide. Normal bromobutane is mixed with one-third the theoretical quantity of bromine, together with water, and the mixture exposed to sunlight in a small, closed flask until it is colourless. The product is then distilled, and the fraction boiling below 160° is treated again with bromine in a similar manner. The successive products boiling above 160° are mixed and fractionated, when they yield ethylethylene bromide boiling at 166° and free from isomerides.

When ethylethylene bromide is treated with alcoholic potash in the ordinary manner, it yields monobromobutylene boiling at 88° under a pressure of 759 mm.; it is a colourless liquid with an alliaceous odour; sp. gr. 1·282 at 21°. Since the boiling point is 3° below that of Boutlerow's bromisobutylene, CMe_2:CHBr, it is almost certain that it has the bromine at the end of the chain that is removed from the ethylethylene bromide. If the compound is heated at 100° in a sealed tube with alcoholic potash, it yields a light, mobile liquid which has a strong alliaceous odour, and boils at 14—14·5° under a pressure of 761 mm. With ammoniacal cuprous chloride, it forms a deep sulphur-yellow compound, and with ammoniacal silver nitrate, a white compound, both of which yield the hydrocarbon when treated with dilute acids. The hydrocarbon is probably identical with the ethylacetylene obtained by Bruylants from methyl ethyl ketone chloride.

In view of this decomposition, the monobromobutylene may be called ethylacetylene α-hydrobromide. It combines with bromine with great energy, yielding a tribromobutane, $CH_2Me{\cdot}CBr_2{\cdot}CH_2Br$, which boils at 112—115° under a pressure of 40 mm. and with partial decomposition at 214—218° under the ordinary pressure; it is a colourless liquid of sp. gr. 2·136 at 17°. It is not identical with the product of the action of bromine on normal butyl bromide in presence of sunlight; the latter boils at 117—122° under 40 mm., and its sp. gr. at 17° is 2·171.

Ethylacetylene α-hydrobromide combines slowly with aqueous hydrobromic acid in the cold, but more rapidly at 100°, yielding a mixture of the bromide boiling at 166° and a lower bromide, probably $CH_2Me{\cdot}CMeBr_2$. Boutlerow's bromisobutylene behaves differently under similar conditions.

C. H. B.

Penterythritol: a Tetrahydric Alcohol obtained from Formaldehyde and Acetaldehyde. By B. Tollens and P. Wigand (*Annalen*, **265**, 316—340).—A crystalline compound, which the

authors name penterythritol, is formed, together with volatile fatty acids, amorphous, syrupy substances, aldehydes, and small quantities of a crystalline substance, the nature of which has not yet been determined, when a mixture of formaldehyde (194 grams), acetaldehyde (60 grams), water (9 litres), and calcium hydroxide (160 grams) is kept for one to two months, or longer, at the ordinary temperature with frequent shaking. The boiling, filtered solution is treated with a quantity of oxalic acid exactly sufficient to precipitate the calcium in solution, then filtered, and evaporated to a syrup; on keeping for some time, the residue solidifies to a mass of yellowish crystals, and is purified by recrystallisation from water with the addition of animal charcoal. The yield of the crude, crystalline product, dried on porous earthenware, is about 115 grams.

Penterythritol, $C_5H_8(OH)_4$, crystallises from hot water in large, well-defined prisms, melts at 250—255°, and is soluble in about 18 parts of water at 15°; its molecular weight was determined in glacial acetic acid solution with results in accordance with the molecular formula ascribed to it above. Its aqueous solution is optically inactive, even in presence of borax; when a neutral aqueous solution of penterythritol is added to a small quantity of a solution of borax, the latter acquires a distinctly acid reaction. When penterythritol is heated quickly, it gives off an odour recalling that of decomposing glycerol; it does not give the iodoform reaction. The *tetracetyl* derivative, $C_5H_8(OAc)_4$, prepared by heating the alcohol with acetic anhydride and sodium acetate, is a crystalline substance melting at 84°; molecular weight determinations in acetic acid solution gave results agreeing with those required by a compound of the molecular formula given above.

The di-iodhydrin, $C_5H_8I_2(OH)_2$, is formed when penterythritol is heated with concentrated hydriodic acid and amorphous phosphorus at 170—180°; it forms colourless crystals, melts at 130°, and is readily soluble in alcohol, but only sparingly in water. The tri-iodhydrin, $C_5H_8I_3{\cdot}OH$, is produced, together with the tetriodide described below, when penterythritol is heated with concentrated hydriodic acid and amorphous phosphorus at 190° in sealed tubes; when the product is boiled with water, the residue dissolved in alcohol, and the cold solution evaporated, large, rhombic plates melting at 70° are deposited; if these crystals of the tri-iodhydrin are dissolved in hot alcohol, and the solution then allowed to cool, the compound is obtained in lustrous needles melting at 62°. The *tetriodide*, $C_5H_8I_4$, is isolated by extracting that portion of the product which is insoluble in alcohol with boiling benzene, from which it is deposited on cooling in colourless plates melting at 225°.

When penterythritol is oxidised with nitric acid, it gives oxalic acid and an amorphous product the nature of which has not been determined; when treated with chromic acid, it yields formic acid and carbonic anhydride. The constitution of the alcohol is most probably expressed by the formula $C(CH_2{\cdot}OH)_4$. F. S. K.

A Sugar from Quince-juice. By R. W. Bauer (*Landw. Versuchs-Stat.*, 469—470).—When quince-juice is boiled with 5 per cent.

sulphuric acid, it yields a sweet syrup which has approximately the same rotatory power as dextrose, and from which a yellow osazone melting at 204° can be obtained. F. S. K.

Cellulose Gum. By W. Hoffmeister (*Landw. Versuchs-Stat.*, **39**, 461—468; compare Abstr., 1890, 581).—When cellulose, prepared in the usual manner, by extracting certain vegetable products with ether, alcohol, water, and cold dilute ammonia successively, is treated with 5 per cent. soda, a considerable, but variable, quantity of wood gum passes into solution; this gum is completely soluble in an ammoniacal solution of copper oxide, and is not destroyed by the "chlorine mixture" previously referred to. If, after extracting with soda, the cellulose is dissolved in an ammoniacal solution of copper oxide, and reprecipitated with hydrochloric acid in the cold, or if it is treated with the chlorine mixture, glacial acetic acid, or dilute ammonia, to free it from incrusting substances, it again yields a considerable quantity of soluble carbohydrates on extraction with 5 per cent. soda; when the portion insoluble in soda is again treated with any of the above-named reagents, a further quantity is rendered soluble, and, by repeating the treatment many times, the whole of the cellulose is obtained in a form which is soluble in 5 per cent. soda.

The quantity which is rendered soluble by any single treatment depends on the source of the cellulose; it would seem, therefore, that cellulose is not a homogeneous substance. For the soluble product obtained in the manner described, Tollens proposes the name cellulose gum; this substance also exists in various forms. F. S. K.

Constitution of the Ligno-celluloses. By C. F. Cross and E. J. Bevan (*Chem. News*, **64**, 63—64).—Cold, dilute, aqueous chromic acid forms a compound with the substance of jute fibre, which by treatment with mineral acids is converted into a brittle, soft substance, lustrous and greenish in appearance, containing from 2 to 2·5 per cent. of chromic oxide, and convertible into an oxycellulose, the alkaline solution of which reduces Fehling's solution on boiling. The yield of the chromium compound from a fibre which gave 74 per cent. of cellulose by the chlorination method was 85—90 per cent., so that a portion of the jute convertible into soluble derivatives by chlorination, here appears to yield products more intimately connected with cellulose. The soluble products of the oxidation are brown, gummy substances, which, when chlorinated, yield substitution products having characteristic colour reactions. The formation of the chromium compound may be regarded as a step in the process of lignification.

The authors draw attention to the substance which Lindsey and Tollens (*Inaug. Diss., Göttingen*, 1891) have isolated from the gummy residue left on evaporation of the waste liquors from the Mitscherlich (bisulphite) fir-wood paper-pulp process; it has the composition

$$C_{24}H_{24}Me_2SO_{12},$$

and appears to be related to the ketonic substance, lignone, previously obtained from jute (Trans., 1889, **55**, 213). Jn. W.

Thio-derivatives of Ethylamine. By S. Gabriel (*Ber.*, **24**, 3098—3104; compare Abstr., 1891, 815).—The action of various substances on ethylmercaptophthalimide, $C_8H_4O_2{:}N{\cdot}CH_2{\cdot}CH_2{\cdot}SH$, has been studied.

A warm solution of ethylmercaptophthalimide (11 grams) in absolute alcohol (25 c.c.) is treated with sodium ethoxide (2·3 grams of sodium in 25 c.c. of alcohol) and bromethylphthalimide (14 grams), and boiled for half an hour in a reflux apparatus. The solution is cooled, and the crystals washed with alcohol and hot water; *diphthalimidoethyl sulphide*, $(C_8H_4O_2{:}N{\cdot}C_2H_4)_2S$, melting at 128—129°, is thus obtained, the yield being two-thirds of the theoretical.

When a solution of ethylmercaptophthalimide (20 grams) in alcohol (50 c.c.) is gradually heated with sodium ethoxide (2·3 grams of sodium in 50 c.c. of alcohol) and then with ethylene chlorhydrin (10 grams), boiled for half an hour in a reflux apparatus, the alcohol driven off, and the residue treated with water, a colourless syrup (20 grams), which will not crystallise, separates; it is doubtless *β-hydroxy-β-phthalimidoethyl sulphide*, $OH{\cdot}C_2H_4{\cdot}S{\cdot}C_2H_4{\cdot}N{:}C_8H_4O_2$. When warmed with double the volume of phosphorus oxychloride, it yields *β-chloro-β-phthalimidoethyl sulphide*, $C_2H_4Cl{\cdot}S{\cdot}C_2H_4{\cdot}N{:}C_8H_4O_2$, which separates out when the mass is poured into water as an oil that gradually crystallises. Recrystallised from acetic acid and alcohol, it forms colourless needles, melts at 76—77°, and dissolves easily in ether, benzene, carbon bisulphide, chloroform, and boiling light petroleum. *β-Bromo-β-phthalimidoethyl sulphide*,

$$C_2H_4Br{\cdot}S{\cdot}C_2H_4{\cdot}N{:}C_8H_4O_2,$$

is obtained in a similar manner by using the pentabromide, instead of the oxychloride, of phosphorus. It crystallises from hot light petroleum in long needles, melts at 89—90°, and dissolves readily in ethyl acetate, warm carbon bisulphide, and ethyl and methyl alcohol.

The oxidation of diphthalimidoethyl sulphide has also been studied. When a slight excess of bromine water is added to a solution of the sulphide (3 grams) in hot acetic acid (15 c.c.), *diphthalimidoethyl sulphoxide*, $(C_8H_4O_2{:}N{\cdot}C_2H_4)_2SO$, is formed, and separates, when the solution is cooled, in long needles melting at 191°. When this substance (18 grams) is boiled with 20 per cent. hydrochloric acid (250 c.c.) for three hours in a reflux apparatus, a complex decomposition takes place, resulting in the formation of diamidoethyl sulphoxide, taurine, ammonia, and thioethylamine; for details as to the separation of these, reference must be made to the original paper. *Diamidoethyl sulphoxide picrate*, $SO(C_2H_4{\cdot}NH_2)_2,2C_6H_3N_3O_7$, forms a yellow, crystalline powder which softens at 190°, and melts with decomposition at 200°. *Thioethylamine picrate*, $S(C_2H_4{\cdot}NH_2)_2,2C_6H_3N_3O_7$, forms long, broad prisms softening at 190°, and melting with decomposition at 213°. The *platinochloride*, $S(C_2H_4{\cdot}NH_2)_2,H_2PtCl_6$, forms orange-yellow needles. The *benzoyl* derivative, $S(C_2H_4{\cdot}NHBz)_2$, crystallises from ethyl acetate in scales which soften at 106° and melt at 109—110°.

When diphthalimidoethyl sulphide (6 grams) is dissolved in a

mixture of acetic acid (60 c.c.) and water (6 c.c.) on the water-bath, and chromic acid (5 grams) added, transparent, colourless crystals of *diphthalimidoethylsulphone*, $SO_2(C_2H_4{\cdot}N{:}C_8H_4O_2)_2$, separate (6 grams). This softens at 250°, melts at 255—256° and dissolves very sparingly in most solvents, slightly in hot acetic acid, and can be crystallised from hot nitrobenzene. The same compound may be obtained, although less conveniently, by oxidising an acetic acid solution of the sulphide with potassium permanganate. When the sulphone (3 grams) is heated with alcohol (20 c.c.) and 33 per cent. aqueous potash (3 c.c.), it dissolves, and *ethylsulphonediphthalamic acid* crystallises out when the solution is diluted with water, acidified with hydrochloric acid, and cooled. It forms broad, colourless needles, readily soluble in ammonia and boiling water. The *silver salt*, $SO_2(C_2H_4{\cdot}NH{\cdot}CO{\cdot}C_6H_4{\cdot}COOAg)_2$, forms an amorphous precipitate which changes to a crystalline powder. When the acid is boiled with hydrochloric acid, it is decomposed into phthalic acid and *diamidoethylsulphone*, the *hydrochloride* of which, $SO_2(C_2H_4{\cdot}NH_2)_2,2HCl$, is obtained by filtering and concentrating the solution. The *platinochloride*, $SO_2(C_2H_4{\cdot}NH_2)_2,H_2PtCl_6$, forms sparingly soluble, orange-red, hexagonal tables. The *picrate*, $SO_2(C_2H_4{\cdot}NH_2)_2,2C_6H_3N_3O_7$, crystallises in long needles softening above 170° and melting at 185°.

C. F. B.

δ-Chlorobutylamine, and a Synthesis of Pyrrolidine. By S. Gabriel (*Ber.*, **24**, 3231—3235).—δ-Chlorobutylamine may be prepared from γ-chlorobutyronitrile in the following manner :—35 grams of γ-chlorobutyronitrile is mixed with 32 grams of phenol, and added to a solution of 8 grams of sodium in 100 grams of alcohol. After boiling for an hour, the alcohol is distilled off, water added, and the oily layer which separates taken up with ether and fractionated ; the fraction boiling at 285—290° consists of *γ-phenoxybutyronitrile*, $OPh{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CN$, and solidifies on cooling to crystals melting at 45—46°. The same compound has been obtained by Lohmann from γ-bromopropyl phenyl ether (Abstr., 1891, 1467). On reduction with sodium in alcoholic solution, this compound yields *δ-phenoxybutylamine*, $OPh{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2$, a colourless, alkaline oil, boiling at 254—257°, which is converted by hydrochloric acid at 180—185° into phenol and *δ-chlorobutylamine hydrochloride*,

$$CH_2Cl{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2,HCl.$$

The former is extracted with ether, and the acid aqueous solution evaporated ; the oily residue solidifies after some time to a crystalline mass which deliquesces in the air, and may be purified by dissolving it in hot amyl alcohol and adding ethyl acetate. The *picrate*, $C_4H_{10}NCl,C_6H_3N_3O_7$, forms amber-yellow, oblique prisms or plates, and melts at 120—121° ; and the *platinochloride*, $(C_4H_{10}NCl)_2,H_2PtCl_6$, crystallises in orange scales.

When δ-chlorobutylamine hydrochloride is treated with more than 2 mols. alkali in aqueous solution, and steam passed through the liquid, a base distils over, having an odour closely allied to that of piperidine ; it boils at 87·5—88·5°, has the sp. gr. 0·8520 at 22·5°, mixes with water forming a strongly alkaline solution, and fumes in

the air. Its *platinochloride*, $(C_4NH_9)_2,H_2PtCl_6$, crystallises in compact, yellowish-red prisms, which become dark at 190°, and melt at about 200°; the *aurochloride*, $C_4NH_9,HAuCl_4$, becomes plastic at 200° and melts at 205—206° with decomposition; the *picrate*, $C_4NH_9,C_6H_3N_3O_7$, becomes plastic at 105°, and melts at 111—112°; and the *cadmioiodide*, $(C_4NH_9)_2,H_2CdI_4$, forms long, silky needles which become plastic at 210°, and melt at 217—219°. These properties agree, except in the case of the cadmioiodide, with those ascribed by Ladenburg (Abstr., 1886, 528; 1887, 499, 1052) and by Petersen (Abstr., 1888, 498) to pyrrolidine, with which it must therefore be identical. That it is not the isomeric butallylamine, $CH_2{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2$, is shown by the fact that it does not decolorise bromine-water in acid solution.

H. G. C.

Action of Nitrous Acid on Nonylamine. By M. Freund and F. Schönfeld (*Ber.*, **24**, 3350—3366).—Methylhexylcarbinol is prepared by heating castor oil (100 parts) with 15 per cent. potash (150 parts) for half an hour; water (200 parts) is then added gradually, and after remaining for some time the product crystallises. These crystals (500 grams) are mixed with finely powdered potassium hydroxide (170 grams), and the whole rapidly distilled; the distillate is finally dried over potassium hydroxide and fractionated. The pure alcohol boils at 176·5—177°. The iodide is obtained by treating the alcohol with hydrogen iodide at 60°; the yield is almost quantitative. The cyanide, $CN{\cdot}CHMe{\cdot}C_6H_{13}$, is formed from the iodide by the action of potassium cyanide; the actual yield is 14—15 per cent. of the theoretical. It is suggested by the authors that methyl cyanide should be termed *carbin cyanide*, and that the names of the higher homologues should be derived from this in a similar manner to that prevailing in the case of the alcohols; the above compound would therefore be termed *methylhexylcarbin cyanide*.

Nonenylamidoxime, $NH_2{\cdot}C(:NOH){\cdot}C_8H_{17}$, is prepared by the action of hydroxylamine hydrochloride and sodium ethoxide on the preceding compound; it crystallises from light petroleum in short, square prisms, and melts at 84°.

Nonylamine, $NH_2{\cdot}CH_2{\cdot}CHMe{\cdot}C_6H_{13}$, is obtained by the reduction of the cyanide with sodium in alcoholic solution, and is purified by means of the hydrochloride; it is a colourless liquid with a fishy odour, and boils at 185—186°. The *hydrochloride* crystallises from light petroleum, and melts at about 130°; the *platinochloride* is deposited from its alcoholic solution in yellow needles.

Nonyldithiocarbamic acid is deposited in crystals on mixing nonylamine with carbon bisulphide.

Nonylcarbamide, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_9H_{19}$, crystallises from water in colourless, lustrous, square prisms which melt at 92°. *Dinonyloxamide*, prepared by the action of nonylamine on ethyl oxalate in ethereal solution, crystallises from alcohol in small, colourless needles, and melts at 92°.

Phenylnonylcarbamide, $NHPh{\cdot}CO{\cdot}NH{\cdot}C_9H_{19}$, is deposited from dilute alcohol in groups of long, prismatic crystals, and melts at 63°.

Phenylnonylthiocarbamide, $NHPh{\cdot}CS{\cdot}NH{\cdot}C_9H_{19}$, crystallises from dilute alcohol in small plates, and melts at 58—60°.

Nonylamine hydrochloride in aqueous solution is digested with argentic nitrite in excess at temperatures below 50°, and the clear solution distilled; nitrogen is evolved, and on drying and fractionating the distillate, two portions are obtained, the one boiling at 135—150°, the other at 170—192°. The lower fraction consists of *β-methylhexylethylene*, $CH_2{:}CMe{\cdot}C_6H_{13}$; it boils at 141·5—143°, has the sp. gr. = 0·7318 at 11°/11°, and readily absorbs bromine at ordinary temperatures. The constitution of the compound is shown by the mode of its formation. The higher boiling portion of the distillate proved to be *dimethylhexylcarbinol*, $C_6H_{13}{\cdot}CMe_2{\cdot}OH$; this boils at 183—184°, has a sp. gr. of 0·8211 at 12°/12°, and combines with barium oxide. The yield of alcohol is increased by allowing the mixture of nonylamine hydrochloride and argentic nitrite to remain for three days at the ordinary temperature, the reaction being then completed by gently warming.

On oxidation with dilute sulphuric acid and potassium dichromate, dimethylhexylcarbinol yields carbonic anhydride, acetic acid, and caproic acid, thus proving its constitution; with hydrogen iodide, the corresponding *iodide*, $C_6H_{13}{\cdot}CMe_2I$, is formed, and yields, on heating with alcoholic potash, a hydrocarbon which boils at 140—144°; whether the latter is identical with the one described above (b. p. 141·5—143°), or whether it is *α-dimethylheptylethylene*, $CMe_2{:}CH{:}C_5H_{11}$, could not be determined. J. B. T.

Formation of Tetralkylammonium Iodides. By H. Malbot and A. Malbot (*Compt. rend.*, **113**, 554—556).—The three types of reaction between amines and ethereal salts pointed out by one of the authors do not appear to depend on the nature of the alcohols from which the salts and amines are derived. Trimethylamine reacts in the cold with normal propyl iodide, primary isobutyl iodide, primary isoamyl iodide, primary allyl iodide, and secondary isopropyl iodide. The reaction proceeds comparatively rapidly, but is favoured by heating to 100°.

The solutions of the tetralkylammonium iodides formed are precipitated when added to potash; they are not decomposed by boiling with the latter. With silver oxide (not necessarily freshly prepared), they all yield hydroxides. The platinochlorides are generally insoluble in alcohol.

Normal propyl iodide reacts with methylamine more rapidly than isoamyl iodide, and still more rapidly than isobutyl iodide. Isopropyl iodide, although secondary, reacts more rapidly than primary isobutyl iodide. With allyl iodide, the reaction is very violent, like its reaction with bromine.

The union between certain systems of amines and ethereal salts is accompanied by elimination of hydrocarbons, due not so much to the decomposition of the ethereal salt by heat as to a new type of reaction occurring, which corresponds with a greater development of energy (compare *Ann. Chim. Phys.* [6], **13**, 451). W. T.

Benzoyl Derivatives of Glucosamine. By G. Pum (*Monatsh.*, **12**, 435—440).—The author confirms the statement of Kueny (Abstr., 1890, 578), that glucosamine hydrochloride does not form benzoyl derivatives when it is heated for a long time with excess of benzoic anhydride.

Pentabenzoyl glucosamine, $C_6H_8Bz_5NO_5$, is obtained when glucosamine hydrochloride (15 grams) is dissolved in water (60 parts), and the solution shaken with 10 per cent. sodium hydroxide (420 c.c.) and benzoic chloride (60 c.c.). It crystallises in snow-white, slender needles, is insoluble in water, dissolves in hot alcohol and acetic acid, and is reconverted into glucosamine hydrochloride and benzoic acid when treated with concentrated hydrochloric acid. The pure substance melts at 203°; but the author found that, on recrystallising from acetic acid the crude product obtained in one operation, a melting point of 215° was shown. The substance of higher melting point does not appear to differ in composition from that which melts at a lower temperature (compare Kueny, *loc. cit.*). G. T. M.

Chloralimide. By R. Schiff (*Gazzetta*, **21**, 490—497).—Pinner and Fuchs (Abstr., 1877, 584), by the action of ammonium acetate on chloral hydrate, obtained a substance of very indefinite melting point which they supposed to be chloralimide, $CCl_3{\cdot}CH{:}NH$. The author finds this to be a mixture.

Chloral hydrate (3 parts) and ammonium acetate (2 parts) are fused together on the water-bath, the product cooled, and then poured into water; about one-fifth of the mass remains undissolved as a yellow solid. On crystallising this from alcohol, Pinner and Fuchs' chloralimide is obtained; it begins to melt at 80°, and finally melts with decomposition towards 200°. On fractional crystallisation from alcohol, it is split into three distinct compounds melting at 146°, 97°, and 225° respectively. If the heating on the water-bath in the preparation of the mixture be too prolonged, the substance melting at 97° cannot be detected in the product.

The compound melting at 146°, on analysis and determination of its molecular weight by the cryoscopic method in acetic acid solution, is found to be *trimolecular chloralimide*, $(CCl_3{\cdot}CH{:}NH)_3$.

The substance melting at 97° is, in a similar manner, found to be *dimolecular chloralimide*, $(CCl_3{\cdot}CH{:}NH)_2$; on heating to above 146°, it is wholly converted into the trimolecular compound. When the trimolecular compound is heated with acetic anhydride, colourless needles, sparingly soluble in the usual solvents, and melting with decomposition at 235°, are obtained. This is *trimolecular diacetylchloralammonia*, $[CCl_3{\cdot}CH(OAc){\cdot}NHAc]_3$; the mother liquors contain the simple diacetylchloralammonia previously described by the author (Abstr., 1877, 308). When dimolecular chloralimide is employed in place of the trimolecular compound, the same products are obtained.

The compound melting with decomposition at 225° has the composition $C_6H_6Cl_5N_3O$, and seems to be formed by the mutual action of trimolecular chloralimide and ammonium acetate. W. J. P.

Amidoximes and Azoximes. By F. Tiemann (*Ber.*, **24**, 3420—3426).—This paper is an introduction to the following papers. The author has observed that the reaction between orthocyanobenzyl cyanide and hydroxylamine is not normal. Under varying conditions, only 1 mol. of hydroxylamine reacts with 1 mol. of orthocyanobenzyl cyanide, and the product of the reaction does not behave like an amidoxime containing an intact cyano-group, but has properties which show that the cyano- and amidoxime-groups have reacted on each other. The author puts forward two possible formulæ for this compound, $NH{:}C<\begin{matrix}C_6H_4\cdot CH_2\\ O\text{——}N\end{matrix}>C\cdot NH_2$ and $NH_2\cdot C<\begin{matrix}C_6H_4\cdot CH_2\\ NH\\ O\text{——}N\end{matrix}>C.$

An examination of the amidoximes shows that scarcely one, when prepared from the corresponding nitrile, can be isolated as such, since the amidoxime group at once reacts with another group which is present. Thus, hydroxylamine and ethyl orthocyanobenzoate do not react to form ethyl benzenylamidoximeorthocarboxylate,

$$COOEt\cdot C_6H_4\cdot C(NOH)\cdot NH_2,$$

but alcohol is eliminated, and phthalimidoxime, $CO<\begin{matrix}C_6H_4\\ NH\end{matrix}>C{:}NOH$, is produced. The latter is easily converted into phthalimide by the action of ferric chloride and hydrochloric acid, or of nitrous acid.

Rosenthal (*Ber.*, **22**, 2983) has shown that hydroxylamine reacts with a cyano-group contained in a carbon side chain, rather than with one in the benzene nucleus. Hence, orthocyanobenzyl cyanide should first yield orthocyanophenylethenylamidoxime, $CN\cdot C_6H_4\cdot CH_2\cdot C(NOH)\cdot NH_2$, from which a compound of the formula $NH{:}C<\begin{matrix}C_6H_4\cdot CH_2\\ NH\text{——}\end{matrix}>C{:}NOH$ would be formed.

If the latter compound were then converted into a stable isomeride which does not contain a free oximido-group, does not lose ammonia under the action of acids and bases, and has slight basic properties, this compound will probably have the constitution expressed by the second formula given above. The author reserves the further consideration of this compound for a later date.

In conjunction with F. Garny, he brings forward results in support of the above views.

Trimethylene cyanide is converted by hydroxylamine at 60—70° into the normal products, that is, glutarendiamidoxime,

$$NH_2\cdot C(NOH)\cdot CH_2\cdot CH_2\cdot CH_2\cdot C(NOH)\cdot NH_2,$$

and glutarenimidodioxime, $OH\cdot N{:}C<\begin{matrix}C_3H_6\\ NH\end{matrix}>C{:}N\cdot OH$.

If, however, molecular proportions are used, and the action is allowed to take place at the ordinary temperature, a compound is formed similar to that described above as obtained from orthocyanobenzyl cyanide. The author expresses the constitution of this compound by the formula $NH_2\cdot C<\begin{matrix}C_3H_6\\ NH\\ O\text{–}N\end{matrix}>C.$

If the reaction takes place at a somewhat higher temperature, ammonia is evolved, and glutarimidoxime, $CO<^{C_3H_6}_{NH}>C{:}NOH$, is formed.

Ethylene cyanide and hydroxylamine react in molecular proportion to yield succinimidoxime, $CO<^{C_2H_4}_{NH}>C{:}NOH$, just as glutarimidoxime is formed from trimethylene cyanide.

Succinimidoxime is also easily obtained by the action of nitrous acid (1 mol.) on succinenimidodioxime; by the further action of nitrous acid, succinimide is obtained. The author points out that this reaction supports the formula $\begin{matrix}CH_2\cdot CO\\ |\\ CH_2\cdot CO\end{matrix}>NH$ for succinimide.

Glutarimidoxime is obtained in an analogous way from glutarenimidodioxime.

In the glutaric series, the tendency to ring formation is so great that glutarimidoxime is produced by replacing an oximido-group in glutarendiamidoxime by oxygen, and evaporating the solution of butenylamidoximecarboxylamide so produced.

Succinimidoxime cannot be prepared in this way. By the action of hydroxylamine on succinimide, succinaminehydroxamic acid is first formed, and then 2 mols. condense to form disuccinimidodihydroxamic acid, $NH(CO\cdot CH_2\cdot CH_2\cdot CO\cdot NH\cdot OH)_2$.

In conjunction with H. Modeen, the author has examined the action of hydroxylamine on ethyl cyanacetate, and finds that the product consists of methenylamidoximacetohydroxamic acid,

$$OH\cdot N{:}C(NH_2)\cdot CH_2\cdot CO\cdot NH\cdot OH,$$

a compound which is both an amidoxime and hydroxamic acid.

Finally, in conjunction with L. Michaelis, the author has prepared nicotenylamidoxime, $C_5NH_4\cdot C(NH_2){:}NOH$ (see this vol., p. 206), from β-cyanopyridine. It is more stable than the aliphatic amidoximes, and behaves like benzenylamidoxime. E. C. R.

Action of Hydroxylamine on Derivatives of Succinic and Glutaric Acids. By F. Garny (*Ber.*, **24**, 3426—3437).—Ethylene cyanide, the compound from which the first series of compounds described in this paper is derived, is prepared according to Pinner's method, by heating equal weights of ethylene bromide and potassium cyanide in alcoholic solution for two hours in a reflux apparatus on the water-bath. The mixture is kept neutral by successive additions of dilute sulphuric acid. The product is then fractionally distilled.

Succinimidoxime, $CO<^{C_2H_4}_{NH}>C{:}NOH$, is prepared by digesting ethylene cyanide (1 mol.), dissolved in alcohol, with an aqueous solution of hydroxylyamine hydrochloride (1 mol.) and sodium carbonate ($\frac{1}{2}$ mol.) for eight hours at 60—70° in a closed vessel; on evaporating the solution to dryness, ammonia is evolved; the residue is extracted with absolute alcohol and filtered hot. On cooling, the

compound separates in white crystals, melts at about 197° with decomposition, and turns brown before melting. It is soluble in water, sparingly so in hot alcohol, insoluble in ether, benzene, light petroleum, and chloroform, has both acid and basic properties, and dissolves in sodium hydroxide solution with a bluish-green coloration. The *hydrochloride* is soluble in alcohol, crystallises in radiating needles, and melts at 98°. The *picrate* is precipitated on allowing a concentrated solution of succinimidoxime and picric acid to remain some time, and melts at 212°. Silver nitrate gives no precipitate. The *copper* salt is moss-green; the *lead* salt white. With ferric chloride, it gives a reddish-brown coloration; when boiled with Fehling's solution, a reddish-brown, crystalline precipitate is obtained. It is converted into succinimide on adding sodium nitrite to an aqueous solution and then gradually adding hydrochloric acid to the well-cooled mixture.

Succinimidoxime is also prepared by the following methods :—

1. Drouin (*Compt. rend.*, **103**, 675) has obtained the nitrile of succinaminic acid by heating ethylene cyanide with alcoholic ammonia at 110°. This nitrile is treated with hydroxylamine hydrochloride, as described above; on evaporating the solution to dryness, ammonia is evolved, and on extracting the residue with absolute alcohol succinimidoxime is obtained.

2. Sembritzki (*Ber.*, **22**, 2958) has obtained succinendiamidoxime (m. p. 188°) by the action of hydroxylamine (2 mols.) on ethylene cyanide at the ordinary temperature; if, however, the mixture be heated, ammonia is eliminated and succinenimidodioxime is produced. The latter contains 2 mols. of water of crystallisation, and melts at 207°; after drying, it melts at 198°. Succinimidoxime is obtained by adding sodium nitrite (1 mol.) to this product, dissolved in hydrochloric acid.

Succinendiamidoxime is produced by the action of hydroxylamine (1 mol.) on ethylene cyanide (1 mol.) in the cold.

In the hope of preventing the hydrolysis of the succinimidoxime, which takes place when it is prepared according to the first method given above, ethylene cyanide dissolved in absolute alcohol was digested in a closed vessel for eight hours at 70° with hydroxylamine hydrochloride dissolved in absolute alcohol, and the quantity of sodium ethoxide required to neutralise the hydrochloric acid. But under these conditions succinendiamidoxime is formed.

The author draws attention to the fact that, although the mixture was heated, ammonia is not eliminated from both amidoxime groups; only a very small quantity of succinenimidodioxime could be detected.

Benzoylsuccinimidoxime, $CO<^{C_2H_4}_{NH}>C{:}NOBz$, is obtained by adding the equivalent quantity of benzoic chloride to succinimidoxime, dissolved in the calculated quantity of sodium hydroxide. The mixture is shaken as long as the odour of benzoic chloride can be detected, and then allowed to remain for 12 hours with dilute ammonia, in order to remove the benzoic acid which is formed. The precipitate is collected, dissolved in chloroform, and precipitated with petroleum,

and finally crystallised from chloroform. It forms a white powder, melts at 184°, is soluble in alcohol, benzene, and chloroform, sparingly so in ether, and insoluble in water and light petroleum. It dissolves in hydrochloric acid, but not in potassium hydroxide.

Glutarimidoxime, $CO<^{C_3H_6}_{NH}>C{:}NOH$.—Trimethylene cyanide, from which this compound is obtained, is prepared in the same way as ethylene cyanide, but the action is much slower.

Biedermann (*Ber.*, **22**, 2967) obtained glutarendiamidoxime (m. p. 233°) and glutarenimidodioxime (m. p. 193°) by the action of 2 mols. of hydroxylamine on trimethylene cyanide at 60—70°. By the action of 1 mol. of hydroxylamine on trimethylene cyanide at the ordinary temperature, he obtained a compound which is isomeric with γ-cyanobutenylamidoxime, and melts at 103°.

In order to obtain a compound of the glutaric series analogous to succinimidoxime, trimethylene cyanide (1 mol.) is digested in a closed vessel with hydroxylamine (1 mol.) and sodium carbonate ($\frac{1}{2}$ mol.) in dilute alcohol for eight hours at 60—70°. On cooling, a precipitate is obtained, which consists mainly of glutarendiamidoxime. Ammonia is evolved when the filtrate is evaporated to dryness, and glutarimidoxime is obtained by extracting the residue with absolute alcohol. It melts at 196°, is soluble in hot water and alcohol, almost insoluble in ether, benzene, light petroleum, and chloroform, and dissolves both in hydrochloric acid and potassium hydroxide. Silver nitrate gives no precipitate. The *copper* salt is bright green; the *lead* salt white. With ferric chloride, it gives a brown, with Fehling's solution a green coloration, but no precipitate is formed. When dissolved in hydrochloric acid and treated with the calculated quantity of sodium nitrite, it yields glutarimide; the latter crystallises from alcohol and melts at 152°.

Glutarimidoxime can also be prepared by treating glutarendiamidoxime dissolved in hydrochloric acid with sodium nitrite.

The compound melting at 103°, and described by Biedermann, is not formed under the above conditions.

Benzoylglutarimidoxime is obtained in the same way as benzoylsuccinimidoxime. It crystallises from alcohol in needles, melts at 160°, and is soluble in alcohol, benzene, and chloroform, almost insoluble in ether, and insoluble in water and light petroleum. It dissolves in hydrochloric acid, but not in potassium hydroxide.

Disuccinimidodihydroxamic acid, $NH{\cdot}(CO{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}OH)_2$, is obtained by digesting succinimide (1 mol.) with hydroxylamine hydrochloride (1 mol.) and sodium carbonate ($\frac{1}{2}$ mol.) at 60—70°. The product is evaporated to dryness and extracted with alcohol; on allowing the alcohol to evaporate slowly, beautiful, lustrous needles of the new compound are obtained. It melts at 171°, is very soluble in water, less so in hot alcohol, and only sparingly in ether; it is insoluble in benzene, light petroleum, and chloroform. The aqueous solution has an acid reaction. With ferric chloride, it gives an intense, dark cherry-red coloration, characteristic of the hydroxamic acids. The vapour density cannot be determined, as the substance decomposes when heated above its melting point; neither can the molecular

weight be determined by Raoult's method. The *silver* salt is white, but rapidly blackens in the air. The *sodium* salt is formed by adding sodium ethoxide to an alcoholic solution of the acid. The *copper* salt is bright green, the *lead* salt white. When boiled with hydrochloric acid, it is converted into succinic acid. The *picrate* forms yellow needles, and melts at 266°. The *tetrabenzoyl* derivative melts at 123°, and is soluble in alcohol, ether, benzene, light petroleum, and chloroform, very sparingly so in hot water.

In the hope of obtaining succinhydroxamic acid, succinamide was treated at 60—70° with free hydroxylamine (1 mol.), but under these conditions also disuccinimidodihydroxamic acid is formed.

E. C. R.

Action of Hydroxylamine on Ethyl Cyanacetate. By H. Modeen (*Ber.*, **24**, 3437—3439).—Nitriles are converted by hydroxylamine into amidoximes; and certain ethereal salts are converted by hydroxylamine into hydroxamic acids, the ethereal group being eliminated as alcohol. According to Müller (*Ber.*, **18**, 2485, and **19**, 1491), aromatic compounds which are both nitriles and ethereal salts, when treated with hydroxylamine, are converted into amidoximes, and the ethereal group remains unattacked.

The author has examined the behaviour of ethyl cyanacetate, a cyano-ethereal salt of the aliphatic series, with hydroxylamine, and obtains a result quite different from that of Müller.

Methenylamidoximacethydroxamic acid,

$$OH{\cdot}N{:}C(NH_2){\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}OH,$$

is obtained by heating a clear alcoholic solution of ethyl cyanacetate (30 grams), hydroxylamine hydrochloride (40 grams), and sodium carbonate (82·3 grams) for 3—4 hours at 40°. On cooling, the compound separates in snow-white crystals. It crystallises in well-formed prisms, is insoluble in ether, ethyl and methyl alcohols, light petroleum, benzene, chloroform, carbon bisulphide, acetic acid, and acetone, sparingly soluble in cold water, easily so in hot water, sodium hydroxide, ammonia, and dilute hydrochloric, sulphuric, or nitric acid. It turns brown on heating, decomposes about 150°, and gives off ammonia when heated on platinum foil. The aqueous solution has an acid reaction, gives a deep-red coloration with ferric chloride, and a dirty-coloured precipitate with Fehling's solution.

Methenylamidoximacetohydroxamic acid is also formed by the action of hydroxylamine on ethyl cyanacetate at the ordinary temperature. If hydroxylamine insufficient to decompose the ethereal salt be employed, part of the latter remains unaltered; the rest is converted into the above compound. Hence the cyano- and carboxyethyl-groups are equally attacked. The author has prepared a number of derivatives of the new compound, and hopes to describe them at a later date.

E. C. R.

Saponification by Sodium Ethoxide. By K. Obermüller (*Zeit. physiol. Chem.*, **16**, 152—159; compare Abstr., 1890, 1474; 1891, 1143).—Saponification by sodium ethoxide is more rapid than by the methoxide (which is slowest) or the amyloxide. It was found

that the addition of ether to the mixture stops the process of saponification. The whole process can be divided into two stages, first, a formation of sodium glycerol and an ethyl salt of the fatty acid, which is more easily saponified than the fat; this is saponified by the sodium hydroxide which is formed from the sodium glycerol and the water present. W. D. H.

Metallic Formates. By W. Lossen and G. Voss (*Annalen*, **266**, 33—52).—The statements of Heusser (*Pog. Ann.*, **83**, 37) that barium formate is isomeric with the corresponding manganese, zinc, and copper salts, and that strontium and copper formates are isomeric, are incorrect.

Copper formate crystallises in various forms according to the conditions of the experiment; by slowly evaporating an aqueous solution of the salt at 75—85°, anhydrous crystals are obtained, but at 50—60° monoclinic crystals ($a : b : c = 1{\cdot}33073 : 1 : 1{\cdot}22445$, $\beta = 96° 37'$), having the composition $(CHO_2)_2Cu + 2H_2O$ separate from the solution; when copper formate is crystallised from hot concentrated formic acid, a salt containing 4 mols. H_2O is obtained. The following double salts were prepared:—

$$\left.\begin{array}{l} 2(CHO_2)_2Ba,(CHO_2)_2Cu + 4H_2O \\ 2(CHO_2)_2Ba,(CHO_2)_2Zn + 4H_2O \\ 2(CHO_2)_2Ba,(CHO_2)_2Co + 4H_2O \\ 2(CHO_2)_2Ba,(CHO_2)_2Ni + 4H_2O \end{array}\right\} \text{Triclinic.}$$

$$(CHO_2)_2Ba,(CHO_2)_2Cd + 2H_2O.$$

$$2(CHO_2)_2Sr,(CHO_2)_2Cu + 8H_2O.$$

F. S. K.

Propionates. By R. Gaze (*Arch. Pharm.*, **229**, 486—492; compare Abstr., 1887, 654).—Calcium propionate crystallises both in long (7 cm.), transparent needles with 3 mols. H_2O, and in transparent laminæ with 1 mol. H_2O. Barium propionate crystallises with 1 mol. H_2O, as heretofore accepted. Zinc propionate was obtained in anhydrous, tabular crystals; Renard (Abstr., 1887, 654) obtained it in needles with 1 mol. H_2O. Copper propionate crystallises with 1 mol. H_2O. Cadmium propionate crystallises in silky, opaque laminæ, which are stable in air and contain 2 mols. H_2O (compare Renard, *loc. cit.*). Magnesium propionate can be obtained in small crystals with 1 mol. H_2O. Lead propionate was obtained in laminæ which were anhydrous (compare Renard, *loc. cit.*). A table is given comparing the formates, acetates, and propionates as to their water of crystallisation. A. G. B.

Ethyl Acetoacetate. By J. U. Nef (*Annalen*, **266**, 52—138.)—The author has made a very careful study of the reactions which take place on treating ethyl acetoacetate and its sodium derivative with halogens, acid chlorides, and alkyl halogen compounds; he comes to the conclusion that the course of these reactions can only be satisfactorily explained by assuming that ethyl sodacetoacetate has the constitution represented by the formula ONa·CMe:CH·COOEt. This view accounts for the marked similarity in behaviour between ethyl sodacetoacetate

on the one hand and the sodium derivatives of ethyl succinosuccinate and ethyl dihydroxyterephthalate on the other; it has been previously shown that in the last-named compounds the sodium is directly combined with oxygen.

An important fact in considering the constitution of ethyl sodacetoacetate is that this substance interacts with alkyl halogen compounds with great energy, and usually at the ordinary temperature. Now if, in such reactions as these, the sodium is directly displaced by the alkyl radicle, the reaction should be even more energetic in the case of the copper, lead, or mercury derivative of ethyl acetoacetate. As a matter of fact, this is not the case; solutions of the copper and lead derivatives, for example, do not react with ethyl iodide even at 100°, and do so only very slowly at 130°. This fact alone renders it probable that no direct substitution of the sodium takes place, and a study of the action of bromine on ethyl sodacetoacetate proved the correctness of this view (see below). It was also found that no simple replacement of sodium takes place when ethyl sodacetoacetate is treated with acid chlorides or alkyl halogen compounds; in the case of benzyl chloride, for example, there is first formed a very unstable additive product of the constitution

$$ONa\cdot CMeCl\cdot CH(CH_2Ph)\cdot COOEt,$$

which immediately loses 1 mol. of hydrogen chloride with formation of ethyl sodiobenzylacetoacetate, $ONa\cdot CMe{:}C(CH_2Ph)\cdot COOEt$; the hydrogen chloride produced in this way reacts with the two sodium derivatives now present, and to the greater extent with that of the substance having the less powerful acid properties, so that ethyl benzylacetoacetate and smaller quantities of ethyl acetoacetate are formed. Some of the ethyl sodiobenzylacetoacetate also combines directly with a further quantity of benzyl chloride yielding a compound of the constitution $ONa\cdot CMeCl\cdot C(CH_2Ph)_2\cdot COOEt$, which is finally converted into ethyl dibenzylacetoacetate by the elimination of sodium chloride. If this explanation of the reaction is the true one, then the more negative the group introduced into the molecule of ethyl acetoacetate in the first stage of the reaction the larger must be the proportion of the di-substitution product formed; experiments fully confirmed this conclusion, as will be shown later.

Hitherto it has been found impossible to introduce two acid radicles into the molecule of ethyl acetoacetate; the author shows that such di-substitution products can be obtained by treating metallic derivatives of ethyl acetoacetate with benzoic or acetic chloride, and he discusses at some length the mechanism of these reactions.

The constitution of ethyl acetoacetate is next considered; the behaviour of this compound with phenylhydrazine (see below) and with ammonia and amides and the fact that it has distinctly acid properties all point to its being a hydroxy-compound. The fact that ethyl acetoacetate, and its methyl and ethyl derivatives are not reduced on treatment with sodium in ethereal solution, whereas the diethyl derivative, which is a true ketone, is almost completely converted into ethyl diethylhydroxybutyrate and a pinacone-like substance which is soluble in alkalis, is also strong evidence against the

ketone constitution in the case of the first-named compounds. Furthermore, if ethyl acetoacetate has the ketone constitution, ethyl malonate must have even more strongly marked acid properties; as a matter of fact, it has no acid properties whatever, and does not interact with sodium in absence of alcohol; it also differs from ethyl acetoacetate and the mono-substitution products of the latter in being unacted on by bromine, chlorine, nitrous acid, and fuming nitric acid in the cold. Ethyl acetoacetate is, therefore, in all probability ethyl β-hydroxycrotonate, OH·CMe:CH·COOEt, and its mono-substitution products the corresponding α-substitution products of ethyl β-hydroxycrotonate. These compounds show no tautomerism or desmotropism, and the above view of their constitution accounts satisfactorily for all their reactions; the idea of a labile form may, therefore, be dismissed as regards these substances.

It is interesting to notice to what a great extent the displacement of the α-hydrogen atom affects the behaviour of the hydroxy-group in ethyl acetoacetate; when the substituting group is more positive than hydrogen, the product, ethyl ethylacetoacetate for example, has more marked alcoholic properties. When, on the other hand, the substituting group is strongly negative, the product has a pronounced acid character; the acetyl, benzoyl, and carboxyethyl derivatives of ethyl acetoacetate decompose carbonates, although their ethereal solutions do not react with sodium. This fact led the author to study the action of sodium on ethereal solutions of various acids; he found that in the case of mellitic, phthalic, succinic, and cinnamic acids there is no reaction, whilst with benzoic acid and picric acid a slight reaction takes place, probably owing to the presence of impurities; an ethereal solution of pure phenol reacts very energetically with sodium.

Ethyl phenyl-β-hydrazocrotonate, N_2H_2Ph·CMe:CH·COOEt, can be obtained in a crystalline condition by gradually adding phenylhydrazine (10 grams) to a well-cooled, ethereal solution of ethyl acetoacetate (12·5 grams) containing fused calcium chloride, then washing the solution with 10 per cent. soda and dilute sulphuric acid successively, drying over calcium chloride, and evaporating over sulphuric acid; the crude product (16 grams) is spread on porous earthenware and then repeatedly washed with light petroleum. The pure compound (11 grams) crystallises in long, colourless needles, melts at 50°, and is very readily soluble in all ordinary organic solvents except light petroleum; its solutions rapidly turn yellow, and even when in a dry condition the hydrazide gradually changes into a yellow, fluorescent oil. It is readily decomposed into its components by concentrated hydrochloric acid, and when heated at 200° in a vacuum, it is converted quantitatively into phenylmethylpyrazolone. When treated with acetic chloride in well-cooled, ethereal solution, it yields an oil which boils at 245—250° under a pressure of 150 mm., and has most probably the constitution expressed by the formula CH_2:CMe·NAc·NPhAc.

A compound of the composition $C_{12}H_{13}NO_2$ is obtained in colourless crystals when the hydrazo-derivative just described is dissolved in concentrated sulphuric acid, the solution kept for ten minutes, and

then poured into a large volume of water. This substance crystallises from alcohol in compact, colourless needles, melts at 134°, is very stable, and is, in all probability, an indole derivative; it is only very slowly acted on by boiling alcoholic potash, but when melted with potash, it gives a strong odour of indole; its alcoholic solution gives a deep-red coloration with ferric chloride.

Ethyl phenyl-β-azocrotonate, NPh:N·CMe:CH·COOEt, is formed when an alcoholic solution of the hydrazo-compound is warmed with yellow mercuric oxide; it melts at 51° and is identical with the compound obtained by Bender (Abstr., 1888, 53) by the action of phenylhydrazine on ethyl α-chloracetoacetate.

The ethyl α-bromacetoacetate prepared by Schönbrodt's method (Abstr., 1890, 27) is a pure compound, as is shown by the following facts:—When treated with ethyl sodacetoacetate, it yields only ethyl diacetosuccinate (see below), and on oxidation with fuming nitric acid in the cold, it gives ethyl bromisonitrosoacetate, NOH:CBr·COOEt. The product obtained by treating ethyl acetoacetate with bromine as described by Duisberg (Abstr., 1882, 1193), is not pure ethyl γ-bromacetoacetate, as was supposed by Hantzsch (Abstr., 1890, 1238) and by Steude (Abstr., 1891, 742), but is a mixture of approximately equal quantities of the α- and γ-bromo-derivatives, and contains, in addition, a little dibromo-derivative and some unchanged ethyl acetoacetate; this is proved by the fact that, on oxidation with nitric acid, it yields a mixture of ethyl isonitroso- and ethyl bromisonitrosoacetoacetate, and also by a study of its behaviour with ethyl sodacetoacetate (see below). The product obtained by treating ethyl sodacetoacetate with bromine is also a mixture of the α- and γ-bromo-derivatives; the formation of both these compounds in this way is best explained by supposing that the addition of bromine first takes place, yielding a compound of the constitution ONa·CMeBr·CHBr·COOEt, from which hydrogen bromide is immediately eliminated giving the α-bromo-derivative, ONa·CMe:CBr·COOEt; the hydrogen bromide thus produced acts on a further quantity of ethyl sodacetoacetate with formation of ethyl acetoacetate, which is then attacked by the bromine, yielding both the α- and the γ-bromo-derivatives.

Ethyl α-acetyl-β'-hydroxyhydromuconate,

$$COOEt\cdot C(:CMe\cdot OH)\cdot CH_2\cdot C(OH):CH\cdot COOEt,$$

is formed, together with its isomeride, ethyl diacetosuccinate, and ethyl dihydroxyterephthalate, when an ethereal solution of ethyl bromacetoacetate, prepared by the action of bromine on ethyl acetoacetate (or its sodium derivative) is treated with ethyl sodacetoacetate at the ordinary temperature; after keeping for two hours, the solution is filtered, and the residue repeatedly washed with small quantities of cold water to free it from sodium bromide and traces of ethyl sodacetoacetate. The undissolved substance is a sodium derivative of ethyl acetylhydroxyhydromuconate of the constitution

$$COOEt\cdot C(:CMe\cdot ONa)\cdot CH_2\cdot C(OH):CH\cdot COOEt;$$

it is very sparingly soluble in cold, but more readily in hot water, and it separates from warm alcohol in colourless, granular crystals. On

treatment with dilute sulphuric acid, it is converted into ethyl acetylhydroxyhydromuconate; this compound crystallises from ether in colourless needles, melts at about 65°, and its alcoholic solution gives a blue coloration with ferric chloride; it is very unstable and, on keeping, quickly changes into an oil, probably a furfuran derivative, water being eliminated. The formation of an isomeride of ethyl diaceotsuccinate in the above reaction is a further proof that Duisberg's ethyl bromacetoacetate contains the γ-bromo-derivative.

Ethyl 1 : 2-*methylcarboxyethylpyrrolineacetate*,

$$\mathrm{COOEt{\cdot}C{<}\overset{CMe{\cdot}NH}{\underset{\quad CH}{\quad\quad}}{>}C{\cdot}CH_2{\cdot}COOEt},$$

is obtained when the sodium derivative just described is boiled with a glacial acetic acid solution of ammonium acetate, and the product precipitated with water; it crystallises from dilute alcohol or glacial acetic acid in needles, melts at 186°, and gives the pine-chip reaction in a very marked manner.

Ethyl diacetosuccinate melts at 88°, and is dimorphous; when crystallised slowly, it forms rhombic plates, but when quickly crystallised, it is obtained in needles; the crystals are monosymmetric, $a : b : c = 0{\cdot}85753 : 1 : 0{\cdot}79288$, $\beta = 73°\ 55'$.

Ethyl α-*bromomethylacetoacetate*, $C_7H_{11}O_3Br$, is obtained, as sole product, when bromine is gradually added to a well-cooled ethereal solution of ethyl sodiomethylacetoacetate; this substance, and not the γ-derivative as is generally supposed, is also the principal product of the action of bromine on ethyl methylacetoacetate. It is a colourless oil, boils at 107° under a pressure of 30 mm. (at 121°, 50 mm.), and is not acted on by fuming nitric acid or by bromine in cold chloroform solution. It is insoluble in soda, and when heated at 100° for six hours in a sealed tube, it is converted into tetric acid, with elimination of ethyl bromide; this acid has probably the constitution represented by the formula

$$\mathrm{CH_2{:}C(OH){\cdot}CMe{<}\overset{O{\cdot}CO}{\underset{CO{\cdot}O}{\quad\quad}}{>}CMe{\cdot}C(OH){:}CH_2}.$$

Ethyl α-*bromethylacetoacetate*, $C_8H_{13}O_3Br$, is formed from ethyl ethylacetoacetate under the same conditions as those described in the case of the methyl derivative; it is a colourless oil, boiling at 110° under a pressure of 22 mm. (at 131°, 50 mm.). Its behaviour with bromine and with soda resembles that of the methyl derivative; when heated at 100° in a sealed tube, it yields ethyl bromide and pentic acid, the constitution of which is probably analogous to that of tetric acid.

Some experiments are then described, the results of which confirm Elion's statement that there is only one ethyl sodacetoacetate.

The interaction of ethyl sodacetoacetate and benzoic chloride is then discussed, and it is pointed out that about 10 per cent. of ethyl dibenzoylacetoacetate is invariably present in the crude product; the formation of this compound is explained by assuming that an additive product of the constitution $\mathrm{ONa{\cdot}CMeCl{\cdot}CHBz{\cdot}COOEt}$ is produced, and that the latter immediately loses 1 mol. of hydrogen chloride, at

the same time (when the double linking is in a sort of nascent state) combining with benzoic chloride to form the di-substitution product; ethyl sodiobenzoylacetoacetate, when once formed, that is to say, when the double binding is no longer nascent, does not react with benzoic chloride.

Ethyl dibenzoylacetoacetate, $C_{20}H_{18}O_5$, is, however, best prepared by adding benzoic chloride (150 grams) to the copper derivative of ethyl acetoacetate (50 grams), which has been previously mixed to a paste with pure ether, and then heating for a short time on the water-bath. The yield of the pure compound is 32 grams. It is decomposed by a cold alcoholic solution of sodium ethoxide, yielding ethyl benzoate, sodium benzoate, ethyl acetoacetate, and condensation products, and when treated with phenylhydrazine, it gives benzoic acid, β-benzoylphenylhydrazine (m. p. 168°), and probably also ethyl acetoacetate.

Ethyl triacetylacetate, $CAc_3{\cdot}COOEt$, is formed in small quantity when ethyl sodacetoacetate suspended in ether is treated with acetic chloride; it is best prepared by adding acetic chloride to the copper derivative of ethyl acetoacetate suspended in ether. It boils at 102° under a pressure of 12 mm. (at 111°, 22 mm.; at 116°, 29 mm.) without decomposition, and under the ordinary atmospheric pressure at 212—214° with slight decomposition; it is volatile with steam, and does not combine with bromine, but it is decomposed by fuming nitric acid in the cold. It exhibits the same behaviour with sodium ethoxide, and with phenylhydrazine, as the dibenzoyl derivative just described.

Ethyl acetylcarbintricarboxylate, $COOEt{\cdot}CAc(COOEt)_2$, is formed, together with ethyl acetylmalonate and regenerated ethyl acetoacetate, by the interaction of ethyl sodacetoacetate and ethyl chlorocarbonate under the usual conditions. It boils at 129° under a pressure of 29 mm., is volatile with steam, is not acted on by cold fuming nitric acid, and does not combine with bromine; when treated with sodium ethoxide, it is decomposed into ethyl sodacetoacetate and ethyl carbonate. The ethyl acetylmalonate formed in the above reaction boils at 120° under a pressure of 17 mm., and is identical with the compound obtained by the action of acetic chloride on ethyl sodiomalonate; it decomposes carbonates, and gives a dark-red coloration with ferric chloride in alcoholic solution, but its ethereal solution is not acted on by sodium.

Ethyl phenylhydrazine-β-carboxylate, $NHPh{\cdot}NH{\cdot}COOEt$, is obtained when ethyl acetylcarbintricarboxylate is treated with phenylhydrazine in ethereal solution; it crystallises in colourless needles melting at 82°.

A compound of the constitution $HgCl{\cdot}O{\cdot}CMe{:}CAc{\cdot}COOEt$ is formed, together with mercuric chloride and an oily product, when acetic chloride is added to the mercury derivative of ethyl acetoacetate suspended in ether; it separates from ether in heavy, colourless, asymmetric crystals, $a : b : c = 1{\cdot}7712 : 1 : 0{\cdot}83292$, melting at 105°.

Constitution of 5-Pyrazolone Derivatives.—A further investigation of Knorr's 1.3-phenylmethylpyrazolone has confirmed the views previously expressed by the author regarding its constitution; the experiments described below, together with the fact that the con-

densation product of ethyl acetoacetate and phenylhydrazine has been shown to be a hydrazo-compound, prove that phenylmethylpyrazolone has the constitution represented by the formula $\begin{matrix}\mathrm{CMe{\cdot}NH}\\ \|\\ \mathrm{CH{-}CO}\end{matrix}\!>\!\mathrm{NPh}$, and that its acid properties are due to the presence of an imido-group.

1 : 2 : 3-*Phenylbenzoylmethylpyrazolone*, $\begin{matrix}\mathrm{CMe{\cdot}NBz}\\ \|\\ \mathrm{CH{-}CO}\end{matrix}\!>\!\mathrm{NPh}$, is formed when an alkaline solution of phenylmethylpyrazolone is shaken with benzoic chloride; it can also be obtained from the silver derivative of the pyrazolone in like manner. It crystallises from dilute alcohol or light petroleum in needles, melts at 75°, and is very readily soluble in all ordinary organic solvents except light petroleum; it is insoluble in water, dilute acids, and alkalis, and is not acted on by nitrous acid, but is decomposed by alcoholic potash and by concentrated sulphuric acid, yielding benzoic acid and phenylmethylpyrazolone.

1 : 2 : 4 : 3-*Phenyldibenzoylmethylpyrazolone*, $\begin{matrix}\mathrm{CMe{\cdot}NBz}\\ \|\\ \mathrm{CBz{-}CO}\end{matrix}\!>\!\mathrm{NPh}$, can be obtained by strongly heating phenylmethylpyrazolone or its benzoyl derivative with benzoic chloride; it crystallises from alcohol in colourless needles, and melts at 157°.

1 : 3 : 4-*Phenylmethylbenzoylpyrazolone*, $\begin{matrix}\mathrm{CMe{\cdot}NH}\\ \|\\ \mathrm{CBz\cdot CO}\end{matrix}\!>\!\mathrm{NPh}$, is produced when the preceding compound is decomposed with cold, concentrated sulphuric acid, or with boiling alcoholic potash; it crystallises from dilute alcohol in yellowish needles, melts at 86°, and is not decomposed by boiling alkalis; when its solution in potash is shaken with benzoic chloride, it is reconverted into the dibenzoyl derivative (m. p. 157°).

1 : 2 : 4 : 3-*Phenylbenzoylbromomethylpyrazolone*, $\begin{matrix}\mathrm{CMe{\cdot}NBz}\\ \|\\ \mathrm{CBr{-}CO}\end{matrix}\!>\!\mathrm{NPh}$, can be prepared by treating the benzoyl derivative (m. p. 75°) described above with a glacial acetic acid solution of bromine, and also by shaking an alkaline solution of 1 : 3 : 4-phenylmethylbromopyrazolone with benzoic chloride; it crystallises from a mixture of ether and light petroleum in long, colourless needles, melts at 82·5°, and is decomposed by concentrated sulphuric acid and by alcoholic potash with elimination of the benzoyl group.

1 : 2 : 3 : 4-*Phenylbenzoyldimethylpyrazolone*, $\begin{matrix}\mathrm{CMe{\cdot}NBz}\\ \|\\ \mathrm{CMe\cdot CO}\end{matrix}\!>\!\mathrm{NPh}$, prepared from phenyldimethylpyrazolone, crystallises from dilute alcohol and light petroleum in long, colourless needles, melts at 99°, and is readily decomposed by concentrated sulphuric acid and by alcoholic potash.

Bis-1 : 2 : 3-*phenylbenzoylmethylpyrazolone*, $\mathrm{C_{34}H_{26}N_4O_4}$, obtained by treating an alkaline solution of bis-phenylmethylpyrazolone with benzoic chloride, separates from glacial acetic acid in colourless, granular crystals, melts at 203°, and is insoluble in alcohol; it is decomposed into its components by alcoholic potash, and by concentrated sulphuric acid.

When 1 : 3-phenylmethylpyrazolone (5 grams) is treated with sodium methoxide and methyl iodide, as described by Knorr, it yields not only Knorr's 1 : 3 : 4 : 4-phenyltrimethylpyrazolone (1·15 grams), but also an even larger quantity (1·8 grams) of 1 : 2 : 3-phenyldimethylpyrazolone (antipyrin) and 1 : 2 : 3 : 4-phenyltrimethylpyrazolone (1·4 grams); 1 : 3 : 4-phenyldimethylpyrazolone, under the same conditions, yields approximately equal quantities of 1 : 2 : 3 : 4-phenyltrimethylpyrazolone (methylantipyrin) and 1 : 3 : 4 : 4-phenyltrimethylpyrazolone. These reactions are easily explained if it be assumed that not only is the sodium of the imido-group directly displaced, but also that an addition of methyl iodide takes place at the double linking; this view is borne out by numerous facts.

In conclusion, the author draws attention to other cases of supposed tautomerism and desmotropism, such as those of carbostyril, isatin, &c.; in his opinion, all the reactions of these compounds can be explained without assuming the existence of labile or pseudo-forms.

F. S. K.

Condensation of Levulinic Acid with Aldehydes. By H. Erdmann (*Ber.*, **24**, 3201—3204).—In this paper the author criticises the results of Ludwig and Kehrer's investigation (Abstr., 1891, 1456) on the action of furfuraldehyde on sodium levulinate, and from the corresponding results obtained by him in the case of benzaldehyde, believes that the compound described as β-furfurallevulinic acid is in reality *δ-furfurallevulinic acid*,

$$C_4OH_3\cdot CH{:}CH\cdot CO\cdot CH_2\cdot CH_2\cdot COOH.$$

The anticipation of Ludwig and Kehrer that this compound would yield derivatives of naphthafurfuran will, therefore, probably not be fulfilled, as such compounds could only be formed from the β-derivative. It should, however, be converted into dilevulinic acid,

$$C_2H_4(CO\cdot CH_2\cdot CH_2\cdot COOH)_2,$$

by the action of hydrochloric acid. H. G. C.

Reduction of Ethyl Oxalacetate. By W. Wislicenus (*Ber.*, **24**, 3416—3417).—Inactive malic acid is obtained by the reduction of ethyl oxalacetate with sodium amalgam in acid solution. The malic acid can be isolated and purified by means of the lead salt; the yield is 50 per cent. of the theoretical. J. B. T.

Reduction of Acetonedicarboxylic Acid. By H. v. Pechmann and K. Jenisch (*Ber.*, **24**, 3250—3252).—*β-Hydroxyglutaric acid*, $OH\cdot CH(CH_2\cdot COOH)_2$, is obtained by reducing crude acetonedicarboxylic acid containing about 75 per cent. of the pure acid (100 grams) dissolved in water (1200 c.c.) and neutralised with sodium carbonate (180 grams) with 4 per cent. sodium amalgam (900—1000 grams); the reduction extends over two days, the solution being kept at 0° and a current of carbonic anhydride passed through; an excess of hydrochloric acid is then added, and the solution evaporated to dryness, extracted with alcohol, and the brown syrup which is obtained converted into the copper salt by boiling it with dilute

copper acetate solution; the salt is decomposed by hydrogen sulphide and from the aqueous solution of the acid a colourless syrup is obtained which ultimately solidifies, the yield being 50 grams. It slowly separates from its aqueous solution in stellate groups of needles, melts at 95°, and is readily soluble in water and alcohol, but insoluble in other solvents; on distillation under diminished pressure, glutaconic acid is formed, and the same compound is obtained on boiling it with 60 per cent. sulphuric acid. An aqueous solution of the *sodium* salt gives precipitates with silver, lead, mercury, and copper salts, but not with calcium, barium, zinc, and cadmium salts. The *copper* salt is a blue, crystalline precipitate; the *phenylhydrazide*, $C_5H_6O_3(PhN_2H_2)_2$, produced by heating the acid with three times its weight of phenylhydrazine, crystallises from glacial acetic acid in aggregates of delicate needles, and melts at 234—235°. The acid is not identical with that obtained by Simpson (*Annalen*, **133**, 76) from α-dichlorhydrin and potassium cyanide, which is said to melt at 133°, (the melting point of glutaconic acid). When β-hydroxyglutaric acid is heated with eight times its weight of fuming hydriodic acid in a sealed tube at 180° for four hours, glutaric acid is obtained.

A. R. L.

Alkyl Acetonedicarboxylic Acids. By H. v. Pechmann and K. Jenisch (*Ber.*, **24**, 3248—3249.)—It has been pointed out by Dünschmann and v. Pechmann (Abstr., 1891, 674) that the alkyl substitution derivatives of acetonedicarboxylic acid having an asymmetrical structure, are unstable; as, however, the asymmetry of these derivatives can be conceived in a two-fold sense, first in regard to the relative positions in the molecule of the substituents, secondly in regard to the nature of the latter, and as the asymmetrical compounds hitherto examined have complied with both these conditions, an attempt was made to prepare ethyl methylbenzylacetonedicarboxylate, a compound which only possesses asymmetry in respect to the nature of its substituents. When ethyl acetonedicarboxylate is successively ethylated and benzylated, or when the order of the alkylation is reversed, an oily product which does not show a constant boiling point is obtained; on mixing with alcoholic potash, the fractions passing over at every 10° between 215° and 270°, under a pressure of 40 mm., and decomposing the potassium salts with an acid, carbonic anhydride is the chief product, only minute quantities of oily acids incapable of solidification being obtained. This result favours the view that these acids are only stable when they are symmetrical both as regards the position and nature of the substituent alkyl groups.

A. R. L.

Behaviour of Certain Ketonic Acids towards Sodium Hydrogen Sulphite. By O. Hinsberg (*Ber.*, **24**, 3235—3237).—When dihydroxytartaric acid is added to a concentrated aqueous solution of sodium hydrogen sulphite at 80—100°, it dissolves with the evolution of carbonic anhydride, and, on cooling, crystals of the sodium hydrogen sulphite compound of glyoxal separate; attempts to prepare glyoxalic acid by working at a lower temperature (60—70°) were unsuccessful; a small quantity of glyoxal is obtained

when nitrotartaric acid is treated in a similar manner. Pyruvic acid, when heated with a concentrated solution of the sulphite in a sealed tube at 170°, appears to be unaltered; no decomposition products were recognised. Chloracetic acid dissolves in the sulphite solution at the temperature of the water-bath; but does not yield chloracetone; ethyl acetoacetate remains unaltered even when heated with the same solution at 100° for a long time. A. R. L.

Alkaline Citrates. By T. Salzer (*Arch. Pharm.*, **229**, 547—552).—According to the author's rules (Abstr., 1884, 806), normal salts contain more, or at least as much, water of crystallisation as the corresponding acid salts. Heldt, however (*Annalen*, **43**, 157), states that tripotassium citrate crystallises with 1 mol. H_2O, dipotassium citrate is anhydrous, and monopotassium citrate crystallises with 2 mols. H_2O; the author has, therefore, reinvestigated the alkaline citrates.

Monopotassium citrate is anhydrous when crystallised at the ordinary temperature, and dissolves in $\frac{1}{2}$ part of hot water and somewhat more than 2 parts of cold water; when obtained at a low temperature, it crystallises with 2 mols. H_2O. Dipotassium citrate is also anhydrous. Tripotassium citrate is soluble in $\frac{3}{4}$ part of water at 15°; it can be heated at 170° without loss, but at 200°, it loses 1 mol. water of crystallisation.

Monosodium citrate is anhydrous. The author failed to obtain pure disodium citrate. Trisodium citrate crystallises both with 3 and with $5\frac{1}{2}$ mols. H_2O; the former crystals dissolve in about $1\frac{1}{2}$ parts of water at 15°, the latter in about 1 part of water at 25° and $\frac{1}{2}$ part of boiling water. A. G. B.

Formation of Uric Acid from Cyanacetic Acid and Carbamide. By E. Formánek (*Ber.*, **24**, 3419—3420).—Small quantities of uric acid are formed on heating a mixture of carbamide and cyanacetic acid. Cyanacetic acid (0·5 gram) is cautiously heated with carbamide (2 grams) over a Bunsen burner: a continuous stream of gas is evolved from the melted mass, and, on further heating, the mixture solidifies. The solid mass is dissolved in sodium hydroxide, the solution saturated with ammonium chloride and ammonia, a mixture of magnesium mixture and ammoniacal silver solution added, and the whole allowed to remain, filtered, washed with water, and the silver salt decomposed with sodium sulphide. The silver sulphide is filtered off, the filtrate acidified with hydrochloric acid, and evaporated to a small bulk; the uric acid then separates out. 1 gram of cyanacetic acid and 4 grams of carbamide yielded 20—30 milligrams of pure uric acid. E. C. R.

Hydantoïns and Bases derived from them. By W. Marckwald, M. Neumark, and R. Stelzner (*Ber.*, **24**, 3278—3298).—Thiohydantoïns have been known hitherto only in the aromatic series, having been obtained (Aschan, Abstr., 1884, 907) by melting together aromatic thiocarbamides and amido-acids of the fatty series.

No such reaction takes place in the case of the fatty amido-acids.

Probably these do not exist in the free state as $R{\cdot}CH(NH_2){\cdot}COOH$, but as $R{\cdot}CH{<}\begin{matrix}NH_3\\CO-\end{matrix}{>}O$. If, however, an alkaline solution of the acid, which, doubtless, contains the acid in the form of the salt $R{\cdot}CH(NH_2){\cdot}COOM$, is treated with a thiocarbimide, the reaction does occur, and both aromatic and aliphatic thiohydantoïns were obtained by dissolving the amido-acid in an equivalent quantity of concentrated aqueous potash, and adding an equivalent amount of the thiocarbimide in alcoholic solution. On adding hydrochloric acid, the thiohydantoic·acid first separates as an oil, which rapidly loses water, and becomes converted into crystals of the thiohydantoïn.

Phenylmethylthiohydantoïn, $CS{<}\begin{matrix}NPh{\cdot}CO\\NH\cdot CHMe\end{matrix}'$, prepared from phenylthiocarbimide and alanine, is colourless, and melts at 210°; the yellow substance melting at 180°, which Aschan described, was impure.

Orthotolylthiohydantoïn, $CS{<}\begin{matrix}N(C_6H_4Me){\cdot}CO\\NH\text{———}CH_2\end{matrix}'$, from orthotolylthiocarbimide and glycocine, forms white plates melting at 136°, and dissolves easily in acetic acid, chloroform, and benzene, sparingly in ether and light petroleum.

Orthotolylmethylthiohydantoïn, $CS{<}\begin{matrix}N(C_6H_4Me){\cdot}CO\\NH\text{———}CHMe\end{matrix}'$, from orthotolylthiocarbimide and alanine, resembles the last-mentioned compound, and melts at 198°.

1 : 3 : 4-*Xylylmethylthiohydantoïn*, $CS{<}\begin{matrix}N(C_6H_3Me_2){\cdot}CO\\NH\text{———}CHMe\end{matrix}'$, from xylylthiocarbimide ($Me_2 : NCS = 1 : 3 : 4$) and alanine, forms white needles, melts at 165°, and dissolves readily in ether, alcohol, chloroform, and benzene, very sparingly in light petroleum.

α-Naphthylmethylthiohydantoïn, $CS{<}\begin{matrix}N(C_{10}H_7){\cdot}CO\\NH\text{——}CHMe\end{matrix}'$, from α-naphthylthiocarbimide and alanine, melts at 242°, and is but sparingly soluble in most solvents; it dissolves readily, however, in hot acetic acid.

Phenyldimethylthiohydantoïn, $CS{<}\begin{matrix}NPh{\cdot}CO\\NH\cdot CMe_2\end{matrix}'$, from phenylthiocarbimide and α-amidoisobutyric acid, forms white crystals, melts at 67°, and dissolves readily in most solvents, but only sparingly in water and aqueous alcohol.

Paratolyldimethylthiohydantoïn, $CS{<}\begin{matrix}N(C_6H_4Me)\\NH\text{—}CMe_2\end{matrix}{>}CO$, from paratolylthiocarbimide and α-amidoisobutyric acid, melts at 85°, and is rather more soluble than the preceding compound.

Orthotolyldimethylthiohydantoïn, from orthotolylthiocarbimide and α-amidoisobutyric acid, forms colourless needles melting at 175°, and is less readily soluble than the para-compound. It dissolves, however, in hot alcohol, acetic acid, chloroform, and benzene.

Methylthiohydantoïn, $CS<^{NMe\cdot CO}_{NH\cdot CH_2}$, from methylthiocarbimide and glycocine, forms colourless needles melting at 161°; it dissolves readily in ether, alcohol, and hot water, less readily in cold water and chloroform, and only very sparingly in light petroleum.

Dimethylthiohydantoïn, $CS<^{NMe\cdot CO}_{NH\cdot CHMe}$, from methylthiocarbimide and alanine, forms lustrous, rhombic prisms melting at 166·5°, and dissolves readily in all solvents except light petroleum.

Trimethylthiohydantoïn, $CS<^{NMe\cdot CO}_{NH\cdot CMe_2}$, from methylthiocarbimide and α-amidoisobutyric acid, forms white crystals melting at 53°, and less soluble than the preceding compound in most solvents, but more so in light petroleum.

Allylthiohydantoïn, $CS<^{N(C_3H_5)\cdot CO}_{NH\text{——}CH_2}$, from allylthiocarbimide and glycocine, crystallises only with difficulty. It forms white crystals melting at 108°, and dissolves easily in hot water, alcohol, and acetic acid, sparingly in cold water, chloroform, benzene, and light petroleum.

Allylmethylthiohydantoïn, $CS<^{N(C_3H_5)\cdot CO}_{NH\text{——}CHMe}$, from allylthiocarbimide and alanine, crystallises still less readily. It forms colourless crystals melting at 81·5°, and dissolves readily in alcohol, ether, benzene, acetic acid, and particularly so in chloroform, sparingly in cold water and light petroleum.

Incidentally, an improvement on Tiemann and Friedländer's method (Abstr., 1882, 56) for preparing α-amidoisobutyric acid is described. The *sulphate* of this acid, $C_4H_9NO_2,H_2SO_4 + 2H_2O$, was obtained for the first time. It forms long, pointed, lustrous crystals.

The thiohydantoïns described all show the characteristic properties of thiocarbamides. They yield insoluble silver and mercury salts, which readily decompose, forming the metallic sulphides. They dissolve in alkalis, and when the solutions are boiled, salts of the corresponding thiohydantoic acids are formed. But as the first result of the action of the alkali, compounds of another nature are formed, which have not been isolated, but derivatives of which have been prepared. Take as an example the methylthiohydantoïns derived from alanine. These may react according to either of the formulæ $CS<^{NR\cdot CO}_{NH\cdot CHMe}$ and $SH\cdot C<^{NR\cdot CO}_{N\text{—}CHMe}$. When boiled with potash, they react according to the first, yielding salts of methylthiohydantoic acid. But if they are dissolved in potash and methyl iodide is added, they react according to the second formula, and take up two methyl groups. This may give $SMe\cdot C<^{NR\cdot CO}_{N\text{—}CMe_2}$, an imidazolone, or the thiohydantoïn may react in yet another form, $SH\cdot C<^{NR\cdot C\cdot OH}_{N\text{—}CMe}$, of the second of the two formulæ given above,

yielding $SMe{<}\begin{matrix}NR\cdot C\cdot OMe\\ \|\\ N{-}CMe\end{matrix}$, an imidazole. In reality, the compound formed has the last formula, for it is different from the substance that is obtained when the dimethylhydantoïn $CS{<}\begin{matrix}NR\cdot CO\\ |\\ NH\cdot CMe_2\end{matrix}$ (derived from α-amidoisobutyric acid) takes up one methyl group under the same circumstances; this substance must evidently have the formula $SMe\cdot C{<}\begin{matrix}NR\cdot CO\\ |\\ N{-}CMe_2\end{matrix}$, and is, in fact, the other compound that might theoretically be formed when the methylhydantoïn takes up two methyl groups. The imidazoles described below were prepared by treating the methylthiohydantoïns derived from alanine with 2 mols. each of potash and methyl iodide in alcoholic solution; the imidazolones by treating the dimethylhydantoïns derived from α-amidoisobutyric acid with 1 mol. each of potash and methyl iodide in alcoholic solution.

ν-Phenyl-α-methoxy-β-methyl-μ-thiomethylimidazole,

$$SMe\cdot C{<}\begin{matrix}NPh\cdot C\cdot OMe\\ \|\\ N{-}CMe\end{matrix},$$

forms an oil which can only be obtained in white crystals with great difficulty; it melts at 90°, and dissolves readily in most solvents, sparingly in water. The *hydrochloride*, $C_{12}H_{14}N_2SO,HCl$, forms small, white crystals melting at 140°, and easily soluble in water and alcohol. The *platinochloride*, $(C_{12}H_{14}N_2SO)_2,H_2PtCl_6$, forms yellowish-red crystals, melts with decomposition at 213°, and dissolves readily in water, sparingly in alcohol. The *picrate*, $C_{12}H_{14}N_2SO,C_6H_3N_3O_7$, forms yellow needles melting with decomposition at 192°, and dissolves sparingly in water, readily in alcohol.

ν-Paratolyl-β-methyl-α-methoxy-μ-thiomethylimidazole,

$$SMe\cdot C{<}\begin{matrix}N(C_6H_4Me)\cdot C\cdot OMe\\ \|\\ N{-}\!\!-\!\!-\!\!-\!\!-\!\!-CMe\end{matrix}$$

resembles the preceding compound; it forms small, white, lustrous plates melting at 109°. The *hydrochloride*, $C_{13}H_{16}N_2SO,HCl$, forms a white, crystalline powder melting at 123°, and is very soluble in water. The *platinochloride* is yellow, and decomposes at 210° without melting. The *picrate* is yellow, and melts at 180°.

ν-Orthotolyl-β-methyl-α-methoxy-μ-thiomethylimidazole,

$$SMe\cdot C{<}\begin{matrix}N(C_6H_4Me)\cdot COMe\\ \|\\ N{-}\!\!-\!\!-\!\!-\!\!-\!\!-CMe\end{matrix},$$

is more easily obtained crystalline than the two preceding compounds. It forms large, white plates, melts at 118—120°, and dissolves readily in alcohol, ether, chloroform, and benzene, sparingly in water. The *hydrochloride*, $C_{13}H_{16}N_2SO,HCl$, is white, and melts at 120°. The *platinochloride*, $(C_{13}H_{16}N_2SO)_2,H_2PtCl_6$, is orange-red, and decomposes at 205° without melting. The *sulphate* melts at 205°.

The yellow *picrate*, $C_{13}H_{16}N_2SO,C_6H_3N_3O_7$, melts with decomposition at 200°, and dissolves readily in alcohol, sparingly in water.

νβ-Dimethyl-α-methoxy-μ-thiomethylimidazole,

$$SMe\cdot C\begin{cases}NMe\cdot C\cdot OMe\\ \|\\ N\text{—}CMe\end{cases},$$

is a liquid. The acid sulphate, $C_7H_{12}N_2SO_4$, forms a white, crystalline powder, soluble in alcohol, insoluble in ether. The *platinochloride*, $(C_7H_{12}N_2SO)_2,H_2PtCl_6$, forms a yellow precipitate.

ν-Phenyl-β-dimethyl-μ-thiomethylimidazolone, $SMe\cdot C\begin{cases}NPh\cdot CO\\ |\\ N\text{—}CMe_2\end{cases}$, is a colourless liquid boiling without decomposition at 222—225°. The *hydrochloride*, $C_{12}H_{14}N_2SO,HCl$, is very soluble in water and alcohol. The *platinochloride*, $(C_{12}H_{14}N_2SO)_2,H_2PtCl_6$, forms reddish-yellow needles melting at 132°, and dissolves readily in alcohol, sparingly in water. The *picrate*, $C_{12}H_{14}N_2SO,C_6H_3N_3O_7$, forms dark-yellow prisms melting with decomposition at 174°, and dissolves easily in alcohol and ether, sparingly in water.

ν-Paratolyl-β-dimethyl-μ-thiomethylimidazolone,

$$SMe\cdot C\begin{cases}N(C_6H_4Me)\cdot CO\\ |\\ N\text{———}CMe_2\end{cases},$$

forms a colourless oil, which decomposes when distilled. The *sulphate* melts at 210°. The *platinochloride*, $(C_{13}H_{16}N_2SO)_2,H_2PtCl_6$, forms dark-red needles melting at 152°. The *picrate*,

$$C_{13}H_{16}N_2SO,C_6H_3N_3O_7,$$

forms yellow prisms which decompose at 190°.

ν-Orthotolyl-β-dimethyl-μ-thiomethylimidazolone,

$$SMe\cdot C\begin{cases}N(C_6H_4Me)\cdot CO\\ |\\ N\text{———}CMe_2\end{cases},$$

is an oil which decomposes when distilled. The white, hygroscopic *hydrochloride*, $C_{13}H_{16}N_2SO,HCl$, melts at 118°; the *acid sulphate* at 208°. The *platinochloride*, $(C_{13}H_{16}N_2SO)_2,H_2PtCl_6$, is reddish-yellow, and dissolves readily in alcohol and ether, sparingly in water. The *picrate*, $C_{13}H_{16}N_2SO,C_6H_3N_3O_7$, forms yellow prisms, melts with decomposition at 212°, and dissolves easily in alcohol, sparingly in water.

νβ-Trimethyl-μ-thiomethylimidazolone, $SMe\cdot C\begin{cases}NMe\cdot CO\\ |\\ N\text{—}CMe_2\end{cases}$, is an oil. The yellow *platinochloride*, $(C_7H_{12}N_2SO)_2,H_2PtCl_6$, melts at 150°; the white *acid sulphate*, $C_7H_{13}N_2SO,H_2SO_4$, at 138°. C. F. B.

Chemical and Physiological Relations of Sulphones. Trisulphones. By E. Laves (*Arch. Pharm.*, **229**, 448—456; compare Abstr., 1889, 1232).—Methyldiphenylsulphone phenyl sulphide (Abstr., 1890, 988) melts at 176°; to convert it into the corresponding trisulphone, which melts at 213° (compare *loc. cit.*), it is dissolved in an alkali, saturated with carbonic anhydride, and poured into permanganate solution; the oxidation is complete in two days.

Ethyl trithioacetate, $CMe(SEt)_3$, is obtained by heating ethyl mercaptan (3 mol. proportions) with 20 per cent. aqueous solution of sodium hydroxide (5 mol. proportions) and methyl chloroform ($1\frac{1}{2}$ mol. proportions) in a strong flask at 100° for two or three days. It is a thick oil of unpleasant odour.

Triethylsulphonemethylmethane, $CMe(SO_2Et)_3$, is prepared by dissolving the foregoing compound in a little benzene and shaking it with a 3 per cent. permanganate solution containing half its volume of 3 per cent. sulphuric acid, the mixture being kept cool until the end of the reaction, when it is slightly warmed and the benzene removed by a current of air; the manganese dioxide is dissolved by the addition of sulphurous acid, when the trisulphone remains as an amorphous, white powder. It crystallises from hot alcohol in vitreous, white needles which melt at 140°; it dissolves easily in chloroform, but not in cold alcohol or ether; at 40° it dissolves in 200 parts of water, and at 15° in 500 parts. It is indifferent to alkalis and is very stable; its taste is very bitter, resembling that of quinine.

3 grams of the powdered sulphone were administered to a dog of 9 kilos. body weight; slight symptoms of lassitude were exhibited at the beginning of the second hour and lasted for half an hour, but there was no further important change; the urine of the next night was found to contain 0·9 gram of unaltered trisulphone. The author administered a dose of 1 gram to himself and experienced very slight lassitude, but his pulse fell in the course of an hour from 75 to 60, and after three hours returned to 72; another dose of 1·5 grams, taken four hours after the first, intensified the action; the urine of the following 24 hours contained 0·85 gram of the unaltered trisulphone. It would appear that the greater part of the trisulphone is not decomposed in the organism, and is therefore without action.

A. G. B.

Ethyl Acetothiënoneoxalate. By A. Angeli (*Gazzetta*, **21**, 444—449).—Part of this paper has appeared before (Abstr., 1891, 550).

Acetothiënoneoxalic acid, $C_4SH_3{\cdot}CO{\cdot}CH{\cdot}CO{\cdot}COOH$, is obtained by dissolving ethyl acetothiënoneoxalate (5 grams) in concentrated sulphuric acid (40 grams) and heating the mixture for a few minutes on the water-bath. The salt is readily soluble, especially on warming. On pouring the product into much cold water, a bulky precipitate of minute, rose-coloured crystals falls; this is recrystallised from dilute alcohol, precipitated several times from its solution in ethyl acetate by light petroleum, and finally crystallised from boiling benzene. The small, yellowish needles thus obtained turn intensely yellow at 150°, become reddish-brown at 170°, and melt with evolution of gas at 180°. The acid dissolves with effervescence in alkali carbonates; it is precipitated from the solution thus obtained by hydrochloric acid, but not by acetic acid. It is readily soluble in alcohol and ethyl acetate, less so in water, only sparingly in benzene and chloroform, and almost insoluble in light petroleum. The solution of the ammonium salt gives an orange-yellow precipitate with silver nitrate, white with mercuric chloride, pale yellow with lead acetate, green, soluble on heating, with copper sulphate, yellowish with barium

nitrate, and dark red with ferric chloride solution. Alkalis decompose the acid into acetothiënone and oxalic acid. W. J. P.

Bromine Carriers. By W. MacKerrow (*Ber.*, **24**, 2939—2947). —The author has already determined that the extraordinary activity of the halogen carrier when one nitro-group is present in the benzene ring entirely fails if two or three nitro-groups are present. In the latter case, the bromine displaces the nitro-group in preference to a hydrogen atom, and then the influence of the halogen carrier induces further bromination.

Metadinitrobenzene, when treated with bromine alone at 230—235°, gives, together with a large proportion of unaltered material, symmetrical tetrabromobenzene and metabromonitrobenzene. The action goes further in the presence of ferric chloride. Dinitrobenzene (10 grams), bromine (1 mol.), and ferric chloride (2 grams) were heated for 14 hours at 180°. The product consisted of a large quantity of unaltered dinitrobenzene with some perbromobenzene. When bromine (3 mols.) and 8—10 grams of ferric chloride are employed and the mixture heated for 24 hours at 180—190° and then for 15 hours at 220°, the product contained hexabromobenzene, *chloropentabromobenzene*, *dichlorotetrabromobenzene*, and some unchanged dinitrobenzene. The two new compounds crystallise in snow-white needles, are very like hexabromobenzene, and are soluble in alcohol, very sparingly so in hot ether, but easily in boiling acetic acid and benzene. When heated on a watch glass, they sublime without melting; heated in a capillary tube, dichlorotetrabromobenzene melts at 277—279°, chloropentabromobenzene at 294—295°. Dichlorotetrabromobenzene is the more easily soluble, and hexabromobenzene less soluble, in benzene.

Since chlorination takes place when ferric chloride is used as a bromine carrier, the author has employed ferric bromide. Dinitrobenzene (10 grams) was heated for 20 hours at 180—190° with ferrous bromide (5 grams) and bromine (3 mols. *plus* the calculated quantity to form ferric bromide). The product consisted of unaltered dinitrobenzene, a minute quantity of a compound melting at 40—50°, and hexabromobenzene.

Symmetrical trinitrobenzene, when heated with bromine (3 mols.) for 30 hours at 230—235°, gave dibromonitrobenzene and an oily product which was not examined. An attempt was then made to prepare monobromodinitrobenzene by heating trinitrobenzene with bromine (1 mol.) for one hour at 200—210°; a large quantity of unaltered trinitrobenzene was recovered, and a product obtained which melted at 75—76°, and seemed to be the monobromo-compound mixed with some dibromonitrobenzene. With bromine and ferric bromide, trinitrobenzene yielded hexabromobenzene. With bromine and ferric chloride, it gave a new tetrachlorodibromobenzene.

Tetrachlorodibromobenzene is obtained by heating trinitrobenzene (5·3 grams) with bromine (12 grams) and ferric chloride (5—6 grams) at 230—235° in a sealed tube. The product is washed with water, a small quantity of trinitrobenzene extracted with alcohol, and the residue crystallised from hot benzene. It crystallises in beautiful

white needles, melts at 241—242°, is insoluble in alcohol, sparingly soluble in hot ether, and somewhat easily so in boiling benzene and acetic acid. When heated on a watch glass, it sublimes without melting.

α-Nitronaphthalene and bromine behave in the way already described by Guareschi (*Annalen*, **122**, 184). The presence of ferric chloride seems to be without influence on the reaction.

Picric acid gives, with bromine alone and in the presence of ferric bromide, orthobromorthoparadinitrophenol, melting at 116·5°. With ferric bromide, the reaction is complete in 12 hours at 100°; without, it requires 20 hours heating at 160—170°, and at this higher temperature some tetrabromoquinone is formed.

Bromodinitrobenzene [$Br : NO_2 : NO_2 = 1 : 2 : 4$] is almost unaltered when heated with bromine and ferric bromide for 14 hours at 130—140°. A small quantity of hexabromobenzene is formed, however.

Pyridine, when treated with bromine and ferric chloride, yields dibromopyridine.

Metanitrobenzoic acid, when heated with bromine and ferric bromide for 10 hours at 130—140°, is, for the most part, unaltered.

Since in the above experiments chlorinated compounds are obtained when ferric chloride is employed as a bromine carrier, the author has examined the action of ferric chloride alone on dinitrobenzene. At 180° no action takes place, and at 200—210° the tube burst with a violent explosion. On performing the experiment in open tubes, it was observed that at 210° gas was evolved, and at 230° the evolution of gas was very violent. The gas was found to be a mixture of carbonic anhydride, nitrogen, hydrogen chloride, and chlorine, and the residue consisted of carbon, ferric chloride, ferrous chloride, and ferric oxide. E. C. R.

Condensation Products of Allyl Alcohol with Methylbenzenes. By G. Kraemer and A. Spilker (*Ber.*, **24**, 3164).—In their paper on the condensation products of allyl alcohol with methylated derivatives of benzene (Abstr., 1891, 1462), the authors overlooked the fact that an oily hydrocarbon of high boiling point was obtained by Baeyer (this Journal, 1873, 885) by the condensation of allyl alcohol with mesitylene by means of concentrated sulphuric acid. A. R. L.

Bromo-derivatives of Carvacrol. By G. Mazzara and G. Plancher (*Gazzetta*, **21**, 470—472).—*Dibromocarvacrol*, [$Br : Pr : Br = 1 : 2 : 3$].—Carvacrol (50 grams) is dissolved in glacial acetic acid (50 grams), cooled, and bromine (107 grams) dissolved in glacial acetic acid (120 grams) slowly added; the product is now poured into much water and the heavy oil which separates is steam-distilled. The pure substance is thus obtained as an oil which does not solidify at −18°. On nitration, dibromocarvacrol yields dinitrocarvacrol together with much resin. The *benzoyl* derivative of dibromocarvacrol is obtained by heating it at 160° with benzoyl chloride. The product is washed with potassium carbonate solution, and on repeated crystallisation from alcohol and light petroleum, is obtained in colourless

parallelopipedons melting at 97—98·5°. The substance is very soluble in light petroleum, less so in alcohol. When heated with alcoholic potash, it yields benzoic acid and the potassium salt of dibromocymenecarboxylic acid. W. J. P.

Behaviour of Carvacrol towards Reducing Agents. By E. Bamberger, B. Berlé, and L. Strasser (*Ber.*, **24**, 3208—3212).—Neither phenol nor carvacrol is acted on by alkaline reducing agents, but the latter is attacked by phosphorus and hydriodic acid at 225—235° with formation of a gaseous hydrocarbon, apparently propane, and an oil consisting mainly of hydrocarbons. The latter, after repeated fractionation, was resolved into seven fractions, which, with the exception of the two largest, appear to be mixtures of hydrocymenes of different composition, containing also in some cases toluene. The two chief fractions boil at 162—163° and 165—168° respectively, and are mobile, pleasant-smelling, colourless liquids, which in many respects closely resemble menthene. The latter compound, however, readily combines with 1 mol. HCl, whilst the fraction 162—163° only combines with one-sixth of that amount, and is therefore probably a mixture of several tetrahydrocymenes, one of which may possibly be identical with menthene.

Attempts have also been made to reduce phenol by electrolysing its solution in fused potash, but they failed owing to the difficulty of finding any material which would resist the combined action of the fused potash and the electric current. By the electrolysis of a solution of phenol in potash and a little water, the authors obtained, in addition to salicylic acid, a small quantity of xanthone,

$$C_6H_4<^{-O-}_{CO}>C_6H_4.$$

H. G. C.

Preparation of Primary Amines by means of Potassium Phthalimide. By S. Gabriel (*Ber.*, **24**, 3104—3107).—Potassium phthalimide has been shown to react with halogen derivatives of the following classes of compounds:—Hydrocarbons, nitrohydrocarbons, nitriles, alcohols, and alkoxy-derivatives of phenols, ketones, and ethereal salts. So far, only primary haloïd derivatives have been shown to react, excepting picryl chloride, $C_6H_3(NO_2)_3Cl$, and desyl bromide, CHPhBr·COPh, but it is probable that the halogen in these two compounds is rendered more easily replaceable by the neighbourhood of the negative groups (CO) and (NO_2). To ascertain if secondary haloïd derivatives react at all with potassium phthalimide, the action of normal propyl bromide has been compared with that of isopropyl bromide. The latter substance does react, but much less readily than the normal compound.

Normal propyl bromide (6 parts) was heated with potassium phthalimide (4 parts) for five hours in a sealed tube at 150—160°. The product was boiled with water; *propylphthalimide*,

$$C_8H_4O_2{:}N{\cdot}CH_2{\cdot}CH_2Me,$$

separated on cooling, and was obtained by crystallisation from small

quantities of alcohol in colourless prisms or plates melting at 66° and boiling at 282—283° under a pressure of 756 mm.

Isopropyl bromide was heated in the same way with potassium phthalimide for seven hours at 160—170°, but the potassium salt was not attacked. The tube was then heated for eight hours at 190°. On opening it, an escape of propylene was observed. The contents were boiled with water to expel the excess of bromide, and the insoluble residue powdered, repeatedly treated with dilute aqueous soda, and recrystallised from small quantities of warm alcohol; *isopropylphthalimide*, $C_8H_4O_2{:}N{\cdot}CHMe_2$, was thus obtained in long, colourless needles melting at 85° and boiling at 272—273° under a pressure of 256 mm.

Since isopropylphthalimide is easily converted into isopropylamine, the above-mentioned reaction of isopropyl bromide will afford the most convenient method of preparing the amine, which has hitherto been obtained only by the reduction of isopropylcarbamine.

C. F. B.

Oxidation Products of Paramidophenetoïl (Paraphenetidine). By W. Kinzel (*Arch. Pharm.*, **229**, 329—355).—The specific gravity of paramidophenetoïl is 1·0613 at 15°, and its boiling point is 254·2—254·7° (corr.) at 760 mm.; Liebermann and Kostanecki give the boiling point as 253° (*Ber.*, **17**, 876; Abstr., 1884, 1146), and elsewhere (*Pharm. Centr.*, 1890, 6, 66) it is given as 242·5°.

Seidel (Abstr., 1890, 490) has shown that the dye obtained by oxidising orthamidophenol is triphenodioxazine, $C_{18}H_{10}N_2O_2$.

By oxidising paramidophenetoïl, a brown colouring matter is obtained, which has the formula $C_{24}H_{22}N_2O_5$ and yields evidence of three ethoxyl groups when treated by Zeisel's method; it may therefore be regarded as *triethoxytriphenodioxazine*, $C_{18}H_7(OEt)_3N_2O_2$, but further investigation of the matter is required. It is best obtained by heating a solution of paramidophenetoïl (41·1 grams) with sulphuric acid (83 grams), water (500 c.c.), and a 3 per cent. solution of hydrogen peroxide (680 grams) at 100°, and after some days evaporating with more sulphuric acid and hydrogen peroxide until no more carbonic anhydride is evolved; the crystals which separate are boiled several times with much water, and finally digested twice with 300 grams of alcohol at 60°. 134 grams of paramidophenetoïl yield 57 grams of the dye. The new compound forms a cinnamon-brown, crystalline powder which partially sublimes in iridescent, brown needles. It is a feeble base and, with concentrated mineral acids, yields violet or blue salts which are soluble in excess of the acid with an intensely blue colour; when such solutions are diluted, the original compound is precipitated unchanged. 1 milligram of the compound will impart a sky-blue colour to 1000 c.c. of concentrated sulphuric acid. Triethoxytriphenodioxazine dissolves in about 900 parts of alcohol, more easily in xylene, benzene, aniline, and chloroform, and most easily in glacial acetic acid, from which it will crystallise, and in pyridine; in water and ether it is almost insoluble. The *acetyl* derivative is of uncertain composition; it appears to contain more acetyl than would suffice to replace the three ethoxyl groups. The *platinochloride* is unstable, and dissolves in sulphuric acid with a blue colour. The *leuco*-base, $C_{24}H_{24}N_2O_5$, ob-

tained by heating the dye with xylene and phenylhydrazine (compare Seidel, *loc. cit.*), crystallises in microscopic, white needles, which are converted into the original dye during the process of drying. The *hydrochloride*, $C_{24}H_{22}N_2O_5,2HCl$, forms crystals which are violet by transmitted light, and nearly black, with a greenish lustre, by reflected light.

Quinone, carbonic anhydride, acetic acid, oxalic acid, and resinous substances are also produced by the oxidation of paramidophenetoïl; when the oxidation is effected by potassium permanganate in the cold, the yield of carbonic anhydride and quinone is much less, and parazophenetoïl melting at 159° (Beilstein, *Handbuch*, gives 157° and 160°) is produced to a considerable extent. This is the product of the oxidation which gives a blood-red colour with sulphuric acid, and the author attributes the red colour of the earlier samples of commercial phenacetin to the presence of this substance.

From the mother liquor of the permanganate mixture from which the parazophenetoïl had crystallised out, brownish needles of a *compound* $C_{16}H_{18}N_2O_3 + H_2O$ were obtained; these melted at 178°, and their formula corresponds with that of parazoxyphenetoïl. As this substance has not yet been described, the author prepared it (see below), and found that the crystals melting at 178° are not identical with it; so the constitution of the said crystals is still uncertain, but inasmuch as they give the same carmine-red colour with fused chloral hydrate as azoxy-compounds, including parazoxyphenetoïl, generally do, there is strong evidence that they are paroxyazophenetoïl.

Parazoxyphenetoïl, $C_{16}H_{18}N_2O_3$, is prepared by reducing paranitrophenetoïl (5 grams) in 95 per cent. alcohol (100 grams) with 10 per cent. sodium amalgam at 10°, keeping the mixture at 0° for two hours with frequent shaking. When recrystallised, it forms bright-yellow tables which melt at 136·6° (uncorr.), and dissolve easily in hot alcohol.

Parahydrazophenetoïl, obtained by reducing parazophenetoïl with ammonium sulphide in alcohol, crystallises in white needles which melt at 118—119°.

The red colour of commercial carbolic acid is probably to be attributed to the presence of the colouring matter described in this paper.

A. G. B.

Action of Nitric Acid on Dimethylorthanisidine (Dimethylorthomethoxyaniline). By P. van Romburgh (*Compt. rend.*, **113**, 505—508).—Grimaux and Lefèvre obtained a substance melting at 135° by heating dimethylorthanisidine with ordinary nitric acid and, when nitrous vapours appeared, immediately precipitating with water. They gave to this compound the formula

$$OMe\cdot C_6H_2(NO_2)_2\cdot NMe\cdot CH_2\cdot NO_2$$

(*Compt. rend.*, **112**, 727). This result appears to differ from what has been observed in connection with other aromatic amines by the author (*Rec. trav. Chim.*, **3**, 409), and confirmed by Gattermann (*Ber.*, **18**, 1482).

The author has prepared the product melting at 135° by the method given by Grimaux and Lefèvre. It contains 22·2 per cent. of nitrogen;

a substance of the above formula would contain 19·58 per cent. When boiled with phenol, the solution becomes red, and on the addition of alcohol, a reddish-orange product is obtained, melting at 168°. The author has shown that nitramines under these circumstances have a nitro-group displaced by hydrogen (*Rec. trav. Chim.*, **5**, 241); he now finds the same reaction to occur with nitrosamines. The orange-red product is also obtained on boiling the nitramine of dinitromethylorthanisidine with phenol. Its composition is as follows:—

$$OMe\cdot C_6H_2(NO_2)_2\cdot NHMe.$$

To prove that the substance melting at 135° has the composition $OMe\cdot C_6H_2(NO_2)_2\cdot NMe\cdot NO$, the author has prepared it from the corresponding nitramine, certainly containing only one methyl group. The preparation melts at 135°, and has the same characters as the substance prepared by the method of Grimaux and Lefèvre. W. T.

Phenacetin. Metethoxyorthophenylenediamine. By W. Autenrieth and O. Hinsberg (*Arch. Pharm.*, **229**, 456—467.)—To distinguish between antifebrin, antipyrin, and phenacetin, the substance is boiled for a short time with 10—12 per cent. nitric acid; under these conditions, phenacetin colours the solution yellow to orange, and an intensely yellow nitro-derivative crystallises on cooling.

Orthonitrophenacetin,

$$NO_2\cdot C_6H_3(OEt)\cdot NH\cdot COMe\ [OEt : NO_2 : NHCOMe = 4 : 2 : 1],$$

is prepared as described above. It crystallises from water in long, soft, silky, yellow needles, melts at 103°, and dissolves in hot water, hot dilute alcohol, absolute alcohol, ether, and chloroform. When dissolved in hot alcohol and boiled for a short time with rather more than the theoretical quantity of potassium hydroxide, it is converted into *orthonitrophenetidine*, $NO_2\cdot C_6H_3(NH_2)\cdot OEt\ [OEt : NO_2 : NH_2 = 4 : 2 : 1]$, which crystallises as the solution cools in brilliant, red, lustrous prisms, melts at 113°, and dissolves in hot alcohol, ether, and chloroform.

Metethoxyorthophenylenediamine, $C_6H_3(NH_2)_2\cdot OEt\ [OEt : (NH_2)_2 = 4 : 2 : 1]$, is prepared by reducing orthonitrophenetidine with zinc-dust in boiling alcoholic soda; the frothing of the solution indicates the end of the reaction; the liquid is filtered and evaporated in hydrogen; the residue is treated with a little water, which separates the diamine as a brown oil; this is washed with water, dried on a porous plate, and distilled. The new compound, when freshly distilled, forms long, white, slender needles, which rapidly resinify and become red or brown in air. From ether, it crystallises in brilliantly lustrous, greyish-white laminæ which are pretty stable when dry. It melts at 71—72° and distils between 294° and 296°; it dissolves partially in water and easily in alcohol, ether, and chloroform; it is a fairly strong base, turns litmus blue, and forms crystalline salts with bibasic acids, of which the *sulphate* and *oxalate* are described.

Metethoxydihydroxyquinoxaline,

$$OEt\cdot C_6H_3<\begin{matrix}N:C\cdot OH\\ |\\ N:C\cdot OH\end{matrix}\ [OEt : N_2 = 6 : 2 : 3],$$

is prepared by heating metethoxyorthophenylenediamine with excess of oxalic acid in an oil-bath at 140—150° for half an hour (compare *Annalen*, **237**, 327), treating the product with sodium hydroxide solution, filtering, and precipitating the quinoxaline from the filtrate by strong hydrochloric acid. It crystallises from alcohol in slender, pale-yellow needles, melts above 280°, and dissolves sparingly in cold water and alcohol, but hardly at all in ether. The *sodium* salt was obtained.

Metethoxydiacetylorthophenylenediamine,

$$OEt{\cdot}C_6H_3(NHAc)_2\ [OEt : (NHAc)_2 = 4 : 2 : 1],$$

obtained from the diamine and acetic anhydride, crystallises from water in lustrous, colourless prisms which melt at 189°; it dissolves sparingly in cold water, but rather better in hot water, alcohol, and ether. The corresponding *dibenzoyl* derivative, $OEt{\cdot}C_6H_3(NHBz)_2$ $[OEt : (NHBz)_2 = 4 : 2 : 1]$, is obtained by shaking an aqueous solution of the diamine with benzoic chloride and excess of sodium hydroxide; it crystallises from alcohol in slender, white needles, melts at 191—192°, and is insoluble in water, but somewhat freely soluble in hot alcohol.

Metethoxydiphenylsulphonorthophenylenediamine,

$$OEt{\cdot}C_6H_3(NH{\cdot}SO_2Ph)_2\ [OEt : (NHSO_2Ph)_2 = 4 : 2 : 1],$$

is obtained when the diamine is shaken with phenylsulphonic chloride and sodium hydroxide (compare Abstr., 1891, 49); the product is dissolved in dilute sodium hydroxide solution, and reprecipitated by strong hydrochloric acid; it crystallises in slender, white needles which melt at 159—160°, and dissolves in alcohol and ether, but not in water. The *diethyl* derivative, $OEt{\cdot}C_6H_3(NEt{\cdot}SO_2Ph)_2$, formed by heating the diphenylsulphone compound with excess of ethyl iodide and sodium hydroxide in a reflux apparatus, crystallises in slender needles, and melts at 121°. A. G. B.

Action of Diazobenzene on Acetonedicarboxylic Acid. By H. v. Pechmann and K. Jenisch (*Ber.*, **24**, 3255—3260).—The action of diazobenzene salts on certain fatty compounds containing a methylene group, the hydrogen atoms of which are displaceable, does not always give rise to compounds of the same type, for example, Japp and Klingemann (Trans., 1888, 521, 538) showed that the so-called benzeneazoacetone from acetoacetic acid and diazobenzene chloride is pyruvaldehydrazone; whilst Beyer and Claisen (Abstr., 1888, 827) obtained azo-compounds by the action of diazobenzene chloride on derivatives of acetone.

Disbenzeneazoacetone, $CO(CH_2{\cdot}N_2Ph)_2$, is produced when crude acetonedicarboxylic acid (50 grams) is dissolved in water (5 parts) cooled to 0°, a solution of diazobenzene chloride (2 mols.) carefully stirred in, and sodium acetate added; the red precipitate is collected, dried, washed with benzene, and crystallised from dilute alcohol, when it separates in stellate groups of yellowish-red needles, and melts at 175—176°. It has both acidic and basic properties in a slight degree, and dissolves in concentrated mineral acids with a violet colour. On

adding concentrated hydrochloric acid to its alcoholic solution, small, blue needles separate which become red on exposure to the air; it is soluble in boiling sodium hydroxide solution; it can be reduced by tin and hydrochloric acid, and when heated with an equal weight of phenylhydrazine at 120° for half an hour, it yields the *hydrazone*, $NHPh{\cdot}N{:}C(CH_2{\cdot}N_2Ph)_2$, which crystallises in hexagonal plates, melts at 166°, and dissolves in concentrated sulphuric acid with a green colour. When the hydrazone is boiled with 3 to 4 times its weight of acetic anhydride, the *pyrazole derivative*, $CMe\leqslant^{NPh—N}_{C(N_2Ph)}\geqslant C{\cdot}CH_2{\cdot}N_2Ph$, is formed; this crystallises from light petroleum in lustrous, golden plates, and melts at 125°. In conclusion, attention is drawn to the fact that the above-described azo-compound is quite distinct from the compound $C_{15}H_{14}N_4O$, obtained by Bamberger and Wulz (Abstr., 1891, 1449) by the action of acetone on diazobenzene chloride in the presence of alkali. A. R. L.

Action of Phenylhydrazine on Acetonedicarboxylic Acid. By H. v. Pechmann and K. Jenisch (*Ber.*, **24**, 3252—3255).—When a mixture in molecular proportions of crude acetonedicarboxylic acid, dissolved in water (8 parts), concentrated hydrochloric acid, and phenylhydrazine is heated on the water-bath for several hours, and sodium carbonate is added to incipient turbidity, methylphenylpyrazolonecarboxylic acid (Abstr., 1891, 673) separates after a time in crystals, and a further quantity is obtained on adding sodium carbonate to the filtrate. When the last-mentioned acid is heated at 160°, and then distilled under a pressure of 100 mm., Knorr's methylphenylpyrazolone passes over.

When crude acetonedicarboxylic acid (50 grams) is dissolved in a little water, neutralised with sodium carbonate, cooled to 0°, and treated with a solution of phenylhydrazine hydrochloride (2 mols.), in water (400 grams), carbonic anhydride is evolved, and yellowish needles separate; the substance is insoluble in cold water, but soluble in the hot liquid, and is perhaps the *phenylhydrazine salt of the hydrazone of acetoacetic acid*, $N_2HPh{:}CMe{\cdot}CH_2{\cdot}COOH,N_2H_3Ph$. It remains unaltered for several days in the presence of water, but in the dry state decomposes with the evolution of carbonic anhydride yielding an oil of disagreeable odour; when the latter is dissolved in dilute hydrochloric acid, reprecipitated with alkali, and dissolved in 50 per cent. alcohol, the addition of alcoholic oxalic acid causes a precipitate of phenylhydrazine oxalate, whilst acetonephenylhydrazone, boiling at 195—200° (20 mm.), can be extracted from the filtrate by means of ether. A. R. L.

Symmetrical Bisphenylhydrazone of Mesoxaldehyde. By E. Bamberger (*Ber.*, **24**, 3260—3264).—Pyruvaldehydephenylhydrazone is not the sole compound formed from acetoacetic acid and diazobenzene chloride (see Japp and Klingemann, Trans., 1888, 538), the author having separated a compound $C_{15}H_{14}N_4O$, melting at 134—135°, identical with that recently described by himself and Wulz (Abstr., 1891, 1449), by allowing the benzene filtrate

from the crystals of the pyruvaldehydrazone to evaporate, treating the tarry residue with alcohol, and finally crystallising from boiling alcohol. The following facts prove that this compound is *mesoxaldehydebisphenylhydrazone*, $CO(CH{:}N_2HPh)_2$. When an aqueous solution of acetoacetic acid (1 mol.) is treated at 0° with one of diazobenzene chloride (2 mols.), and a large excess of 20 per cent. sodium hydroxide solution cautiously added, the mesoxaldehydebisphenylhydrazone is precipitated; it is the chief product, and the same compound is formed when a concentrated aqueous solution of diazobenzene chloride (1 mol.) is added to pyruvaldehydrazone (1 mol.) dissolved in alcohol. The azo-derivative, $C_{15}H_{14}N_4O$, obtained by v. Pechmann and Jenisch (preceding abstract) from acetonedicarboxylic acid is formed in small quantities simultaneously with the isomeric mesoxaldehydebisphenylhydrazone, and the further investigation of it is being carried on by the author. A. R. L.

Action of Oximes on Diazo-compounds. By J. Mai (*Ber.*, **24**, 3418).—On adding diazobenzene chloride in aqueous solution to benzaldoxime dissolved in soda, a voluminous precipitate is formed which quickly becomes dark yellow; the compound crystallises from a mixture of alcohol and ether, and is colourless when pure. It probably has the formula $PhN_2{\cdot}O{\cdot}N{:}CHPh$, and is to be regarded either as an ether, or as an hydroxylamine anhydride derivative. On treatment with dilute hydrochloric acid, benzaldehyde and diazobenzeneimide are obtained.

Similar compounds are formed from isobenzaldoxime, acetoxime, and ethylaldoxime, and as other diazo-derivatives may be substituted for the diazobenzene chloride, the reaction appears to be a general one. J. B. T.

Molecular Transformations of the Aldoximes. By R. Behrend (*Ber.*, **24**, 3088—3090).—The author (Abstr., 1891, 1032) has obtained *α-* and *β-paranitrobenzaldoximes* by treating dinitrosoparanitrobenzyl with potash, and found that, while the *β*-oxime is converted into the *α*-variety by the action of hydrochloric acid on its ethereal solution, the *α*-oxime undergoes no corresponding change. He now finds that, as Goldschmidt has informed him by letter, the latter change does take place when an ethereal solution of the *α*-oxime is saturated with hydrogen chloride, whereas, to convert the *β*- into the *α*-oxime, the ethereal solution of the former should be treated with only a moderate amount of hydrogen chloride. C. F. B.

Synthesis of Weselsky's Resorcinol Blue. By R. Nietzki (*Ber.*, **24**, 3366—3369; compare Abstr., 1890, 156).—Resazurin is prepared by dissolving nitrosoresorcinol and resorcinol in molecular proportion in alcohol; the solution is cooled, mixed with finely-divided manganese dioxide (1 mol.), and sulphuric acid (2 mols.) diluted with an equal bulk of water is slowly added, the liquid becomes cherry red, and, as soon as a drop brought on to filter paper gives a pure blue coloration with ammonia, the manganese dioxide is filtered off, and the compound precipitated with water; on treating

the product with soda, green crystals of sodium resazurinate are formed. The mother liquid contains sodium resorufinate. Weselsky's method of preparing resazurin consists in treating resorcinol with a mixture of nitrous and nitric acids; the nitrosoresorcinol, which is probably first formed, immediately condenses with the excess of resorcinol, whilst the nitric acid acts as an oxidising agent, and is reduced to nitrous acid.

The author suggests the formula $C_6H_3O\langle\overset{N\cdot O}{\underset{\quad O}{\quad}}\rangle C_6H_3\cdot OH$ [O : N : O = 1 : 3 : 4; OH : O : O = 1 : 3 : 4] for resazurin, which differs from resorufin inasmuch as it contains the quinonoxime group instead of the quinonimide radicle; the objection that the formula represents the compound as a ring consisting of 7 atoms may be met by writing the oximido-group $O\overset{\|}{N}\cdot H$, with a pentavalent nitrogen atom.

J. B. T.

Aromatic Secondary Chlorocarbamides and Tetra-substituted Carbamides. By S. Paschkowezky (*Ber.*, **24**, 2905—2930). —The author has prepared a number of new aromatic derivatives of carbamide.

Thiodiphenylcarbamic chloride, $S\langle\overset{C_6H_4}{C_6H_4}\rangle N\cdot COCl$, is prepared by heating thiodiphenylamine (10 grams) dissolved in benzene (250 grams) with twice the theoretical quantity of a 20 per cent. toluene solution of carbonyl chloride for $2\frac{1}{2}$ hours on the water-bath. The yield amounts to 75 per cent. of that required by theory. It crystallises from hot alcohol in small, pale-yellow, lustrous, prismatic needles, from toluene in large, well-formed, greenish prisms, and melts at 171—172°. The crystals belong to the monosymmetric system; $a : b : c = 2{\cdot}3615 : 1 : 1{\cdot}4465$. It is sparingly soluble in alcohol and ether, easily so in hot benzene and toluene, sparingly in the cold. At 17·5°, one part dissolves in 219 parts of alcohol (96 per cent.), and in 34 parts of benzene.

Phenyl thiodiphenylcarbamate is obtained by heating an alcoholic solution of the preceding compound with sodium phenoxide on the water-bath. It crystallises from alcohol in white, lustrous needles, melts at 164°, and is soluble in hot alcohol, ether, benzene, and acetic acid. At 16°, one part dissolves in 410 parts of alcohol, and in 50·6 parts of benzene.

Unsymmetrical thiodiphenylcarbamide, $S:(C_6H_4)_2:N\cdot CO\cdot NH_2$, is obtained by heating thiodiphenylcarbamic chloride with alcoholic ammonia on the water-bath for two hours. It crystallises in colourless tablets, melts at 201—202°, and dissolves copiously (but with difficulty) in boiling methyl and ethyl alcohols and ether, easily in benzene. At 17·5°, one part dissolves in 331·5 parts of alcohol, and in 48·4 parts of benzene. When heated in a sealed tube with alcoholic ammonia for three hours at 140—150°, it yields thiodiphenylamine and carbamide. The same two substances are formed when it is distilled from a retort into aqueous ammonia.

Thiotriphenylcarbamide, $S:(C_6H_4)_2:N\cdot CO\cdot NHPh$, is obtained by heating thiodiphenylcarbamic chloride, dissolved in hot xylene, with a

slight excess of aniline. It crystallises from boiling alcohol in white, lustrous needles which turn red on exposure to air, melts at 168—169°, and dissolves copiously, but with difficulty, in boiling alcohol and ether, easily in benzene and chloroform. At 17·5°, one part dissolves in 387 parts of alcohol, and in 26·7 parts of benzene. When heated with excess of aniline, it is easily converted into diphenylcarbamide and thiodiphenylamine. The same products are formed by heating thiodiphenylcarbamic chloride with excess of aniline.

Dithiotetraphenylcarbamide, $CO[N:(C_6H_4)_2:S]_2$, is obtained by heating a mixture of thiodiphenylcarbamic chloride with thiodiphenylamine in molecular proportion at 220—260°. It crystallises from a mixture of alcohol and benzene in colourless needles, having a red lustre, melts at 231°, and is very sparingly soluble in alcohol, ether, and acetic acid, copiously in cold, and very easily in hot benzene. At 17°, one part dissolves in 2300 parts of alcohol, and in 24 parts of benzene. It is also formed when thiodiphenylcarbamic chloride is heated with thiodiphenylcarbamide for two hours at 200—280°. When heated with concentrated hydrochloric acid at 240—250°, hydrogen sulphide is produced together with a solid dark-green product. Unlike tetraphenylcarbamide, it does not yield carbon dioxide under these conditions (*Ber.*, **11**, 711).

Monothiotetraphenylcarbamide, $NPh_2{\cdot}CO{\cdot}N:(C_6H_4)_2:S$, is obtained by heating molecular proportions of thiodiphenylcarbamic chloride and diphenylamine at 220—240° for three hours. The product is purified by dissolving it in benzene and passing hydrogen chloride into the solution, when diphenylamine hydrochloride is precipitated; the filtrate is then evaporated to dryness, and the residue washed with alcohol, and crystallised from hot alcohol. It forms colourless, six-sided plates, softens at 163°, melts at 165°, and is soluble in cold alcohol and ether, easily in cold benzene and boiling alcohol and ether, and very easily in boiling benzene.

Thiotriphenyl-β-naphthylcarbamide, $C_{10}N_7{\cdot}HPh{\cdot}CO{\cdot}N:(C_6H_4)_2:S$, is obtained by heating thiodiphenylcarbamic chloride with phenyl-β-naphthylamine for three hours at 240—260°. It crystallises from alcohol in greyish-white, nodular aggregates, melts at 169—170°, and is easily soluble in boiling alcohol and ether, very easily so in benzene and acetic acid. At 15°, one part dissolves in 190·7 parts of alcohol, and in 29·5 parts of benzene.

Thiodiphenyldi-β-naphthylcarbamide, $N(C_{10}H_7)_2{\cdot}CO{\cdot}N:(C_6H_4)_2:S$, obtained from di-β-naphthylamine in a similar manner to the preceding compound, crystallises from a mixture of benzene and alcohol in nodular aggregates, melts at 225°, and is sparingly soluble in boiling alcohol and ether, easily in benzene and acetic acid. One part dissolves, at 16°, in 801 parts of alcohol, and in 181 parts of benzene.

Thiodi-β-naphthylcarbamic chloride, $S<\begin{matrix}C_{10}H_7\\C_{10}H_7\end{matrix}>N{\cdot}COCl$, is obtained by heating thiodi-β-naphthylamine with carbonyl chloride at 160—170° for five hours. It forms small, white needles, melts at 254—255°, is almost insoluble in cold alcohol, very sparingly soluble in hot alcohol and cold benzene, more so in hot benzene and cold xylene, and easily in boiling xylene. At 16·5°, one part dissolves in 1420 parts

of alcohol, and in 134 parts of benzene. When boiled with alcoholic soda, it yields thiodi-β-naphthylamine.

Phenyl thiodi-β-naphthylcarbamate, $S:(C_{10}H_6)_2:N\cdot COOPh$, is obtained by heating the preceding compound with alcoholic sodium phenoxide; it forms small, greyish-white needles, melts at 215°, and is sparingly soluble in both cold and hot alcohol and ether, cold benzene, and acetic acid, but easily in hot benzene and acetic acid. At 16°, one part dissolves in 489·5 parts of alcohol, and in 83 parts of benzene.

Unsymmetrical thiodi-β-naphthylcarbamide, $S:(C_{10}H_6)_2:N\cdot CO\cdot NH_2$, is obtained by heating thiodi-β-naphthylcarbamic chloride with excess of alcoholic ammonia at 140—145° for three hours; it crystallises from benzene in almost colourless needles, which turn green on exposure to air, decomposes at 215° without melting, and is almost insoluble in cold alcohol, ether, and benzene, sparingly soluble in boiling alcohol and ether, more so in boiling benzene, and easily in xylene.

Thiodi-β-naphthylphenylcarbamide, $S:(C_{10}H_6)_2:N\cdot CO\cdot NHPh$, is obtained by heating thiodi-β-naphthylcarbamic chloride dissolved in xylene with twice the molecular proportion of aniline for ¾ hour in a reflux apparatus. It darkens at 180°, decomposes at 215—220° without melting, and is sparingly soluble in alcohol, ether, and cold benzene, xylene, and chloroform, fairly soluble in hot benzene, and easily so in hot xylene and chloroform. At 17·5°, one part dissolves in 275·2 parts of alcohol, and in 551·5 parts of benzene. When boiled with excess of aniline, it yields thiodi-β-naphthylamine and carbanilide.

Dithiotetra-β-naphthylcarbamide, $CO[N:(C_{10}H_6)_2:S]_2$, is prepared by heating a mixture in molecular proportion of thiodi-β-naphthylcarbamic chloride and thiodi-β-naphthylamine dissolved in xylene at 280° for five hours. It crystallises from benzene in yellowish, lustrous leaflets, melts above 350°, and is very sparingly soluble in cold alcohol, ether, benzene, and acetic acid, sparingly so in the boiling solvents, but easily in hot xylene.

Carbamides containing the group $N:(C_{10}H_6)_2:S$, like thiodi-β-naphthylamine, give a violet coloration with concentrated sulphuric acid.

Ethyl phenyl-β-naphthylcarbamate, $C_{10}H_7\cdot NPh\cdot COOEt$, obtained by the action of sodium ethoxide on phenyl-β-naphthylcarbamic chloride in warm alcoholic solution, crystallises in long, white, silky needles, melts at 93°, and dissolves somewhat easily in cold, easily in hot alcohol and ether, and very easily in cold benzene.

Phenyl phenyl-β-naphthylcarbamate is prepared in a similar way to the preceding salt, crystallises in white needles, melts at 149°, is sparingly soluble in cold alcohol, ether, benzene, and acetic acid, easily so in the hot solvents. At 17°, one part dissolves in 278 parts of alcohol, and in 43·4 parts of benzene.

Symmetrical diphenyldi-β-naphthylcarbamide, $CO(NPh\cdot C_{10}H_7)_2$, is obtained by heating a mixture of phenyl-β-naphthylcarbamic chloride with phenyl-β-naphthylamine in molecular proportion for five hours at 240—260°. It crystallises from alcohol in pale-yellow, polyhedral granules, melts at 185—186°, and dissolves sparingly in cold alcohol and ether, easily in cold, and very easily in hot benzene. When heated with concentrated hydrochloric acid for four hours at 240—250°, it is decomposed into carbonic anhydride, β-naphthol,

and aniline. It is not altered by heating with ammonia or aniline at 270°, or with aqueous potash at 240—250°, and distils almost unchanged at 460°.

Triphenyl-β-naphthylcarbamide, $NPh_2{\cdot}CO{\cdot}NPh{\cdot}C_{10}H_7$, is obtained by heating phenyl-β-naphthylcarbamic chloride with diphenylamine at 200—240° for two hours. It forms a pale-yellow, crystalline powder, melts at 128°, and is easily soluble in cold alcohol and ether, very easily in benzene.

Unsymmetrical diphenyldi-β-naphthylcarbamide, $NPh_2{\cdot}CO{\cdot}N(C_{10}H_7)_2$, is best obtained by heating diphenylcarbamic chloride with β-dinaphthylamine for two hours at 200—220°. It is also obtained by heating di-β-naphthylcarbamic chloride with diphenylamine for three hours at 260°; tetra-β-naphthylcarbamide (m. p. 293—294°) (Kym, *Ber.*, **23**, 1542) being formed at the same time. It melts at 103—104°, and is somewhat easily soluble in cold, easily in hot alcohol and ether or cold benzene, and very easily in hot benzene.

Phenyltri-β-naphthylcarbamide, $N(C_{10}H_7)_2{\cdot}CO{\cdot}NPh{\cdot}C_{10}H_7$, is obtained on heating di-β-naphthylcarbamic chloride with phenyl-β-naphthylamine at 240—260° for three hours. It crystallises from acetic acid in white nodules, melts at 168°, and is sparingly soluble in cold, easily in hot alcohol and ether, and more easily in benzene and acetic acid. At 16°, one part dissolves in 104·5 parts of alcohol, and in 22 parts of benzene.

Carbazole and Carbonyl Chloride.—Various experiments were made with the object of preparing a carbamic chloride by the action of carbonyl chloride on carbazole but without success. Carbonyl chloride is without action on carbazole at 100°, 130°, or 200°, whilst at 250° carbonised products are obtained, together with unaltered carbazole. The potassium derivative of carbazole gives no better results.

E. C. R.

Reduction of Aromatic Aldehydes. By F. Tiemann (*Ber.*, **24**, 3169—3175).—In a former paper, the author has shown (Abstr., 1886, 460) that whilst benzaldehyde readily yields benzyl acetate on treatment with zinc-dust and acetic acid, orthohydroxybenzaldehyde is thus converted into diorthohydroxyhydrobenzoïn diesoanhydride. Further investigation has shown that the reduction of aromatic aldehydes with zinc-dust and acetic acid proceeds differently according to the conditions under which it is carried out; thus parahydroxybenzaldehyde, which usually yields the corresponding alcohol or its acetate, can even be converted into paracresol by long-continued boiling with the reagents. If the reduction proceeds slowly, so that mixtures of the alcohol and aldehyde are subjected for some time to the action of zinc acetate and acetic acid, condensation takes place with formation of substances resembling hydrobenzoïn, according to the equation

$$R{\cdot}CHO + R{\cdot}CH_2{\cdot}OH = R{\cdot}CH(OH){\cdot}CH(OH){\cdot}R.$$

The compound obtained by the author by the reduction of salicylaldehyde, and described as diorthohydroxyhydrobenzoïn diesoanhydride, is in reality a mixture of two isomerides melting at 116—117°

and 67—68° respectively, both of which have probably the constitutional formula $\begin{matrix} C_6H_4\cdot CH\cdot O \\ | \quad\quad | \\ O\text{—}CH\cdot C_6H_4 \end{matrix}$.

Hydrobenzoïn itself contains two asymmetrical carbon atoms, and should therefore exist in three isomeric forms; the anhydride of diorthohydroxyhydrobenzoïn should also, according to theory, form a similar number of isomerides: both of the above compounds are, however, optically inactive, and could not be separated into optically active constituents. The one melting at 67—68° is converted, on boiling in acetic acid solution, into the higher melting isomeride.

If the reduction is carried out quickly, and at as high a temperature as possible, a portion appears to be converted into *diorthohydroxyhydrobenzoïn*, $HO\cdot C_6H_4\cdot CH_2\cdot CH(OH)\cdot C_6H_4\cdot OH$, which, on distillation, splits up into *diorthohydroxystilbene*, $C_2H_2(C_6H_4\cdot OH)_2$, and water.

The experimental details of this research are given in the following abstract. H. G. C.

Reduction of Salicylaldehyde by Zinc-dust and Acetic Acid. By C. D. Harries (*Ber.*, **24**, 3175—3180; see also previous abstract).—In order to prepare the diorthohydroxyhydrobenzoïn diesoanhydride melting at 116—117°, a solution of salicylaldehyde in acetic acid is boiled for 12 hours with an excess of zinc-dust, the solution diluted with water, neutralised with soda, and extracted with ether. After distilling off the ether, the residue is treated with potash, and the insoluble portion recrystallised from alcohol. The anhydride is thus obtained in transparent needles readily soluble in ether and benzene, sparingly in alcohol and acetic acid, and only slightly in hot water; it has a pleasant aromatic odour resembling that of fennel and geranium, dissolves in sulphuric acid with a red coloration, and is not altered by heating with dilute mineral acids or alkalis.

If the action of zinc is allowed to take place at 100°, a mixture of the foregoing compound with an isomeride of lower melting point is formed, which may be separated into its constituents by repeatedly precipitating the alcoholic solution with hot water. The more soluble portion is thus obtained in crystals melting at 67—68°. Both anhydrides appear to distil in a vacuum without decomposition, but the compound of lower melting point is completely converted into its isomeride by boiling in acetic acid solution for some time.

The anhydride of higher melting point is acted on by bromine in acetic acid solution with formation of two *dibromo*-derivatives having the composition $C_{14}H_8O_2Br_2$, which commence to sublime at 235° and 245° respectively.

If the reduction of salicylaldehyde be carried out at 120°, and the product distilled, potash extracts from the distillate *diorthohydroxystilbene*, $C_2H_2\cdot(C_6H_4\cdot OH)_2$, which melts at 95°, is sparingly soluble in water, readily in alcohol and ether, and forms a blue fluorescent solution in alkalis. Its *dibenzoyl* derivative, $C_2H_2(C_6H_4\cdot OBz)_2$, crystallises from alcohol in matted aggregates of needles melting at 107—108°, and unites directly with bromine, forming *dibenzoyldiorthohydroxystilbene dibromide*, $C_{28}H_{20}Br_2O_4$, melting at 58—59°. H. G. C.

Methyl Orthohydroxycinnamyl Ketone (Methyl Orthocumaroketone) and its Derivatives. By C. D. HARRIES (*Ber.*, **24**, 3180—3184).—Tiemann and Kees have shown (Abstr., 1885, 1073) that helicin undergoes condensation with acetone and alkali, forming methyl gluco-orthocumaroketone, which is converted by the action of emulsin into glucose and methyl orthocumaroketone. The latter compound may also be readily obtained by the action of dilute alkali and acetone on salicylaldehyde; the mixture, after remaining for two days, is acidified with hydrochloric acid and freed from unaltered salicylaldehyde by distilling in a current of steam. The insoluble product remaining in the liquid after cooling is recrystallised from benzene with the addition of animal charcoal, and then melts at 139°, as given by Tiemann and Kees. It is readily soluble in alcohol, ether, and hot water, and is coloured bluish-violet by ferric chloride in aqueous solution. When the ketone is dissolved in alcoholic sodium ethoxide and ether added, the *sodium* compound separates in pure condition as a deep yellow substance.

When methyl orthocumaroketone is treated with benzoic chloride in alkaline solution, it yields the *benzoyl* derivative, $C_{10}H_9O_2Bz$, which crystallises from dilute alcohol in white needles melting at 87—88°; the *acetyl* and *methyl* derivatives are oils. The ketone also readily combines with phenylhydrazine and hydroxylamine, forming the *phenylhydrazone*, $C_{10}H_{10}O{:}N_2HPh$, and the *oxime*, $C_{10}H_{10}O{:}N{\cdot}OH$; the former separates in yellow flakes, which, after recrystallisation from dilute alcohol, melt at 159—160°, and the latter forms white crystals melting at 84—85°.

On reduction with sodium amalgam, methyl orthocumaroketone is converted into secondary methylorthocumaryl alcohol,

$$HO{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CHMe{\cdot}OH,$$

which, after purification, forms compact plates melting at 47—48°. It is readily soluble in alcohol, ether, benzene, and hot water, gradually becomes pink in the air, dissolves in sulphuric acid with a reddish-violet colour, and does not form an anhydride resembling coumarin. Reducing agents appear to have no effect on the ethylene linking in the side chain, nor does the ketone unite directly with bromine. H. G. C.

Action of Sodium on Ketones and Aldehydes. By E. BECKMANN and T. PAUL (*Annalen*, **266**, 1—28; compare Abstr., 1889, 78).—The authors have made a study of the sodium derivatives of various ketones and of benzaldehyde; their experiments have shown that many of these substances resemble the organo-metallic compounds in being very readily oxidised on exposure to the air, in being immediately decomposed by water, and in combining with carbonic anhydride to form salts of carboxylic acids. The sodium derivatives were prepared by treating a solution of the ketone or aldehyde in pure ether or benzene with excess of sodium, in the form of wire or ribbon, air and moisture being excluded as far as possible; the products were then washed and dried in an atmosphere of pure hydrogen, in an apparatus specially devised for the purpose; in spite of all

precautions, it was found impossible to avoid partial oxidation, and the preparations usually contained a little metallic sodium. When dry carbonic anhydride is passed into ether containing one of these sodium derivatives in solution or in suspension, combination generally takes place, accompanied usually by a change in colour; the compounds produced in this way are extremely hygroscopic, and decompose on exposure to the air.

The sodium derivative of benzophenone (*loc. cit.*) is immediately decomposed by water, yielding benzopinacone (m. p. 184°), benzophenone, and benzhydrol (m. p. 67°), the relative quantities of these three products depending greatly on the conditions of the experiment. It combines with carbonic anhydride under the conditions just stated, being thereby converted into a yellow powder; this substance is decomposed by water, yielding approximately equal quantities of the sodium salt of benzilic acid and benzophenone. These reactions are best explained by assuming that sodiobenzophenone and its carboxyl derivative have the constitutions expressed by the formulæ $CPh_2Na{\cdot}O{\cdot}CPh_2{\cdot}ONa$ and $COONa{\cdot}CPh_2{\cdot}O{\cdot}CPh_2{\cdot}O{\cdot}COONa$ respectively; analyses of the two compounds gave results in accordance with these formulæ.

The sodium derivative of phenyl α-naphthyl ketone is a greenish-yellow powder, and is decomposed by water, yielding a yellow oil; this oil is doubtless a mixture of various compounds, and was proved to contain a crystalline substance melting at about 130°, which is most probably phenyl-α-naphthylpinacoline. When phenyl sodio-α-naphthyl ketone is treated with carbonic anhydride, it is converted into a yellow powder, which on decomposition with water yields the sodium salt of phenyl-α-naphthylglycollic acid and phenyl α-naphthyl ketone; it seems probable, therefore, that this carboxy-derivative has a constitution analogous to that of the corresponding benzophenone derivative, a view which is in agreement with the analytical results.

Phenyl-α-naphthylglycollic acid, $C_{18}H_{14}O_3$, can be conveniently prepared from phenyl sodio-α-naphthyl ketone, as it is unnecessary to purify the carboxy-derivative. It crystallises from hot water or dilute alcohol in colourless, well-defined plates or needles, which contain 2 mols. H_2O and melt at 108—115° with elimination of water; it separates from benzene and carbon bisulphide in anhydrous, short prisms melting at 148°.

When acetophenone is treated with sodium, the ethereal solution turns greenish, and then a colourless powder is deposited; if, however, this powder is left in contact with sodium for a long time, it first turns brown and then dark-violet. On decomposing sodacetophenone with water, acetophenonepinacone (m. p. 122·5°), acetophenone, and other compounds are formed. When the sodium derivative is treated with carbonic anhydride, it yields a yellowish substance which is decomposed by water; if the alkaline solution is extracted with ether, the same compounds are obtained as from sodacetophenone, and benzoylacetic acid (m. p. 100°) remains in the aqueous solution. The constitution of these two sodium compounds is probably expressed by the formulæ $ONa{\cdot}CPhMe{\cdot}CPh(OH){\cdot}CH_2Na$ and $COONa{\cdot}O{\cdot}CPhMe{\cdot}CPh(OH){\cdot}CH_2{\cdot}COONa$ respectively.

The sodium derivative of deoxybenzoïn is very readily soluble in ether, and is best obtained by treating a concentrated solution of the ketone in pure benzene with sodium; it is a very hygroscopic, pale-yellow substance, and is readily decomposed by water, yielding deoxybenzoïn. The benzene mother liquors obtained in the preparation and purification of this sodium derivative contain deoxybenzoïnpinacone (m. p. 213°) and toluylene hydrate (m. p. 62°). On passing carbonic anhydride into an ethereal solution of sodiodeoxybenzoïn, a reddish-yellow substance is precipitated; this compound is decomposed by water, yielding deoxybenzoïn and an acid which could not be isolated, but which is most probably phenylbenzoylacetic acid. When the aqueous solution of the acid formed in this way is quickly separated from the ethereal solution of deoxybenzoïn and then treated with hydroxylamine, a crystalline acid which melts at 159·5°, and which has probably the constitution $\begin{matrix}\mathrm{N}-\\ \|\\ \mathrm{CPh}\end{matrix}\!>\!\mathrm{CPh{\cdot}COOH}$, is obtained. From these reactions, and from the results of analyses of the two sodium derivatives, the authors conclude that they have the constitution COPh·CHNaPh and COPh·CHPh·COONa respectively.

When an ethereal solution of benzile is treated with sodium, there is formed a yellow, flocculent substance which afterwards changes to a deep violet powder; this compound oxidises very energetically on exposure to the air, and is decomposed by water into benzile and benzoïn, but it seems to be unacted on by carbonic anhydride; its constitution is probably expressed by the formula

$$\mathrm{COPh{\cdot}CPh(ONa){\cdot}CPh(ONa){\cdot}COPh.}$$

The compound formed by the action of sodium on a benzene solution of benzaldehyde is a dark-green powder, which becomes much lighter in colour when washed and dried; it oxidises very readily on exposure to the air, and when treated with water it gives hydrobenzoïn and a trace of benzoic acid. It combines with carbonic anhydride, yielding a brownish-yellow substance which is quickly decomposed by water with formation of hydrobenzoïn, sodium hydrogen carbonate, and a trace of benzoic acid. The following formulæ, ONa·CHPh·CHPh·ONa and COONa·O·CHPh·CHPh·O·COONa, probably represent the constitutions of these two sodium derivatives.

F. S. K.

Bromination of Bromobenzoic Acids. By A. Claus and A. Reh (*Annalen*, **266**, 203—209).—Dibromobenzoic acid [COOH : Br_2 = 1 : 3 : 4] is formed in small quantities by the bromination of benzoic acid, but the reaction is a very complicated one; by the bromination of metabromobenzoic acid at 220—230°, the 3 : 4-dibromo-acid is produced in even smaller quantities, if at all. When benzoic acid is treated with nascent bromine, in very dilute aqueous solution, at a temperature below 70—80°, not inconsiderable quantities of para-bromobenzoic acid are obtained, but dibromo-acids are not produced in any appreciable quantity.

When orthobromobenzoic acid is heated with bromine (1 mol.) and water at 150—160° for 8 to 10 hours, dibromobenzoic acid [COOH : Br_2

= 1 : 2 : 5] is produced; parabromobenzoic acid is not acted on at 180°, but at 200° it is converted into tribromobenzoic acid [COOH : Br_3 = 1 : 3 : 4 : 5], some of the monobromo-acid remaining unchanged.

These experiments show that in benzoic acid substitution is not limited solely to the meta-position relatively to the carboxyl group, but that, under certain conditions, the ortho- and para-hydrogen atoms may also be displaced. F. S. K.

Nitration of Orthochloroparatoluic Acid. By A. Claus and N. Davidsen (*Annalen*, **265**, 341—350).—The following experiments prove that the nitrochlorotoluic acid (m. p. 180°) previously described (Abstr., 1889, 988) has the constitution [COOH : Cl : Me : NO_2 = 1 : 2 : 4 : 5]; the *magnesium* salt of this acid is readily soluble in water, from which it crystallises in large, hexagonal plates containing 8 mols. H_2O.

Nitrochloroparatoluidine [NH_2 : Cl : Me : NO_2 = 1 : 2 : 4 : 5] is best prepared by treating dry chlorotoluidine nitrate with pure sulphuric acid cooled to about −15°; the yield is quantitative. It crystallises from hot alcohol in orange-red plates, melts at 129·5° (uncorr.), and is only sparingly soluble in boiling water and dilute acids, but readily in ether, alcohol, &c. The *acetyl* derivative, $NO_2 \cdot C_6H_2ClMe \cdot NHAc$, crystallises from alcohol in small, almost colourless needles, melts at 143° (uncorr.), and is not decomposed by boiling sulphuric acid; when heated with fuming hydrochloric acid at 150°, it is reconverted into nitrochloroparatoluidine.

Nitrochloroparatoluidine [NH_2 : Cl : Me : NO_2 = 1 : 2 : 4 : 6] is formed when dry chlorotoluidine nitrate is treated with 80 per cent. sulphuric acid cooled to about 0°; it is best obtained by treating chloroparacetotoluidide with nitric acid of sp. gr. 1·5 at about 20°, and then decomposing the product with sulphuric acid. It crystallises from alcohol in orange-coloured plates, melts at 70·5, and is readily volatile with steam. The *acetyl* derivative crystallises in almost colourless needles and prisms melting at 196° (uncorr.).

Nitrochloroparatolunitrile [CN : Cl : Me : NO_2 = 1 : 2 : 4 : 5] is easily obtained from the corresponding amido-derivative; the yield of the pure compound is 70 per cent. of the theoretical. It crystallises from ether or alcohol in long, almost colourless needles melting at 93° (uncorr.); when boiled with sulphuric acid or with very dilute potash, it is converted into the nitrochloroparatoluic acid (m. p. 180—181·5°) referred to above.

Amidochloroparatoluic acid [COOH : Cl : Me : NH_2 = 1 : 2 : 4 : 5], prepared by reducing the corresponding nitro-derivative (m. p. 180—181·5) with tin and hydrochloric acid in alcoholic solution, crystallises from hot water in colourless needles melting at 220° (uncorr.). The *hydrochloride* crystallises in slender, colourless needles, and melts at about 245° with decomposition. The stannochloride is readily soluble in water, and crystallises in colourless needles. When the diazo-derivative of the amido-acid is treated with cuprous chloride, it is converted into dichloroparatoluic acid [COOH : Cl_2 : Me = 1 : 2 : 5 : 4], melting at 187° (uncorr.). The *barium* salt of this acid crystallises from cold water in needles containing 4 mols. H_2O.

Bromochloroparatoluic acid [COOH : Cl : Br : Me = 1 : 2 : 5 : 4], prepared by decomposing the diazo-derivative of the amido-acid with cuprous bromide, is almost insoluble in water, but readily in alcohol, from which it crystallises in colourless, nacreous needles melting at 192—193° (uncorr.). The *barium* salt is readily soluble in water, from which it crystallises in colourless needles containing $1\frac{1}{2}$ mols. H_2O.

Nitrochloroparatoluic acid [COOH : Cl : NO_2 : Me = 1 : 2 : 3 : 4] is formed in small quantities on nitrating orthochloroparatoluic acid, and is best prepared from the isomeride (m. p. 181°) referred to above by means of its *magnesium* salt, with $3\frac{1}{2}H_2O$, which is more soluble in water than that of the isomeric acid. It crystallises from dilute alcohol in colourless needles, melts at 192° (uncorr.), and is insoluble in light petroleum; when treated with a mixture of nitric and sulphuric acids, it is converted into the dinitrochloroparatoluic acid previously described. F. S. K.

Nitration of Metachloroparatoluic Acid. By A. Claus and P. Böcher (*Annalen*, **265**, 351—363).—Three isomeric nitro-derivatives are invariably produced when metachloroparatoluic acid is nitrated under various conditions; 60—70 per cent. of the crude product consists of the acid of the constitution [COOH : Cl : Me : NO_2 = 1 : 3 : 4 : 6], 20—30 per cent. of the corresponding 1 : 3 : 4 : 5-derivative, and 5—10 per cent. of the 1 : 3 : 4 : 2-acid. The three compounds can be separated from one another by systematic fractional crystallisation of the free acids and their barium salts alternately; they are all very readily soluble in acetone, ether, and alcohol, but only sparingly in light petroleum, and very sparingly in benzene.

The 1 : 3 : 4 : 6-acid can also be obtained in a pure condition from nitrochloparatoluidine in the manner described below.

Nitrochloroparacetotoluide [NHAc : Cl : Me : NO_2 = 1 : 3 : 4 : 6] is prepared by nitrating chloroparacetotoluidide with acid of sp. gr. 1·52; it crystallises from alcohol in lustrous plates and in small needles, both forms melting at 113° (uncorr.).

Nitrochloroparatoluidine [NH_2 : Cl : Me : NO_2 = 1 : 3 : 4 : 6], obtained by decomposing the acetyl derivative with boiling alcoholic potash, crystallises from hot alcohol, in which it is readily soluble, in lustrous, golden plates, melts at 165° (uncorr.), and is only sparingly soluble in hot water; it is readidly volatile with steam. The corresponding *nitrile* crystallises in large plates, sublimes without decomposition, melts at 157° (uncorr.), and is readily soluble in alcohol. The corresponding *acid*, obtained by treating the nitrile with concentrated sulphuric acid at about 200°, crystallises from alcohol in colourless needles, melts at 184—185°, and sublimes without decomposition. The *barium* salt, with $1\frac{1}{2}H_2O$, crystallises in large, colourless, hexagonal plates. The *calcium* salt and the bluish-green *copper* salt are anhydrous, but the *potassium* salt crystallises in plates containing $\frac{1}{2}$ mol. H_2O.

Amidochloroparatoluic acid [COOH : Cl : Me : NH_2 = 1 : 3 : 4 : 6] is obtained when the nitro-acid just described is reduced with iron and hydrochloric acid; it crystallises from alcohol in colourless needles, and melts at about 220°. When its diazo-derivative is treated with cuprous chloride, dichloroparatoluic acid (m. p. 187°) is ob-

tained. This fact proves that the nitro-acid has the constitution assigned to it above.

Nitrochloroparatoluic acid [COOH : Cl : Me : NO_2 = 1 : 3 : 4 : 5] is moderately easily soluble in water, from which it crystallises in slender, colourless needles melting at 159° (uncorr.); it is identical with the acid obtained by Claus and Beysen from dilute nitroparatoluic acid, and both compounds yield one and the same dichloroparatoluic acid (m. p. 188°). The *barium* salt crystallises from water, in which it is readily soluble, in short, thick prisms containing 1 mol. H_2O. The *calcium* salt crystallises in colourless, anhydrous needles. The *ammonium* salt and the *potassium* salt are readily soluble in water, but the *silver* salt is insoluble.

Nitrochloroparatoluic acid [COOH : Cl : Me : NO_2 = 1 : 3 : 4 : 2] crystallises from water, in which it is readily soluble, in colourless, nacreous plates, and melts at 211°. The *barium* salt, with $1\frac{1}{2}H_2O$, crystallises in characteristic stellate forms. The *calcium* salt crystallises in lustrous, anhydrous needles. F. S. K.

Nitration and Bromination of Orthobromoparatoluic Acid. By A. Claus and J. Herbabny (*Annalen*, **265**, 364—378).—When orthobromoparatoluic acid is treated with nitric acid, two isomeric nitro-derivatives are obtained; the compounds are most easily separated by means of their magnesium salts.

The *nitrobromoparatoluic acid* of the constitution

[COOH : Br : Me : NO_2 = 1 : 2 : 4 : 5]

is formed in by far the larger quantity; it crystallises from alcohol in colourless, nacreous plates, melts at 203° (uncorr.), and is very readily soluble in ether, and moderately easily in hot benzene, but only sparingly in hot water. The *sodium* salt, with $4\frac{1}{2}H_2O$, crystallises in large, efflorescent plates, and is readily soluble in water and alcohol. The *potassium* salt, with $1H_2O$, and the *barium* salt, with $5H_2O$, crystallise in needles; the calcium salt, with $5H_2O$, forms large, efflorescent plates or prisms. The *magnesium* salt, with $7\frac{1}{2}H_2O$, crystallises in lustrous plates. The *chloride*, $NO_2{\cdot}C_6H_2BrMe{\cdot}COCl$, crystallises from light petroleum in colourless plates, melts at 60° (uncorr.), and is readily soluble in chloroform. The *amide*, $NO_2{\cdot}C_6H_2BrMe{\cdot}CO{\cdot}NH_2$, crystallises in colourless needles, melts at 191° (uncorr.), and is readily soluble in alcohol, but more sparingly in water. The *ethyl* salt, $NO_2{\cdot}C_6H_2BrMe{\cdot}COOEt$, melts at 61° (uncorr.), and crystallises from alcohol in colourless, lustrous needles. When the acid is oxidised with potassium permanganate, it yields a bromomonitroterephthalic acid; this compound crystallises from hot water in colourless needles, which seem to melt at 260—261°.

Nitrobromoparatoluidine [NH_2 : Br : Me : NO_2 = 1 : 2 : 4 : 5] is easily obtained by dissolving orthobromotoluidine nitrate in sulphuric acid cooled to 0°; it crystallises from glacial acetic acid or alcohol in pale-yellow needles, melting at 121° (uncorr.). The corresponding *nitrile* [CN : Br : Me : NO_2 = 1 : 2 : 4 : 5] melts at 132° (uncorr.), and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in hot water; when boiled with moderately concentrated sulphuric acid, it is converted into the nitrobromoparatoluic acid (m. p. 203°) described above.

Nitrobromoparatoluic acid [COOH : Br : NO_2 : Me = 1 : 2 : 3 : 4] is only formed in small quantities (6—8 per cent.) in nitrating orthobromoparatoluic acid; it crystallises from alcohol and hot water in slender, colourless needles, melts at 214° (uncorr.), and sublimes in slender needles. The *magnesium* salt, with $3\frac{1}{2}H_2O$, crystallises in colourless plates, and is more readily soluble in water than the corresponding salt of the isomeric acid described above. The *barium* salt, with $4H_2O$, crystallises in large rhombic plates.

Nitrobromoparatoluonitrile [CN : Br : Me : NO_2 = 1 : 2 : 4 : 6] can be prepared by diazotising nitrobromotoluidine (m. p. 64°) in ice-cold 70—80 per cent. sulphuric acid solution, and immediately adding a solution of copper sulphate and potassium cyanide; it crystallises from alcohol in yellowish needles, melts at 130° (uncorr.), and is very sparingly soluble in hot water, but readily in benzene, ether, and chloroform.

Nitrobromoparatoluamide [$CO{\cdot}NH_2$: Br : Me : NO_2 = 1 : 2 : 4 : 6] is formed when the preceding compound is boiled with dilute (1 : 1) sulphuric acid for 8—10 hours; it crystallises from boiling water in colourless needles, melts at 171° (uncorr.), and is readily soluble in alcohol, ether, benzene, and chloroform.

Nitrobromoparatoluic acid [COOH : Br : Me : NO_2 = 1 : 2 : 4 : 6] is obtained in small quantities when the corresponding amide is heated at 220—230° with 20—25 per cent. hydrochloric acid; it crystallises from boiling water in small, colourless needles, melts at 206°, and is very readily soluble in ether, alcohol, chloroform, &c.

When orthobromoparatoluic acid is heated with bromine and water at 90—95° for 4—5 hours, the sole product is a dibromoparatoluic acid, [COOH : Br_2 : Me = 1 : 3 : 6 : 4] melting at 199° (uncorr.), which has been previously prepared by Schultz and Fileti. The *sodium* salt of this dibromo-acid crystallises in large plates containing 7 mols. H_2O. The *chloride*, $C_6H_2Br_2Me{\cdot}COCl$, forms colourless, lustrous needles, and melts at 60°.

Dibromoparatoluic acid [COOH : Br_2 : Me = 1 : 2 : 3 : 4] was obtained in small quantities from the corresponding nitrobromoparatoluic acid; it forms colourless crystals, and seems to melt at 194°.

Dibromoparacetotoluidide [NHAc : Br_2 : Me = 1 : 2 : 6 : 4], can be prepared by heating dibromoparatoluidine (m. p. 73°) with acetic chloride at 100°; it crystallises in long, colourless needles, melts at 183° (uncorr.), and is reconverted into dibromoparatoluidine by boiling alcoholic potash.

Dibromoparatoluonitrile [CN : Br_2 : Me = 1 : 2 : 6 : 4], prepared from dibromoparatoluidine, crystallises in long, colourless needles, melts at 156° (uncorr.), sublimes in needles, and is readily volatile with steam; it is insoluble in water, but dissolves freely in alcohol, ether, benzene, and chloroform. When boiled with 50 per cent. sulphuric acid, it is converted into the corresponding *amide;* this compound crystallises from boiling water in small, colourless plates melting at 148° (uncorr.), and is readily soluble in alcohol, ether, and chloroform.

Dibromoparatoluic acid [COOH : Br_2 : Me = 1 : 2 : 6 : 4] is obtained when the amide just described is heated with concentrated sulphuric acid at 240°; it crystallises and sublimes in colourless needles, melts at 182° (uncorr.), and is only sparingly soluble in hot water, but dissolves freely in ether, alcohol, and chloroform. F. S. K.

Dibromoparatoluic Acid. By A. Claus and R. Seibert (*Annalen*, **265**, 378—380).—*Dibromoparatoluonitrile* [CN : Br_2 : Me = 1 : 3 : 5 : 4], prepared from the corresponding dibromotoluidine, crystallises from alcohol in lustrous needles melting at 49° (uncorr.); it is readily volatile with steam, and dissolves freely in alcohol, ether, chloroform, and hot water. The corresponding *acid* is obtained when the nitrile is boiled with potash; it crystallises from alcohol in slender needles, melts at 235—236° (uncorr.), and is readily soluble in alcohol, ether, and chloroform, but only sparingly in water. The *sodium* salt, with $1H_2O$, *potassium* salt, with $1\frac{1}{2}H_2O$, and the *barium* salt, with $4H_2O$, are colourless, crystalline compounds. The *chloride*, $C_6H_2Br_2Me{\cdot}COCl$, crystallises from ether in colourless needles melting at 80° (uncorr.). The *amide* separates from ether in small needles, and melts at 117° (uncorr.). The *ethyl* salt, $C_6H_2Br_2Me{\cdot}COOEt$, crystallises from alcohol in colourless needles melting at 79—80° (uncorr.). F. S. K.

Nitration of Orthonitroparatoluic Acid. By A. Claus and J. Joachim (*Annalen*, **266**, 209—222; compare Rozanski, Abstr., 1890, 52).—Two dinitro-compounds are formed when orthonitroparatoluic acid (m. p. 164°) is heated at about 100° for 4—5 hours with a mixture of nitric and sulphuric acids; the two products are separated by fractional crystallisation from water.

The dinitroparatoluic acid of the constitution [COOH : $(NO_2)_2$: Me = 1 : 2 : 3 : 4] is always produced in by far the smaller quantity, and is much more sparingly soluble in water than the isomeride described below; it crystallises in short, colourless, lustrous prisms, melts at 248° (uncorr.), has an intensely bitter taste, and is readily soluble in alcohol. The barium salt, with $3H_2O$, and the calcium salt, with $1\frac{1}{2}H_2O$, are colourless, crystalline compounds, only moderately easily soluble in water.

Diamidoparatoluic acid [$(NH_2)_2$ = 2 : 3], prepared by reducing the preceding compound with tin and hydrochloric acid, crystallises in yellowish needles, melts at 192°, decomposes at a higher temperature, and is only sparingly soluble in cold water, but readily in alcohol and hot water; in its aqueous solution, ferric chloride produces a red, flocculent precipitate, and its solutions in acids yield with rhodizonic acid a brown azine, which dissolves in alkalis with a violet coloration. The *hydrochloride*, $C_8H_{10}N_2O_2{,}2HCl$, forms granular crystals, which soon assume a reddish hue. The *barium* salt is moderately easily soluble in water, and crystallises in small, reddish-yellow plates.

Dinitroparatoluic acid [COOH : $(NO_2)_2$: Me = 1 : 2 : 5 : 4] is the principal product of the nitration of paratoluic acid; it is readily soluble in alcohol, and moderately easily in hot water, crystallising in colourless plates which melt at 194°. The *barium* salt, with $2H_2O$, and the *calcium* salt, with $2H_2O$, are colourless, crystalline compounds, only moderately easily soluble in water. The corresponding *diamido*-compound crystallises from boiling water in lustrous, blue or violet needles, melts at 240° (uncorr.) with decomposition, and is very readily soluble in alcohol; when heated with ferric chloride in aqueous solution,

a reddish-brown precipitate is formed, and a strong odour of toluquinone is observed. The *hydrochloride* forms brownish-red crystals.

Dinitroparatoluic acid [COOH : $(NO_2)_2$: Me = 1 : 3 : 5 : 4] is the sole product of the nitration of metanitroparatoluic acid; it melts at 159° (uncorr.). The barium salt and the calcium salt contain water of crystallisation. The corresponding *diamido*-acid crystallises from water in light grey needles, melts at 212° (uncorr.) without decomposition when quickly heated, and is readily soluble in alcohol; its aqueous solution, even when very dilute, gives an intense yellow coloration with nitrous acid. The *barium* salt crystallises in anhydrous, light grey plates. F. S. K.

Dinitroparatoluic Acids and their Derivatives. By A. Claus and C. Beysen (*Annalen*, **266**, 223—239).—*Dinitroparatoluonitrile* [CN : $(NO_2)_2$: Me = 1 : 2 : 6 : 4] can be obtained by adding sodium nitrite in small portions at a time to a well-cooled sulphuric acid solution of 2 : 6-dinitroparatoluidine and, after keeping for a short time, pouring the mixture drop by drop into ice-cold water; the solution is filtered from unchanged dinitroparatoluidine, mixed in the cold with a solution of copper cyanide, and then warmed on the water-bath to complete the reaction. It crystallises from alcohol in golden needles, melts at 103° (uncorr.), and is readily soluble in alcohol, ether, chloroform, benzene, and glacial acetic acid, but only sparingly in hot water. The corresponding *amide*, prepared by boiling the nitrile with moderately concentrated sulphuric acid, crystallises in yellow needles, melts at 255—257° (uncorr.), and is readily soluble in alcohol, ether, chloroform, and hot water.

Dinitroparatoluic acid [$(NO_2)_2$ = 2 : 6] is formed when the amide just described is heated at 220—230° for 8 hours with concentrated hydrochloric acid; it crystallises from boiling water in almost colourless plates or prisms, melts at 226° (uncorr.), sublimes in needles, and has an intensely bitter taste; it dissolves freely in alcohol, ether, benzene, chloroform, glacial acetic acid, and hot water, but is only sparingly soluble in cold water. The *barium* salt, with $1H_2O$, crystallises in yellow prisms, and is very readily soluble in hot water.

Azimidoparatoluic acid, $\overset{1}{\mathrm{COOH}}\cdot\mathrm{C_6H_2}\overset{4}{\mathrm{Me}}<\overset{2}{\underset{3}{\mathrm{NH}}}>\mathrm{N}$, is formed when the hydrochloride of the 2 : 3-diamido-acid already described (compare preceding abstract) is treated with sodium nitrite in aqueous solution; it crystallises from hot water or alcohol in colourless, lustrous needles, melts at 295° (uncorr.) with decomposition, and is readily soluble in ether and chloroform. The *barium* salt, with $3H_2O$, and the *calcium* salt, with $2H_2O$, crystallise in colourless needles, and are very readily soluble in hot water.

When the diamido-compound, obtained from the 2 : 5-dinitrotoluic acid (*loc. cit.*), is diazotised and the product treated with cuprous bromide, it is converted into dibromoparatoluic acid [COOH : Br_2 : Me = 1 : 2 : 5 : 4].

Nitramidoparatoluic acid [COOH : NO_2 : Me : NH_2 = 1 : 2 : 4 : 5] is

obtained when a solution of the 2:5-dinitro-acid in warm, concentrated ammonia is treated with hydrogen sulphide; it crystallises from boiling water in long, yellow prisms and needles, melts at 220° with decomposition, and is readily soluble in alcohol, ether, and hot water. The *barium* salt crystallises in yellowish-brown plates or prisms, and is anhydrous.

Nitrobromoparatoluic acid [$COOH : NO_2 : Me : Br = 1:2:4:5$], prepared by decomposing the diazo-derivative of the preceding compound with cuprous bromide, crystallises in colourless needles, melts at 181° (uncorr.) and is readily soluble in hot water, alcohol, ether, and chloroform, but almost insoluble in cold water. The corresponding chloro-derivative, obtained in like manner, melts at 184° (uncorr.), and is identical with the metachloroparatoluic acid previously described by Claus and Böcher (this vol., p. 173).

Nitramidoparatoluic acid [$COOH : NO_2 : Me : NH_2 = 1:3:4:5$], obtained by reducing the corresponding dinitro-compound (see preceding abstract) with ammonium sulphide, or with the theoretical quantity of stannous chloride in alcoholic hydrochloric acid solution, crystallises from water in lemon-yellow, lustrous needles, melts at 214° (uncorr.), and sublimes without decomposition; it is only sparingly soluble in cold water, but readily in alcohol, ether, and hot water. The *barium* salt, with $4H_2O$, *calcium* salt (anhydrous), *sodium* salt, with $\frac{3}{4}H_2O$, and the *magnesium* salt, with $5H_2O$, are yellow, crystalline compounds. The *nitrobromo*-acid [$COOH : NO_2 : Me : Br = 1:3:4:5$], prepared by decomposing the diazo-derivative of the amido-acid with cuprous bromide, crystallises from dilute alcohol in small, colourless needles, melts at 181° (uncorr.), and is readily soluble in ether, alcohol, and chloroform, but only sparingly in boiling water; its *barium* salt crystallises from boiling water, in which it is readily soluble, in compact needles. The corresponding nitrochloro-acid, prepared in like manner, melts at 158°, and is identical with the acid obtained by Claus and Böcher (*loc. cit.*) by nitrating metachloroparatoluic acid.

Dichloroparatoluic acid [$COOH : Cl_2 : Me = 1:3:5:4$] was prepared from the diamido-acid (m. p. 212°) described in the preceding abstract; it was found to be identical with the compound obtained from chloronitrotoluic acid (m. p. 159°) by Claus and Böcher (*loc. cit.*).

F. S. K.

Derivatives of Ethyl Dinitrophenylacetate. By M. Dittrich and V. Meyer (*Annalen*, **266**, 29—30).—Claus has pointed out that some of the compounds lately described by the authors (Abstr., 1891, 1224) were prepared by him a short time ago (Abstr., 1890, 979); the authors acknowledge Claus' claim to priority. F. S. K.

Diphenylmaleïc Anhydride. By S. Gabriel and G. Cohn (*Ber.*, **24**, 3228—3230).—From the constitutional formulæ of maleïc anhydride and phthalic anhydride, it seems probable that both compounds would show similar reactions, and observations have already been made which confirm this supposition; thus both yield ketonic acids with aromatic hydrocarbons, as, for example,

$COPh{\cdot}CH{:}CH{\cdot}COOH$ and $COPh{\cdot}C_6H_4{\cdot}COOH$;

and both are converted into fluoresceïns by the action of resorcinol (Abstr., 1882, 1074; 1884, 1340).

The authors have further examined the behaviour of diphenylmaleïc anhydride towards phenylacetic acid, and find that it acts in a similar manner to phthalic anhydride, forming a substance closely resembling benzalphthalide (Abstr., 1878, 734; 1886, 265). The diphenylmaleïc anhydride was prepared according to the method given by Reimer (Abstr., 1881, 169), and was heated with phenylacetic acid and sodium acetate at 190°, the temperature being raised to 220—225° as soon as the reaction had moderated. The product is powdered, freed from impurities by extraction with alcohol, and recrystallised from acetic acid, when it is obtained in yellowish needles, having the composition $C_{23}H_{16}O_2$; it is sparingly soluble in alcohol, readily in acetic acid and acetone, and very easily in chloroform and boiling benzene. It is formed according to the equation

$$\begin{matrix}\mathrm{CPh{\cdot}CO}\\ \|\\ \mathrm{CPh{\cdot}CO}\end{matrix}\!\!>\!O + CH_2Ph{\cdot}COOH = \begin{matrix}\mathrm{CPh{\cdot}C(CHPh)}\\ \|\\ \mathrm{CPh\text{———}CO}\end{matrix}\!\!>\!O + CO_2 + H_2O.$$

and may, therefore, be termed *benzaldiphenylmaleïde*. In all its reactions, it closely resembles benzalphthalide.

Diphenylmaleïc anhydride also combines with phenol, resorcinol, and dimethylmetamidophenol forming coloured compounds, and with quinaldine yields a colouring matter resembling quinophthalone. All these substances are being further investigated. H. G. C.

Composition and Crystalline Form of Barium Isophthalate. By W. Lossen and C. Rahnenführer (*Annalen*, **266**, 30—33).—When a solution of barium isophthalate evaporates at the ordinary temperature, well-defined, triclinic crystals of the composition $C_8H_4O_4Ba + 6H_2O$, are deposited; these crystals rapidly effloresce when kept over sulphuric acid, but only slowly in the air. The authors' experiments point to the non-existence of the salts containing 3 and $3\frac{1}{2}$ mols. H_2O, which have been described by Fittig and Velguth and by Kelbe respectively. F. S. K.

Opianic Acid. By G. Goldschmiedt (*Monatsh.*, **12**, 474—478).—When a solution of opianic acid (10 grams) and acetone (6 grams) in water (750 grams) is treated with a 10 per cent. solution of sodium hydroxide (30 c.c.), and allowed to remain for 24 hours at the ordinary temperature, condensation takes place with formation of the compounds $C_{23}H_{22}O_9$ and $C_{13}H_{14}O_5$. The former crystallises from alcohol, in which it is but sparingly soluble, in felted needles, does not dissolve in cold solutions of the alkali carbonates, is not changed by bromine in ethereal solution, and melts at 151°. The latter, which is the chief product of the reaction, crystallises from dilute alcohol in white needles, melts at 117°, and resembles the former compound in its behaviour towards bromine and the alkalis.

Under like conditions, opianic acid and acetophenone give the compound $C_{18}H_{16}O_5$, which crystallises from alcohol in beautiful,

glistening plates, and melts at 127—128°. It also is unacted on by bromine and by cold solutions of the alkalis.

The three new compounds above described are not acids, nor do they contain doubly-linked carbon atoms. Their constitution is probably to be regarded as $CO[CH_2{\cdot}CH<^{C_6H_2(OMe)_2}_{O\text{———}}>CO]_2$, $\begin{matrix}CO\text{———}O\\|\\C_6H_2(OMe)_2\end{matrix}>CH{\cdot}CH_2{\cdot}COMe$, and $\begin{matrix}CO\text{———}O\\|\\C_6H_2(OMe)_2\end{matrix}>CH{\cdot}CH_2{\cdot}COPh$, respectively. It is obvious in this case that opianic acid does not behave as an aldehydic acid; for if it did, feeble, unsaturated acids of the formulæ $CO[CH{:}CH{\cdot}C_6H_2(OMe)_2{\cdot}COOH]_2$,

$COOH{\cdot}C_6H_2(OMe)_2{\cdot}CH{:}CH{\cdot}COMe$, and

$COOH{\cdot}C_6H_2(OMe)_2{\cdot}CH{:}CH{\cdot}COPh$,

respectively, would result from the condensation with acetone and benzophenone (compare Goldschmiedt and Egger, Abstr., 1891, 1371).

G. T. M.

Oximes of Opianic and Phthalaldehydic Acids. By O. Allendorff (*Ber.*, **24**, 3264—3266).—In a recent paper (Abstr., 1891, 1369), the author stated that the oxime of opianic acid was not known, he having at the time overlooked its description by W. H. Perkin, jun. (Trans., 1890, 1069).

A. R. L.

Metahemipinic Acid. By O. Rossin (*Monatsh.*, **12**, 486—500; compare Goldschmiedt, Abstr., 1889, 167).—This acid has the constitution $C_6H_2(OMe)_2(COOH)_2$ [= 1 : 2 : 4 : 5], and forms an *ethyl hydrogen* salt which melts at 127°, and a *diethyl salt* which is an uncrystallisable syrup, and can be distilled unchanged under a reduced pressure of 160 mm. The acid is converted by concentrated nitric acid into *dinitroveratroïl*, $C_8H_6O_6N_2$, which crystallises from dilute alcohol in pale-yellow needles, melts at 131—132°, is only slightly soluble in water, and appears to be identical with Merck's dinitroveratroïl (*Annalen*, **108**, 60). On heating the acid with hydriodic or hydrochloric acid, *normetahemipinic acid*, $C_8H_6O_6$ [$(OH)_2 : (COOH)_2$ = 1 : 2 : 4 : 5], was obtained. It crystallises with 1 mol. H_2O, which is not expelled on heating at 100° under the ordinary pressure, and is only slowly given up at that temperature in a vacuum. This acid is readily soluble in alcohol, dissolves sparingly in ether, crystallises from water in rhombic prisms [$a : b : c$ = 1 : 0·08837 : 0·5879], and from acetone in beautiful needles. At 180° it gives a trace of a yellow sublimate, which increases in quantity and turns red on further heating, whilst at 247·5° it melts, having been converted into normetahemipinic anhydride.

The *ethyl hydrogen* salt of norhemipinic acid, $C_{10}H_{10}O_6$, is obtained on heating normetahemipinic anhydride and absolute alcohol in a reflux apparatus for three hours. It crystallises from alcohol and ether in needles, which, if quickly heated, melt at 182°, but, if heated more gradually, melt at 175°. The *diethyl* salt, $C_{12}H_{14}O_6$, crystallises in

small needles which melt at 148·5—149·5°, and is readily soluble in alcohol. With ferric chloride, both the acid and its ethyl salts give an emerald-green coloration, which is characteristic of substances derived from protocatechuic acid. G. T. M.

Derivatives of Tannin. By C. Böttinger (*Arch. Pharm.*, **229**, 439—447; compare Abstr., 1890, 1275).—*Ethyl ditannacetoacetate*, $C_{34}H_{32}O_{22}$, is prepared by heating a mixture of tannin (20 grams) and potassium hydrogen sulphate (30 grams) with ethyl acetoacetate (30 grams) at 190—200° for 15 minutes, and then adding more ethyl acetoacetate (10 c.c.), and heating for another five minutes. The melt is extracted with water and ether, whereby the larger quantity of the ethyl ditannacetoacetate is left as a semi-solid mass, which is dried in a desiccator.

Ethyl ditannacetoacetate is a yellowish powder, which dissolves freely in alcohol, ethyl acetate, and ethyl acetoacetate, but very little in cold water; in hot water it is somewhat soluble, but is decomposed thereby, for, on cooling, slender, felted needles separate, which differ from the original compound in containing 1 mol. less of water. When boiled with water, ethyl ditannacetoacetate is decomposed with evolution of acetone; when heated in a sealed tube with water at 160°, acetone, carbonic anhydride, gallic acid, and tannin can be recognised as decomposition products. Several minor reactions are given in the paper.

Ethyl tannacetoacetate, $C_{20}H_{20}O_{12}$, is formed when the heating, in the process for preparing the di-derivative, is continued for 40 minutes. The melt is extracted as described above, and the residue dissolved in alcohol, mixed with ether, filtered, and evaporated at a gentle heat. The semi-liquid residue is poured into cold water, when the ethyl tannacetoacetate is separated; it is dried in a desiccator. Ethyl tannacetoacetate behaves with solvents similarly to the di-derivative, but does not dissolve in hot water more than in cold. When heated with water at 160°, it behaves like the di-derivative.

Hydrotannic and isohydrotannic acids are obtained when tannin (20 grams) is mixed with potassium hydrogen sulphate (30 grams) and glycerol (30 grams), and heated at 190—200° for 54 minutes. The melt is extracted with water and the residue dried and extracted with absolute alcohol; this extract is evaporated and the semi-liquid residue is treated with much alcohol and ether; the isohydrotannic acid is thus precipitated, whilst the hydrotannic acid remains in solution, and is precipitated by pouring the solution into water.

The *hydrotannic acid*, $C_{14}H_{14}O_7 + H_2O$, is purified by dissolving it in acetic acid and precipitating it again by the addition of water and a few drops of hydrochloric acid. It is a brown powder, which dissolves easily in cold alcohol, dilute acetic acid, and warm acetic anhydride, but not in water; when heated with zinc-dust, it gives the same sharp odour which was noticed with hydroquercic acid (Abstr., 1891, 1061). It dissolves in ammonia with a brown colour; the solution absorbs oxygen, and is reprecipitated by acetic and hydrochloric acids. It yields a yellow *acetyl* derivative, $C_{14}H_{10}Ac_4O_7$, when heated with acetic anhydride at 100°.

Isohydrotannic acid, $C_{14}H_{14}O_7$, is insoluble in cold water and absolute alcohol, but dissolves slightly in hot water, and easily in hot, aqueous alcohol; it behaves similarly to hydrotannic acid, and yields a brown *acetyl* derivative, which is probably $C_{14}H_{11}Ac_3O_7$.

The author concludes that these acids have high molecular weights, are not glycerides, and contain no glycerol residue. A. G. B.

1:2:4-Chloronitrobenzenesulphonic Acid and 1:4:2-Chloronitrobenzenesulphonic Acid. By P. Fischer (*Ber.*, **24**, 3185—3197).—Of the ten possible chloronitrobenzenesulphonic acids, only three have hitherto been prepared, and the exact constitution of these is known in only one case, namely, that of the 1:4:3-chloronitrobenzenesulphonic acid (Abstr., 1882, 593). The remaining two were prepared by Post and Meyer (Abstr., 1881, 1037), and were also obtained by Allert (Abstr., 1881, 902) who regarded them as a single acid; the latter further erroneously supposed that the chlorine occupied the adjacent position to the sulphonic acid group, and his conclusions are therefore incorrect.

1:2:4-*Chloronitrobenzenesulphonic acid*, $NO_2{\cdot}C_6H_3Cl{\cdot}SO_3H$, may be obtained either by the sulphonation of orthochloronitrobenzene or by the nitration of parachlorobenzenesulphonic acid; the latter method gives the best results, as commercial orthochloronitrobenzene contains large quantities of the para-compound. To prepare the sulphonic acid, 100 grams of chlorobenzene is treated with a mixture of 140 grams of crystallised pyrosulphuric acid and 140 grams of concentrated sulphuric acid, and the whole warmed for some time on the water-bath to convert into the sulphonic acid a small quantity of paradichlorodiphenylsulphone, which is always simultaneously formed; the nitration is carried out by adding 280 grams of barium nitrate, after which the whole is treated with a little water and the nitrous fumes removed by passing a strong current of air through the liquid. The acid is isolated as the barium salt, the latter being decomposed with sulphuric acid; it separates from a concentrated aqueous solution in slender, deliquescent needles, is soluble in alcohol, acetone, and acetic acid, insoluble in ether and benzene, and has a pleasant, aromatic odour and bitter, astringent taste. The *barium* salt, $(NO_2{\cdot}C_6H_3Cl{\cdot}SO_3)_2Ba + H_2O$, forms compact, yellow crystals or pale-yellow, lustrous plates; the *ammonium* salt, colourless, anhydrous needles; and the *copper* salt, emerald-green needles. The *sulphochloride*, $NO_2{\cdot}C_6H_3Cl{\cdot}SO_2Cl$, crystallises from ether in large, transparent crystals melting at 40—41°, and the *sulphonamide*,

$$NO_2{\cdot}C_6H_3Cl{\cdot}SO_2NH_2,$$

separates from water in pale-yellow prisms, and from alcohol in yellowish-white needles melting at 175—176°.

When the above sulphonic acid is reduced with ferrous sulphate and baryta-water, according to Claisen and Thompson's method (*Ber.*, **12**, 1946; **13**, 2126), it yields the *barium* salt of 1:2:4-*chloramidobenzenesulphonic acid*, $(NH_2{\cdot}C_6H_3Cl{\cdot}SO_3)_2Ba + 4H_2O$, which crystallises in colourless needles and only loses the last mol. of water of crystallisation at 210—215°. The *potassium* salt forms colourless,

anhydrous needles or plates. The free acid is obtained from the barium salt by exact precipitation with sulphuric acid, and separates from the solution in long, lustrous, white needles, the aqueous solution of which is coloured dark brown by ferric chloride.

1 : 4 : 2-*Chloronitrobenzenesulphonic acid* is obtained by heating 1 part of parachloronitrobenzene with a mixture of 4 parts of crystallised pyrosulphuric acid and 2 parts of concentrated sulphuric acid in a sealed tube at 120—130°, and is isolated as usual by means of the barium salt. It crystallises in beautiful, long needles or large, transparent crystals containing 2 mols. H_2O, and is not hygroscopic. The *barium* salt forms colourless, lustrous, anhydrous plates; the *potassium* salt, lustrous, white needles; the *sulphochloride*, beautiful, transparent crystals melting at 89—90°; and the *sulphonamide*, lustrous, white plates or small, colourless needles.

1 : 4 : 2-Chloronitrobenzenesulphonic acid is also readily reduced by ferrous sulphate and baryta-water with formation of 1 : 4 : 2-*chloramidobenzenesulphonic acid*, $NH_2{\cdot}C_6H_3Cl{\cdot}SO_3H$, which is obtained from the barium salt by the action of sulphuric acid, and crystallises in anhydrous, lustrous, white needles; the *barium* salt with $4H_2O$, forms colourless needles. H. G. C.

Note by Abstractor.—1 : 4 : 2-Chloronitrobenzenesulphonic acid has also been recently described by Claus and Mann (Abstr., 1891, 1488), together with all its above-mentioned derivatives. Both descriptions agree well together, except in the case of the barium salt of 1 : 4 : 2-chloroamidobenzenesulphonic acid, which, according to Claus and Mann, contains $6H_2O$ instead of $4H_2O$, as given by Fischer. H. G. C.

Diphenylenazone. By E. Täuber (*Ber.*, **24**, 3081—3088; compare Abstr., 1891, 570).—*Diphenylenazone dioxide*, $\begin{matrix}NO{\cdot}C_6H_4\\ |\!|\quad\ |\\ NO{\cdot}C_6H_4\end{matrix}$ [NO : NO = 6 : 6′], is prepared by dissolving orthodinitrodiphenyl (*loc. cit.*) (5 grams) in boiling 90 per cent. alcohol (100 c.c.), adding 40 per cent. aqueous potash (3 c.c.), and then zinc-dust (15 grams) in successive small portions, and finally boiling for half an hour in a reflux apparatus and filtering the solution. The yield is about 25 per cent. of the theoretical. The substance crystallises from alcohol in needles or in lustrous plates very faintly tinged with yellow. It melts with decomposition at 240°, explodes when heated, and is reduced to the azone by sodium amalgam. It is insoluble in water, dissolves very slightly in concentrated hydrochloric acid, light petroleum, and cold alcohol, sparingly in ether and cold acetic acid, rather sparingly in boiling alcohol, benzene, and toluene, easily in hot acetic acid, very easily in chloroform and phenol.

Diphenyleneazonemonoxide, $O<\begin{matrix}N{\cdot}C_6H_4\\ |\!|\quad\ |\\ N{\cdot}C_6H_4\end{matrix}$ [N_2O = 6 : 6′], is obtained from the mother liquor of the dioxide, and is separated from the latter substance by a long and tedious process of recrystallisation from alcohol and fractional precipitation from a solution in hydrochloric acid by the addition of water. It can also be obtained by

reducing orthodinitrodiphenyl with sodium amalgam. It crystallises from dilute alcohol in long, pale-yellow needles, with a silky lustre, melts at 152°, dissolves very readily in chloroform, readily in alcohol, boiling benzene, toluene, and acetic acid, sparingly in hot water, very sparingly in cold water and ether, and not at all in light petroleum. It dissolves readily in concentrated, sparingly in dilute, acids; the solvents have a deep-yellow colour. By sodium amalgam, it is reduced to the azone.

Diphenylenazone, $C_{12}H_8N_2$ [N : N = 6 : 6′], is obtained by dissolving orthodinitrodiphenyl (5 grams) in methyl alcohol (200 c.c.), adding, gradually, 3 per cent. sodium amalgam (250 grams) to the cooled solution, filtering, concentrating to a small bulk, and adding water. The substance is dissolved in hydrochloric acid and precipitated with ammonia, and then recrystallised from dilute alcohol. The yield was 2 grams. It melts at 156°, and boils above 360°, almost without decomposition. It crystallises with great readiness; especially fine crystals are obtained from a solution in benzene. It is pale greenish-yellow in colour, and gives, with acids, yellow solutions, from which, however, no salts can be isolated. It dissolves very readily in chloroform and acetic acid, readily in alcohol, benzene, and toluene, sparingly in ether and light petroleum, and not at all in water. When reduced with zinc-dust and hydrochloric acid, it yields *diphenylenehydrazone*, $C_{12}H_8{\cdot}N_2H_2$ [NH : NH = 6 : 6′], the *hydrochloride* of which, $C_{12}H_{10}N_2,HCl$, forms white needles insoluble in 20 per cent. hydrochloric acid. The salt, and still more so the base itself, is very unstable, oxidising in the air to the azone. It is unaffected by reducing agents.

Diamidodiphenyleneazone, $\begin{matrix} N{\cdot}C_6H_3{\cdot}NH_2 \\ \| \quad\quad | \\ N{\cdot}C_6H_3{\cdot}NH_2 \end{matrix}$ [NH_2 : N = 4 : 6 and 4′ : 6′], is prepared by reducing a solution of metadinitrobenzidine in methyl alcohol with sodium amalgam. The residue left after evaporating the alcohol is dissolved in dilute acetic acid, reprecipitated with ammonia, and crystallised from very dilute alcohol. It forms small, dark-red prisms, $C_{12}H_{10}N_4 + 2H_2O$, which lose 1 mol. H_2O over sulphuric acid, and the second at 100°. The anhydrous substance begins to decompose at 260° and melts at 267°. It dissolves readily in alcohol, sparingly in chloroform, toluene, benzene, and ether, very sparingly in water, and not at all in light petroleum. When dissolved in a small quantity of hydrochloric acid, it combines with 2 mols. HCl and forms a greenish-grey solution; on adding more acid, it combines with a third molecule of hydrogen chloride, and the colour changes to reddish-violet. It is a basic dye, and colours tanned cotton greenish-grey. C. F. B.

Stilbene, Thionessal, and Tolallyl Sulphide (Tolane Sulphide).—By E. Baumann and M. Klett (*Ber.*, **24**, 3307—3314.)—When the polymeric thiobenzaldehyde which melts at 83—90°, $(C_6H_5{\cdot}CHS)_n$, n = 10 or 12, is heated at 150°, it is decomposed into sulphur and stilbene, CHPh:CHPh, and at 190° the reaction takes place more readily. But if the temperature rises above 200°, some

hydrogen sulphide is evolved and thionessal formed. The two trithiobenzaldehydes melting at 167° and 225° respectively behave in a similar manner, except that the latter is not attacked until heated above its melting point, when some thionessal is also formed.

There was little doubt that the thionessal mentioned above was formed by a secondary action of the sulphur on the stilbene, and it was found that when stilbene and sulphur are heated together at 250°, hydrogen sulphide is evolved and thionessal formed. Thionessal, which melts at 183—184°, is thus *tetraphenylthiophen*, $\left.\begin{matrix}\mathrm{CPh{:}CPh}\\ \mathrm{CPh{:}CPh}\end{matrix}\right\rangle \mathrm{S}$, and its formation is precisely analogous to that of thiophen itself on passing ethylene through boiling sulphur.

Tolallyl sulphide cannot be obtained by further heating stilbene or thionessal with sulphur, but is formed on heating benzyl sulphide or bisulphide, and by distilling phenylacetic acid with sulphur; it melts at 174°. It was shown by Raoult's method to have the formula $C_{14}H_{10}S$. Since tolallyl sulphide may be converted, by oxidation, into oxylepiden, which contains four phenyl groups, it must itself contain phenyl groups, and has, doubtless, the formula $\left.\begin{matrix}\mathrm{CPh}\\ \mathrm{CPh}\end{matrix}\right\rangle \mathrm{S}$. A better name for it would be *tolane sulphide*. C. F. B.

Action of Nitrous Acid on Tetramethyldiamidobenzophenone. By W. Herzberg and M. Polonowsky (*Ber.*, **24**, 3197—3201).—By the action of nitrous acid on tetramethyldiamidobenzophenone, E. Bischoff (Abstr., 1888, 1197; 1889, 511) obtained a substance to which he assigned the constitution

$$\mathrm{NMe_2{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_2(:NOH){\cdot}NMe_2}.$$

The authors find that when the reaction is carried out according to Bischoff's instructions, a yellow precipitate is formed, amounting to about 30 per cent. of the ketone taken; this crystallises from alcohol in yellow plates melting with evolution of gas at 182—183°. The compound has, however, the composition $C_{16}H_{17}N_3O_2$, and is, in reality, the *nitrosamine* of *trimethyldiamidobenzophenone*,

$$\mathrm{NMe_2{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_4{\cdot}NMe{\cdot}NO}.$$

By the action of concentrated hydrochloric acid, it is converted into *trimethyldiamidobenzophenone*, $\mathrm{NMe_2{\cdot}C_6H_4{\cdot}CO{\cdot}C_6H_4{\cdot}NHMe}$, which crystallises from alcohol in pale-yellow plates, melts at 203—204°, and yields an *acetyl* derivative, $C_{16}H_{17}N_2O_2Ac$, melting at 145°. The compound described by Wichelhaus (Abstr., 1886, 362) as trimethyldiamidobenzophenone is probably a mixture of the trimethyl and tetramethyl compounds. In Bischoff's experiments, he did not separate the precipitate, but added alkali, and thus obtained a mixture of the nitrosamine with unaltered ketone. If double the quantity of sodium nitrite be taken, the yield of nitrosamine can be raised to 60 per cent. of the ketone, a small quantity of a substance sparingly soluble in hot alcohol being then also obtained.

Nitrous acid acts in a different manner on tetramethyldiamidodiphenylmethane, converting it partially into paranitrodimethylaniline.

H. G. C.

Derivatives of Paraphenylbenzophenone. By G. Koller (*Monatsh.*, **12**, 501—511; compare Goldschmidt, *ibid.*, **2**, 437).—Paraphenylbenzophenoxime, $C_6H_4Ph{\cdot}CPh{:}NOH$, is obtained on treating paraphenylbenzophenone in alcoholic solution with an aqueous solution of hydroxylamine hydrochloride and potash. It crystallises in needles, melts at 193—194°, is insoluble in water, dissolves readily in alcohol and ether, and, when heated at 100° with a mixture of acetic acid and acetic anhydride saturated with hydrochloric acid, is converted into the isomeric acid-anilide, which melts at 224°, and is resolved into aniline and paraphenylbenzoic acid (m. p. 218—219°) when heated at 160° with fuming hydrochloric acid.

The *benzoyl derivative* of the oxime, $C_6H_4Ph{\cdot}CPh{:}NOBz$, crystallises from alcohol in slender, white needles, and melts at 193°. On treatment with sodium amalgam, the oxime is reduced to the amidobase, $C_6H_4Ph{\cdot}CHPh{\cdot}NH_2$, which crystallises from ether in slender, white needles, melts at 77°, and forms an *acetate* which crystallises in needles melting at 161°, a *hydrochloride* which melts at 252°, a *nitrate* which melts at 211°, and a *platinochloride* which crystallises in yellow needles containing 4 mols. H_2O, and melts at 191°.

The *phenylhydrazone*, $C_6H_4Ph{\cdot}CPh{:}N_2HPh$, is obtained by the action of phenylhydrazine on paraphenylbenzophenone, and crystallises from absolute alcohol in yellow needles which melt at 144°.

G. T. M.

Claus' Theory of the Benziloximes. By K. Auwers and V. Meyer (*Ber.*, **24**, 3267—3271).—Claus (this vol., p. 50) has recently put forward the view that the isomerism of the benziloximes is due to differences of molecular structure rather than to those of the relative positions in space of the atoms within the molecule (stereochemical isomerism), and in defending the latter hypothesis the authors state that Claus has not taken into account the following facts:—Benzophenone and its symmetrical di-substitution derivatives yield only one oxime, whereas its mono-substitution derivative yields two, for which reason such formulæ as those proposed by Claus for the benziloximes are inadmissible for the benzophenonoximes, and it is specially to be noted that the isomerism of the oximes of both series have been proved by numerous experiments to be strictly analogous.

Claus represents benzile-α-monoxime as a true oximido-derivative, $CPh{\cdot}C(:NOH){\cdot}COPh$, and benzile-$\gamma$-monoxime as a nitroso-alcohol, $CPh{\cdot}C(NO){:}CPh{\cdot}OH$, and such a difference of structure would necessitate a corresponding difference in chemical behaviour, but the single fact which Claus adduces is that the α-derivative is converted by an excess of hydroxylamine with greater ease into a dioxime than is the γ-derivative; this being a difference of degree and not of kind. In reality, the α-derivative reacts with both hydroxylamine and its hydrochloride, whereas the γ-derivative only reacts with the free base; towards all other reagents the two compounds show complete similarity in their behaviour; apart from

this, however, the formula ascribed by Claus to the γ-monoxime is incompatible with the facts to be mentioned. It is well known that isonitroso-compounds (oximes) are more stable than true nitroso-derivatives, and it is difficult to understand why a nitroso-derivative is formed by a reaction which should yield an oxime as the direct product, and also that the same oxime is converted into a nitroso-derivative on heating its alcoholic solution at 100°; it is necessary to admit both of these, however, on Claus' hypothesis. Claus' formula for the γ-benzilemonoxime is entirely negatived by the observation that the benzyl-derivative of this oxime is formed by the interaction of α-benzylhydroxylamine and benzile (Abstr., 1889, 1193), thus: $\begin{matrix}\mathrm{Ph{\cdot}CO}\\ \mathrm{Ph{\cdot}CO}\end{matrix} + \mathrm{NH_2{\cdot}O{\cdot}CH_2Ph} = \begin{matrix}\mathrm{Ph{\cdot}C{:}NO{\cdot}CH_2Ph}\\ \mathrm{Ph{\cdot}CO}\end{matrix}$; whereas to admit that a compound of the formula $\begin{matrix}\mathrm{PhC{\cdot}NO}\\ \mathrm{PhC{\cdot}O{\cdot}CH_2Ph}\end{matrix}$ is produced would at once render it impossible to rely on the constitution of a compound which had been deduced from synthetical considerations. If, therefore, one of the benzilemonoximes is a nitroso-alcohol, it can only be the unstable α-modification, the benzyl derivative of which has not, up to the present, been prepared from benzile and α-benzylhydroxylamine, but then from this nitroso-alcohol (the α-monoxime), the α-dioxime, which Claus regards as a true dioxime, would be formed on treating it with hydroxylamine; whilst the true monoxime (the γ-monoxime) would be converted into the nitrosohydroxylamide $\begin{matrix}\mathrm{Ph{\cdot}C{\cdot}NO}\\ \mathrm{Ph{\cdot}C{\cdot}NH{\cdot}OH}\end{matrix}$, which, according to Claus, represents the γ-dioxime. The authors dismiss the three benzildioximes with only a few remarks, and conclude with the statement that, as their investigations on all these compounds have shown that they have the same structure, they have no other alternative, in accordance with the present views, than to regard the isomerism as stereochemical.

A. R. L.

Dyes of the Triphenylmethane Group. By E. Noelting (*Ber.*, **24**, 3126—3136; 3136—3139; 3139—3143; compare Abstr., 1891, 727).—*Tetramethyltriamidodiphenyltolylmethane*,

$$\mathrm{\overset{3}{N}H_2{\cdot}C_6H_3\overset{6}{M}e{\cdot}\overset{1}{C}H(C_6H_4{\cdot}\overset{4}{N}Me_2)_2},$$

is prepared by mixing finely powdered tetramethyldiamidobenzhydrol (27 grams) with cooled concentrated sulphuric acid (270 grams), adding paratoluidine (11 grams), raising the temperature to 40—50° to complete dissolution, and finally heating on the water-bath at 50—60° for 6 to 8 hours. The product is poured into water (3 litres), cautiously neutralised with soda, and any unaltered paratoluidine driven over with steam; the base is then dissolved in hydrochloric acid, reprecipitated with ammonia, extracted with ether, and light petroleum added to the dried ethereal solution to incipient turbidity, it being then placed over sulphuric acid in a vacuum, when the leuco-base slowly separates in the form of white needles, the yield being 90—95 per cent. of the theoretical. It melts at 160°, is sparingly

soluble in light petroleum, more readily in ether and alcohol, and insoluble in water. On oxidation with lead peroxide, it yields a bluish-green, soluble dye, homologous with metamidobenzaldehyde-green. The *dibenzyl derivative*, $C_{24}H_{27}N_3(C_7H_7)_2$, is obtained by boiling the leuco-base (1 mol.) with benzyl chloride (2·5 mols.), sodium acetate (1 mol.), and water (6—7 parts), in a reflux apparatus for 8—10 hours, the excess of benzyl chloride being then driven over with steam; it is dissolved in hydrochloric acid (1 : 5), concentrated hydrochloric acid added, whereby the hydrochloride melting at 186° separates in white needles, or, for the preparation of the free base, it is preferably converted into the zincochloride, from which the base is obtained on treatment with ammonia. The base, when crystallised from a mixture of ether and light petroleum, melts at 120°, is not acted on by acetic anhydride, yields a greenish-blue dye on oxidation, and is converted into sulphonic acids by the action of fuming sulphuric acid; these give bluish-green dyes on oxidation which colour wool and silk in an acid-bath. When the first-mentioned leuco-base is ethylated, and subsequently oxidised, a bluish-green dye is likewise obtained. The presence of the methyl group in the ortho-position relatively to the fundamental carbon atom appears to have the effect of rendering the derived dye much bluer than those from the lower homologue. The *phenol*, $OH\cdot C_6H_3Me\cdot CH(C_6H_4\cdot NMe_2)_2$ (OH: 3, Me: 6, CH: 1, $C_6H_4\cdot NMe_2$: 4), is obtained by dissolving the leuco-base (36 grams) in a mixture of concentrated sulphuric acid (70 grams) and water (3 litres), diazotising the cooled solution with sodium nitrite (7 grams), heating on the water-bath, precipitating with ammonia, and finally extracting with ether; it separates from a mixture of ether and light petroleum in white needles, melts at 156°, and is sparingly soluble in light petroleum and aqueous alkalis, easily in ether, alcohol, and acids, but insoluble in water; on oxidation, it yields a dye of a less bluish shade than those obtained from the amido-derivative.

Tetramethyltriamidodiphenyltolylmethane,

$$NH_2\cdot C_6H_3Me\cdot CH(C_6H_4\cdot NMe_2)_2$$

(NH$_2$: 2, Me: 5, CH: 1, $C_6H_4\cdot NMe_2$: 4),

is produced by heating a mixture of tetramethyldiamidobenzhydrol, paratoluidine, hydrochloric acid of 22° Baumé (27 grams of each), and water (100 c.c.) on the water-bath for 12—15 hours. The pure leuco-base crystallises from alcohol in needles, and melts at 180°, the yield being 75—80 per cent. of the theoretical. It gives a faint, bluish-violet dye on oxidation; the *dibenzyl derivative* is less readily oxidised than the above-described isomeride, whilst, on oxidising the *diacetyl derivative*, a green dye is obtained, which, on treatment with hydrochloric acid or alcoholic soda, is converted into a bluish-green dye with the elimination of the acetyl groups. The corresponding *phenol* crystallises from a mixture of light petroleum and ether in white needles, melts at 129—130°, and is more soluble in light petroleum than its isomeride; its constitution is proved by the fact that it is obtained by condensing homosalicylaldehyde with dimethylaniline in the presence of zinc chloride.

The condensation of asymmetrical-metaxylidine, mesidine, ψ-cum-

idine, isoduridine, and prehnidine (consecutive tetramethylaniline) with tetramethyldiamidobenzhydrol has also been effected by the author. In the presence of sulphuric acid, asymmetrical metaxylidine yields a leuco-base melting at 158°, and giving a green dye of a less bluish shade than that obtained from paratoluidine; mesidine, a leuco-base melting at 142°, giving a green dye of a more bluish shade; whilst ψ-cumidine and isoduridine yield leuco-bases melting at 132° and 157° respectively, the former giving a green dye of a very bluish shade, and the latter one of a less bluish shade. The reaction proceeds with difficulty with prehnidine, and the leuco-base withstands oxidation to a marked extent. In the presence of hydrochloric acid, asymmetrical metaxylidine yields a leuco-base melting at 145°, and ψ-cumidine one melting at 163—164°; both behave towards oxidising agents like the base from prehnidine, whilst mesidine and isoduridine yield the same products as in the presence of sulphuric acid.

Tetrethyltriamidodiphenyltolylmethane,

$$NH_2{\cdot}C_6H_3Me{\cdot}CH(C_6H_4{\cdot}NEt_2)_2,$$

prepared from tetrethyldiamidobenzhydrol and paratoluidine in the presence of concentrated sulphuric acid, melts at 103°, and yields a dye of a less bluish shade than that of the corresponding tetramethyl derivative.

The base obtained from tetramethyldiamidobenzhydrol and dibenzylparatoluidine in the presence of sulphuric acid is entirely different from the above-described dibenzyltetramethyltriamidodiphenyltolylmethane; it yields a pure green dye on oxidation, and condensation has perhaps taken place in the benzyl residue; that such is possible is proved by the fact that benzylamine condenses with the hydrol under the same conditions, and the product yields a green dye on oxidation.

Paranitrodimethyldiamidodiphenyltolylmethane,

$$\overset{3}{N}H_2{\cdot}C_6H_3\overset{6}{M}e{\cdot}\overset{1}{C}H(C_6H_4{\cdot}\overset{4}{N}Me_2){\cdot}C_6H_4{\cdot}\overset{4}{N}O_2,$$

is prepared by dissolving paranitrodimethylamidobenzhydrol (27 grams) in concentrated sulphuric acid (300 grams), adding paratoluidine (20 grams), and heating the mixture on the water-bath at 60—70° for 12 hours. The base separates from a mixture of alcohol and benzene in yellow needles, and melts at 202°; on oxidation with lead peroxide or chloranil, a brown dye is obtained which only imparts a faint colour to cotton mordanted with tannin; the presence of an amido-group in the meta-position relatively to the fundamental carbon atom appears to hinder the ready oxidation of the compound. The acetyl derivative crystallises in white needles, and, on oxidation with chloranil, yields a dye, which colours mordanted cotton orange-red; the shade remains unaltered when the acetyl groups are eliminated by heating the dye with acids.

Dimethyltriamidodiphenyltolylmethane,

$$\overset{3}{N}H_2{\cdot}C_6H_3\overset{6}{M}e{\cdot}\overset{1}{C}H(C_6H_4{\cdot}\overset{4}{N}Me_2){\cdot}C_6H_4{\cdot}\overset{4}{N}H_2,$$

is obtained by reducing the last-described nitroleuco-base with tin and hydrochloric acid; it crystallises from a mixture of ether and light petroleum in white needles, melts at 154°, and, on oxidation with lead peroxide, yields a bluish-green dye; whereas the acetyl derivative, on oxidation with chloranil, yields a dye colouring cotton mordanted with tannin a beautiful red. When the base is dissolved in methyl alcohol and heated in a reflux apparatus with methyl iodide and soda, *hexamethyltriamidodiphenyltolymethane* is formed; it crystallises from a mixture of ether and light petroleum in white plates, melts at about 100°, and yields a bluish-green dye on oxidation.

Tetramethyltriamidotriphenylmethane, prepared by the condensation of paranitrobenzaldehyde with dimethylaniline, and also from tetramethyldiamidobenzhydrol and aniline (D.R.-P. 27032), melts at 151—152°, and not at 65° as stated by Nathansohn and Müller (Abstr., 1889, 1190); it has, furthermore, the constitution

$$\overset{4}{N}H_2\cdot C_6H_4\cdot\overset{1}{C}H(C_6H_4\cdot\overset{4}{N}Me_2)_2;$$

the compound of the constitution given by Nathansohn and Müller is described by O. Fischer and Schmidt (Abstr., 1884, 1315), and melts at 134—135°; the methiodide melts at 193° with decomposition.

Tetramethyldiamidodiphenylquinolylmethane,

$$C_9NH_6\cdot\overset{3,1}{C}H(C_6H_4\cdot\overset{4}{N}Me_2)_2,$$

is obtained by heating a mixture of tetramethyltriamidotriphenylmethane (4 grams), glycerol (3·8 grams), sulphuric acid (6 grams), and nitrobenzene (0·9 gram) at 140—150° for 10—12 hours. It crystallises from alcohol in white needles which become greenish in the air, melts at 165°, is soluble in ether and benzene, and insoluble in light petroleum and water, and yields a green dye on oxidation; the *hydrochloride*, $C_{26}H_{27}N_3,3HCl$, is readily soluble, and the *platinochloride* sparingly soluble, in water.

Tetramethyltriamidodiphenylmethoxytolylmethane,

$$\overset{4}{N}H_2\cdot C_6H_2\overset{2}{Me}(\overset{5}{O}Me)\cdot\overset{1}{C}H(C_6H_4\cdot\overset{4}{N}Me_2)_2,$$

is prepared by heating a mixture of tetramethyldiamidobenzhydrol (10 grams), amidomethylmethoxybenzene, $NH_2\cdot C_6H_2Me\cdot OMe$ [2 : 4 : 1] (5·3 grams), and 36 per cent. hydrochloric acid (10·3 grams) on the water-bath for 4 hours; it crystallises in white needles, melts at 158—159°, is somewhat sparingly soluble in alcohol and ether, and very readily in benzene, and yields a beautiful blue dye on oxidation.

Tetramethyldiamidodiphenylmethoxymethylquinolylmethane,

$$C_9NH_4\overset{4}{Me}(\overset{2}{O}Me)\cdot\overset{3,1}{C}H(C_6H_4\cdot\overset{4}{N}Me_2)_2,$$

is prepared from the last described base, it being, however, found expedient to employ picric acid instead of nitrobenzene in its preparation; the compound crystallises from a mixture of light petroleum

and benzene in white needles, melts at 183°, and yields a green dye on oxidation. A. R. L.

Benzeneazo-α-naphthylglycocine. By A. Donner (*Ber.*, **24**, 2902—2904).—Azo-dyes have previously only been prepared from substituted amines in which the amido-hydrogen atom is replaced by alkyl groups. The author has now obtained azo-dyes from amines in which the amido-hydrogen atom is replaced by a group containing carboxyl group.

Benzeneazo-α-naphthylglycocine is prepared by adding a solution of α-napthylglycocine, dissolved in dilute hydrochloric acid, to a solution of diazobenzene chloride at a temperature not exceeding 0°. After remaining 12 hours, the *hydrochloride* of the new compound separates as a dark-brown, crystalline precipitate; it is collected, washed with dilute hydrochloric acid, and dried. It crystallises from alcohol in needles, melts at 170° with evolution of gas, is sparingly soluble in water, more so in concentrated hydrochloric acid, and easily in alcohol. The solutions are intense reddish-blue and turn yellowish-red on the addition of alkalis. In concentrated sulphuric acid, it dissolves with a deep-blue coloration, which changes to violet on the addition of water. The hydrochloric acid solution dyes silk a violet colour. By continued washing with water, the hydrochloride undergoes partial decomposition into the free base.

Benzeneazo-α-naphthylglycocine behaves as an amido-acid, and forms salts both with acids and bases. The *potassium salt* is obtained by adding a slight excess of potassium hydroxide to the hydrochloride. It crystallises in bronze-red tablets which rapidly discolour in the air, and must be dried in a vacuous desiccator over calcium chloride and potassium hydroxide; it dissolves easily in alcohol and warm water, more sparingly in the cold. The aqueous solution gives, with silver nitrate, a red, and with copper sulphate, a brown precipitate. The *ammonium salt* is prepared in a similar way to the potassium salt and crystallises in well formed, yellowish-red needles. Silk is dyed golden-yellow by solutions of the alkali salts.

The *free base* is best prepared by adding the theoretical quantity of potassium hydroxide to a solution of the hydrochloride, evaporating to dryness, and extracting with alcohol. It crystallises in small, lustrous, green needles, melts at 133° with evolution of gas, and is sparingly soluble in water, more easily in alcohol and ether. The solution is brown. The free base can also be prepared by decomposing the potassium salt with carbonic acid, but at the same time a compound is formed which crystallises in reddish-brown needles and which the author believes to have the constitution

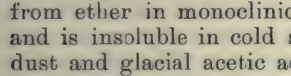
$$N_2Ph\cdot C_{10}H_6\cdot NH\cdot CH_2\cdot COONH_2(CH_2\cdot COOK)\cdot C_{10}H_6\cdot N_2Ph.$$

E. C. R.

Hydronaphthoic Acids. By A. v. Baeyer, R. Schoder, and E. R. Besemfelder (*Annalen*, **266**, 169—202).—This paper has been published somewhat sooner than was intended because of the appearance of an article by v. Sowinski (Abstr., 1891, 1380) on the same subject; it will be seen by comparing the two papers that there are numerous points of disagreement between them, for which reason the

authors think that the publication of their results is by no means a superfluous proceeding.

Labile Δ^2-dihydro-α-naphthoic acid [COOH = 1] is obtained by dissolving α-naphthoic acid (5 grams) and the theoretical quantity of sodium carbonate in water (50 c.c.) and then adding 4 per cent. sodium amalgam (60 grams) to the well-cooled solution, through which a stream of carbonic anhydride is at the same time passed; when the solution is found to be free from naphthoic acid, it is neutralised with dilute sulphuric acid, filtered, mixed with excess of sulphuric acid, and the precipitated acid purified by means of its barium salt, which is very readily soluble in water (the impurities remaining undissolved). It crystallises from light petroleum in slender, colourless, monoclinic needles, melts at 91°, and is readily soluble in ether, ethyl acetate, alcohol, and carbon bisulphide, but more sparingly in benzene, light petroleum, and cold water (1 in 552 parts); it seems to be decomposed by boiling water, and, unlike the $\Delta^{2:5}$-dehydroterephthalic acid, with which it has many properties in common, it immediately decolorises an alkaline solution of potassium permanganate, being converted into phthalic acid, resinous products, and an acid which has the odour of acetic acid. The silver salt separates from water in reddish needles. The dibromide, $C_{10}H_9Br_2$·COOH, prepared by treating the acid with bromine in well-cooled carbon bisulphide solution, separates from a mixture of ether and light petroleum in the form of a crystalline powder, melts at 132°, and is readily soluble in ether and carbon bisulphide, but more sparingly in benzene and light petroleum; it is stable towards potassium permanganate, the violet colour disappearing only on prolonged keeping. It is readily reduced by zinc-dust and glacial acetic acid, being reconverted into the original dihydro-acid, and when warmed with alcoholic potash, it yields naphthoic acid. Stable Δ^1-dihydro-α-naphthoic acid is formed when the labile acid is boiled for a few hours with soda; it separates from ethyl acetate in well-defined, monoclinic crystals, $a : b : c = 1{\cdot}5399 : 1 : 1{\cdot}5657$, $\beta = 59°\ 12'$, melts at 125°, and is moderately easily soluble in alcohol, but only very sparingly (1 in 3512 parts) in cold water. The silver salt crystallises from hot water in colourless needles, which soon turn reddish on exposure to the air. The acid is immediately oxidised by potassium permanganate, yielding orthocarboxyhydrocinnamic acid (m. p. 165°) and small quantities of phthalic acid; the formation of the first-named compound proves that the dihydro-acid has the constitution assigned to it above. The dibromide separates from a mixture of ether and light petroleum in yellowish crystals, melts at 152°, and is reconverted into the original dihydro-acid on reduction with zinc-dust and glacial acetic acid; it is very stable towards potassium permanganate, but is decomposed by boiling methyl alcoholic potash yielding α-naphthoic acid and the dihydro-acid.



Tetrahydro-α-naphthoic acid is formed when α-naphthoic acid or either of its dihydro-derivatives is treated with sodium amalgam in warm alkaline solution; when reduction is at an end, the neutralised solution is filtered and then treated with sodium carbonate and potassium permanganate until the solution retains its violet colour

for a short time. The acid is then precipitated with sulphurous and sulphuric acids and repeatedly recrystallised from ethyl acetate, from which it separates in well-defined, triclinic crystals, melting at 85°; it is soluble in 1052 parts of cold water, and is moderately stable towards potassium permanganate, the violet colour disappearing only after keeping for a few minutes. The silver salt crystallises from hot water, in which it is moderately easily soluble, in colourless needles, which soon assume a reddish hue. When the chloride of the acid is treated with bromine in the cold and the product then warmed with concentrated formic acid, a yellow, crystalline compound, seemingly a monobromo-substitution product of the tetrahydro-acid, is obtained. The *amide* crystallises from alcohol in colourless needles, and melts at 116°.

Two dihydro-acids are formed when β-naphthoic acid is reduced with sodium amalgam as described in the case of the corresponding α-compound (except that potassium carbonate is used instead of the sodium salt); on acidifying, the two acids are precipitated in an oily condition, but this oil quickly solidifies, and, after recrystallisation from hot water, a seemingly homogeneous substance melting at 103—104° is obtained; it is possible, however, by fractional precipitation to resolve this product into the two acids described immediately below.

Labile Δ^3-dihydro-β-naphthoic acid crystallises from dilute alcohol in microscopic, seemingly rhombic prisms, melts at 104—105°, and is soluble in 1734 parts of water at 14°; it is immediately oxidised by potassium permanganate in sodium carbonate solution, yielding phthalic acid and oxalic acid, but on oxidation with potassium ferricyanide it is reconverted into β-naphthoic acid. The silver salt is decomposed by boiling water.

The *lactone* of a bromohydroxytetrahydronaphthoic acid is formed when the preceding compound is treated with bromine in well-cooled carbon bisulphide solution in the dark, the solution then evaporated at the ordinary temperature (whereon hydrogen bromide is evolved), the yellowish-red residue dissolved in ether, and the solution shaken with sulphurous acid and sodium carbonate successively. It separates from ether in monoclinic crystals, melts at 124° with decomposition, and is insoluble in cold sodium carbonate; when treated with zinc-dust and glacial acetic acid, it is reconverted into the labile dihydro-acid, and alcoholic potash transforms it into β-naphthoic acid. This lactone has, doubtless, the constitution represented by the formula

$CH<\begin{matrix}CH_2\cdot C_6H_4\\ CHBr\\ CO\end{matrix}>\begin{matrix}CH\\ \\ O\end{matrix}$, and its formation from the labile acid shows that the latter is the Δ^3-dihydro-derivative; the dibromide, from which the lactone is produced, could not be obtained in crystals.

Stable dihydro-β-naphthoic acid is formed when the labile acid is boiled with soda, but the conversion is never complete, and, in presence of air, naphthoic acid is also formed; it is, therefore, more conveniently prepared by boiling a solution of the potassium salt of β-naphthoic acid with 3 per cent. sodium amalgam, until the whole of the naphthoic acid has been reduced. The stable acid is then separated

from its isomeride and from tetrahydronaphthoic acid by fractionally precipitating its solution in decinormal ammonia with hydrochloric acid of the same concentration. It crystallises from boiling benzene in small, colourless, nacreous plates, melts at 161°, and is very sparingly soluble (1 in 19318 parts) in water at 14°; it dissolves freely in alcohol, ether, and glacial acetic acid, but is more sparingly soluble in benzene and light petroleum, and very sparingly in carbon bisulphide. On oxidation with an alkaline solution of potassium ferricyanide, it yields β-naphthoic acid, and its cold solution in sodium carbonate immediately decolorises potassium permanganate, the crystalline products being phthalic acid and oxalic acid. The silver salt is amorphous and is decomposed by boiling water. The dibromide, $C_{11}H_{10}Br_2O_2$, is formed, without evolution of hydrogen bromide, when the acid is treated with bromine in well-cooled chloroform solution in the dark; it separates from a mixture of light petroleum and ether in monoclinic crystals, melts at 208°, dissolves freely in sodium carbonate, and is very stable towards potassium permanganate. It is readily soluble in alcohol, chloroform, glacial acetic acid, and hot water, but only moderately in ether and light petroleum, and sparingly in cold water; when warmed with alcoholic potash, it is converted into β-naphthoic acid, and on treatment with zinc-dust and glacial acetic acid, it seems to be transformed into the dihydro-acid from which it is derived. This stable dihydro-acid is either the Δ^2- or the Δ^1-derivative, probably the former. Tetrahydro-β-naphthoic acid is best obtained by heating an alkaline solution of β-naphthoic acid with sodium amalgam until the permanganate test shows the absence of oxidisable substances; the precipitated acid is dissolved in sodium carbonate, and potassium permanganate added until a violet coloration is produced, by which means the product is obtained free from all traces of the dihydro-acids. It crystallises from dilute alcohol and boiling water in transparent needles, melts at 96°, and is soluble in 1661 parts of water at 14°; it does not reduce a warm ammoniacal solution of silver nitrate, and its cold solution in sodium carbonate does not immediately decolorise potassium permanganate. It is only slowly oxidised by an alkaline solution of potassium ferricyanide, and it does not combine with bromine in cold chloroform solution in the dark; on oxidation with potassium permanganate at the ordinary temperature, it yields oxalic acid and phthalic acid. The silver salt is more readily soluble than the salts of the dihydro-acids.

The electrical conductivity of the acids described in this paper was measured by Bethmann and Bader with the following results:—

α-Naphthoic acid	K = 0·0197	β-Naphthoic acid	K = 0·00523
Δ^1-Dihydro-α-acid	K = 0·0080	Δ^2-Dihydro-β-acid ...	K = 0·00290
Δ^2-Dihydro-α-acid	K = 0·0114	Δ^3-Dihydro-β-acid ...	K = 0·00515
Tetrahydro-α-acid	K = 0·00445	Tetrahydro-β-acid ...	K = 0·00250

F. S. K.

α-Naphthol-α-sulphonic Acid. By O. N. Witt and H. Kaufmann (*Ber.*, **24**, 3157—3163).—α-Naphthol-α-sulphonic acid is prepared on a technical scale by boiling diazotised naphthionic acid with dilute sulphuric acid (Neville and Winther, *Ber.*, **13**, 1949), or by

fusing naphthionic acid with sodium hydroxide under pressure (D.R.-P. 46307); the products from the two methods are dissimilar in appearance, as are also to some extent the azo-dyes obtained from them, but the latter, after repeated crystallisation, are found to be identical. On reducing these dyes with an acid solution of stannous chloride (Witt, Abstr., 1889, 270), a sparingly soluble amidonaphtholsulphonic acid separates, after a time, in the form of iridescent, greyish needles and plates; this can be purified by repeatedly dissolving in disodium sulphite solution, reprecipitating by hydrochloric acid and finally washing with water, alcohol, and ether; it contains 1 mol. H_2O. It is probable that the impurity in the naphtholsulphonic acid prepared by the fusion method is due to the presence of an isomeride, which may perhaps be produced by intramolecular change during the fusion, but the acid prepared by Neville and Winther's method also contains an impurity, the nature of which has not as yet been determined.

β-Nitroso-α-naphthol-α-sulphonic acid is obtained when sodium α-naphthol-α-sulphonate (24·6 grams) is dissolved in water (300 c.c.), 39 per cent. hydrochloric acid (19 c.c.) added, and sodium nitrite (6·9 grams) in concentrated solution slowly dropped into the cooled mixture; the precipitated compound is collected and crystallised from a mixture of water (500 c.c.) and hydrochloric acid (50 c.c.), when it separates in brownish-yellow, lustrous crystals, the yield being 20 grams. It contains $3\frac{1}{2}$ mols. H_2O, and is rendered anhydrous at 115°, after which it is very hygroscopic; it is easily soluble in water and alcohol; concentrated sulphuric acid dissolves it with an orange-red colour, which, on dilution, becomes yellow, whilst nitric acid, on heating, converts it into dinitronaphthol. The acid dissolves in ammonia and in sodium hydroxide solution with a reddish-brown colour, forming the *normal salts*, and from these solutions, on addition of barium chloride and alcohol, a gelatinous *barium salt* is precipitated. The *salt*, $OH{\cdot}C_{10}H_5(NO){\cdot}SO_3Na$, separates on adding an excess of sodium acetate to the hot aqueous solution of the acid in the form of orange-yellow needles and prisms; the *barium salt*, $(C_{10}H_6NSO_5)_2Ba + 3H_2O$, is precipitated in small, vermilion crystals on adding barium chloride to a solution of the preceding sodium salt. The acid gives a red colour with cobalt salts and a green colour with iron salts; when heated with aniline, naphthaquinonedianilide (Zincke, Abstr., 1882, 967) is formed. It reacts with orthodiamines with the production of scarlet dyes, probably belonging to the eurhodine group; the base obtained with 1 : 2-diamidotoluene forms golden-yellow needles, and melts at 257°. On careful reduction with acid stannous chloride solution, or when heated with sodium hydrogen sulphite solution, it yields the same amidonaphtholsulphonic acid as the azo-dyes derived from α-naphthol-α-sulphonic acid (see above), and must therefore have the constitution [OH : NO : SO_3H = 1 : 2 : 4].

Sodium β-naphthaquinone-α-sulphonate, $C_{10}H_5O_2{\cdot}SO_3Na$, is prepared by gently heating the last-mentioned amidonaphtholsulphonic acid (5 grams) with nitric acid, sp. gr. 1·4 (10 c.c.), and adding a saturated solution of sodium chloride (40 c.c.); it separates in yellow needles, and is crystallised from dilute alcohol; it is readily soluble in water

and almost insoluble in alcohol; sulphurous acid converts it into the corresponding quinol-derivative. The quinone reacts with 1 : 2-diamidotoluene, forming an azine which crystallises in red needles, thus proving its constitution. A. R. L.

Sulphonic Acids of β-Naphthaquinone. By O. N. Witt (*Ber.*, **24**, 3154—3157).—The amidonaphtholsulphonic acids are very readily oxidised; thus, in alkaline solution they are converted by the oxygen of the air into greenish-brown compounds, which may be derivatives of β-naphthaquinhydrone; in acid solution, when ferric chloride or potassium dichromate is used as the oxidising agent, β-naphthaquinonesulphonic acids appear to be formed, which cannot, however, be isolated on account of their great affinity for these metals.

Ammonium β-naphthaquinonesulphonate, $C_{10}H_5O_2 \cdot SO_3NH_4$, is obtained by adding amido-β-naphthol-β-sulphonic acid (10 grams) in small portions at a time to nitric acid, sp. gr. 1·2 (10 c.c.); the semi-solid product is spread upon a porous tile, and finally crystallised from a very small quantity of water, the solution being cooled by ice; in this way, a product, representing 60—75 per cent. of the starting material, is obtained in the form of golden-yellow needles; it is dried at 100—110°. The compound is very soluble in water and somewhat less so in alcohol; on treating it with sodium hydroxide, the sodium salt is formed, but an excess of the alkali decomposes it; it reacts with orthodiamines with the formation of azinesulphonic acids. The corresponding quinol-derivative is formed when the salt is reduced with aqueous sulphurous acid, but it is more conveniently prepared as follows:—The amidonaphtholsulphonic acid is mixed with water and the calculated quantity of bromine added; to the solution of the quinone, an excess of sulphurous acid is now added, and the ammonium quinolsulphonate isolated by evaporating the solution; it forms white plates, and is very easily soluble in water; alkalis colour its aqueous solution deep-yellow, and ammonia in the presence of air deep-brown; silver salts are immediately reduced, and it is not oxidised to the quinone by nitric acid of sp. gr. below 1·2. When oxidised in the presence of paradiamines, violet-red dyes, belonging to the group of indophenols, are produced, and it reacts with diazo-compounds with the formation of azo-dyes which yield brownish-red to indigo-blue lakes with metallic mordants. It thus furnishes an exception to the observations that orthodihydroxy-compounds are not capable of forming azo-dyes. The other amidonaphtholsulphonic acids yield similar compounds on oxidation. A. R. L.

Phenanthridine. By H. Pictet and H. J. Ankersmit (*Annalen*, **266**, 138—153; compare Abstr., 1891, 837).—Attempts to synthesise phenanthridine by treating orthohydroxybenzylideneaniline,

$$OH \cdot C_6H_4 \cdot CH:NPh,$$

and benzylideneorthamidophenol, $OH \cdot C_6H_4 \cdot N:CHPh$, with dehydrating agents were unsuccessful; both compounds seem to yield small quantities of acridine on distillation over zinc-dust.

Benzylideneorthamidophenol, $C_{13}H_{11}NO$, prepared by the condensa-

tion of benzaldehyde and orthamidophenol, crystallises from alcohol in grey, hexagonal plates, melts at 89°, and is readily soluble in ether and benzene, but insoluble in water.

Hydroxyphenanthridine, $\begin{matrix}C_6H_4\cdot C(OH)\\ \vert \quad\quad \Vert \\ C_6H_4\cdot N\end{matrix}$, prepared as previously described (*loc. cit.*), crystallises from alcohol in colourless needles, melts above 290°, and is insoluble in cold water, ether, benzene, and alkalis.

Phenanthridine methyl hydroxide, $C_{13}H_9N,MeOH$, prepared by decomposing the methiodide (Abstr., 1890, 390) with alcoholic soda, crystallises in colourless needles, melts at 109°, and dissolves freely in alcohol, ether, and mineral acids, yielding fluorescent solutions.

Dihydrophenanthridine, $\begin{matrix}C_6H_4\cdot CH_2\\ \vert \quad\quad \vert \\ C_6H_4\cdot NH\end{matrix}$, is obtained when phenanthridine hydrochloride is treated with tin and hydrochloric acid; it crystallises from dilute alcohol in colourless needles, melts at 90°, and is almost insoluble in water, but very readily soluble in alcohol and ether, yielding fluorescent solutions. It is readily oxidised, even on exposure to the air, being reconverted into phenanthridine. The *mercurochloride* crystallises from hot water in needles and melts at 204°. The *platinochloride* decomposes at about 220°, but without melting. The *picrate* and the *dichromate* crystallise from hot water in slender, yellow needles. The *nitroso*-derivative is an oil. The *acetyl* derivative, $C_{15}H_{13}NO$, crystallises in colourless prisms melting at 108°.

F. S. K.

Methylphenanthridine and Chrysidines. By A. Pictet and S. Erlich (*Annalen*, **266**, 153—168; compare Abstr., 1891, 217).—*Paramethylphenanthridine*, $\begin{matrix}C_6H_4\text{---}CH\\ \vert \quad\quad \Vert \\ C_6H_3Me\cdot N\end{matrix}$ [N : Me : : = 2 : 5], is formed, together with benzene, toluene, &c., when the vapour of benzylideneparatoluidine is passed over red-hot pumice; it is isolated by means of its mercurochloride. It crystallises from dilute alcohol in long, colourless needles, melts at 131°, and is readily soluble in alcohol, ether, benzene, chloroform, and light petroleum, but only very sparingly in water; its aqueous and alcoholic solutions show a slight, blue fluorescence. The *hydrochloride* is readily soluble in water, from which it crystallises in yellow needles; the *sulphate* and the *nitrate* are also readily soluble. The *platinochloride*, $(C_{14}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in yellow needles, loses its water at 110°, does not melt below 280°, and is decomposed by hot water. The *mercurochloride* forms yellow needles, melts at 215°, and is sparingly soluble in cold water, the solution showing a green fluorescence. The *aurochloride* crystallises in yellow needles melting at 210° with previous decomposition. The *picrate* and the *dichromate* crystallise in needles. The *methiodide*, $C_{14}H_{11}N,MeI$, crystallises from warm alcohol in brown needles melting at 180° with decomposition. The *methyl hydroxide*, $C_{14}H_{11}N,MeOH$, crystallises from dilute alcohol in colourless needles, melts at 136°, and is almost insoluble in water. The *methochloride* crystallises in yellow needles, and is only sparingly soluble in cold water.

Orthomethylphenanthridine, $C_{11}H_{11}N$ [N : Me = 2 : 3], is obtained when the vapour of benzylideneorthotoluidine is passed over red-hot pumice, but the principal product is α-phenylindole (compare Abstr., 1886, 711); it melts at about 70°, is not easily obtained in crystals, and is very readily soluble in alcohol, ether, chloroform, benzene, and light petroleum. The *hydrochloride* crystallises from water in slender, yellow needles, and dissolves freely in cold water, the dilute solutions showing a blue fluorescence. The *platinochloride*, $(C_{14}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in yellow needles and does not melt below 275°. The *mercurochloride* (m. p. 196°), *aurochloride* (m. p. 196—200°), and the *picrate* (m. p. 220° with decomposition) crystallise in yellow needles: the *dichromate* crystallises from hot water in small, orange-red needles. The *methiodide*, $C_{14}H_{11}N,MeI$, separates from alcohol in brownish-yellow needles, melts at 187° with decomposition, and is readily soluble in alcohol and water, but only very sparingly in ether.

α-Chrysidine (Abstr., 1891, 217) crystallises from alcohol in needles, melts at 108°, and is readily soluble in ether, chloroform, and light petroleum, but insoluble in water. The *hydrochloride* crystallises from hot dilute hydrochloric acid in yellow needles, and melts at about 210°. The *nitrate* forms yellow prisms melting at 155°. The *platinochloride*, $(C_{17}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in long, yellow needles, and decomposes at 255°. The *mercurochloride* (m. p. 240—245°), the *aurochloride* (m. p. 228°), and the *picrate* (m. p. 240°) crystallise in yellow needles; the *dichromate* and the zinc double salt (m. p. about 250°) are also crystalline. The *methiodide*, $C_{17}H_{11}N,MeI$, crystallises from alcohol in pale yellow needles, melts at 108°, and is insoluble in ether. The *methyl hydroxide*, $C_{17}H_{11}N,MeOH$, forms colourless needles, and melts at 110°. The *methochloride* crystallises from dilute hydrochloric acid in long, slender needles; its *mercurochloride* melts at 215°, and its *platinochloride*, $(C_{17}H_{11}N)_2,Me_2PtCl_6$, crystallises in yellow needles.

β-Chrysidine (*loc. cit.*) crystallises from alcohol in lustrous, colourless needles, melts at 131°, and resembles the corresponding α-derivative in its properties. The *hydrochloride* crystallises in small, yellow prisms, and melts at about 220°. The *nitrate* is sparingly soluble, and forms yellow needles melting at 187°. The *platinochloride*, $(C_{17}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in yellow needles, and melts at 245° with decomposition. The *dichromate*, $(C_{17}H_{11}N_2)_2,H_2Cr_2O_7 + 2H_2O$, crystallises from hot water in orange needles, and decomposes at about 200°, but without melting. The *mercurochloride* (m. p. 272°), *aurochloride* (m. p. 245° with decomposition), *picrate*, and zinc double salt crystallise in yellow needles. The *methiodide*, $C_{17}H_{11}N,MeI$, crystallises from alcohol in brown needles, melts at 237°, and is only sparingly soluble in cold water and insoluble in ether. The corresponding *hydroxide* forms colourless needles, melts at 133°, and is readily soluble in alcohol and ether, but insoluble in water. The *methochloride* crystallises from dilute hydrochloric acid in lustrous needles; its *platinochloride*, $(C_{17}H_{11}N)_2,Me_2PtCl_6$, forms yellow needles.

Phenanthridine and the four bases described above have many properties in common; they are feeble bases, and their salts are all decomposed by water. Their methiodides are decomposed by soda in

the cold, yielding crystalline hydroxides; these compounds are soluble in alcohol and ether, yielding solutions which show a blue and a violet fluorescence respectively, and they form with acids yellow salts, the aqueous solutions of which show a green fluorescence. F. S. K.

Action of Benzoic Acid on Turpentine. By G. Bouchardat and J. Lafont (*Compt. rend.*, **113**, 551—553).—Benzoic acid appears to unite with French turpentine slowly in the cold; at 150°, employing equal weights of acid and turpentine, the action is rapid; after 50 hours' heating, all the turpentine is taken up. The uncombined acid is removed from the product by treatment with an alkali. The portions volatile below 200° separate into solid camphene boiling at 157°, $[\alpha]_D = -3° 30'$, and an isomeric liquid terpilene boiling at 175—180°, $[\alpha]_D = -3°$ to $-4° 30'$. The production of almost inactive camphene and terpilene is accounted for by the formation of turpentine and terpilene benzoates, which, under the prolonged influence of a temperature of 150°, yield acid and camphene and terpilene respectively, hydrocarbons losing their rotatory power rapidly under these conditions. Camphene has been isolated to the extent of 1/10th, and terpilene of 1/3rd, of the weight of the turpentine. The residue left on distilling at 220° forms nearly half the weight of the turpentine. It decomposes on distillation into benzoic acid and camphene hydrocarbons. It may be distilled at 190—195° under a pressure of 30 mm. when a small residue of polyterpilenes remains, consisting principally of colophene, volatile at about 315°. The portion passing over at 190° is an oily mixture of camphenol and isocamphenol benzoates, which are hardly affected by boiling aqueous alkalis, but are hydrolysed in the cold by alcoholic potash; the product of hydrolysis, when washed with tepid water, is partly crystalline. On fractional distillation, lævocamphenol and dextroisocamphenol are separated.

Camphenol, purified by recrystallisation from light petroleum, melts at 193°, and distils at 212°; its rotatory power is $[\alpha]_D = -32° 10'$ to $-32° 20'$. The derived camphor is solid, and has a rotatory power of 38° to 38° 10′. These rotatory powers of the camphenol and camphor are of the same sign, but inferior to those of lævoborneol from Ngai and feverfew camphor. The differences obtain probably owing to the turpentine not being an optically single compound, and, according to the authors' experiments, to the production from the camphene benzoate of inactive or racemic camphenols not separable by solvents from the lævocamphenol. Isocamphenol, purified in the same way, melts at 47°, and boils at 198—199°; its rotatory power is $[\alpha]_D = +10° 40'$ and does not vary under the prolonged action of acids or high temperatures. Phosphorus pentachloride converts isocamphenol, dissolved in light petroleum, into a liquid chloride, which does not solidify even at −60°, boils from 100° to 105° at 40 mm., and is nearly inactive. Nitric acid converts isocamphenol into a liquid substance having the odour of camphor, which, at −60°, forms crystalline plates melting at −20°. This compound, of the same formula as camphor, boils at 13° lower, that is, at about 191°; it is strongly lævorotatory. It forms a crystalline compound with hydroxylamine. The properties of this isocamphor assimilate it to the natural

compound, fenolone, obtained by Wallach from essence of fennel, and isocamphenol to the fenolic alcohol derived from it.

The action of benzoic acid at 150° on the turpentines gives a practical method of reproducing camphenols and isocamphenols.

W. T.

Terpenes and their Derivatives. By J. W. Brühl (*Ber.*, **24**, 3373—3416).—The present communication deals exclusively with the constitution and properties of various camphene derivatives.

Menthol is readily converted into cymene by heating it with anhydrous cupric sulphate in sealed tubes for several hours at 250—280°. It is not advisable to use potassium dichromate or potassium permanganate in place of cupric sulphate, since at low temperatures the action of these substances is very feeble, and at higher temperatures violent explosions occur.

Menthyl ethyl ether, $C_{10}H_{19}OEt$, is prepared by boiling menthol (50 grams) dissolved in anhydrous toluene (30 grams) with sodium (8 grams) for 15 hours. The solution is separated from the excess of sodium, and heated with ethyl iodide in excess; the sodium iodide and toluene are removed, and the residue dried and fractionated over sodium in a vacuum. The ether boils at 211·5—212°, under a pressure of 750 mm., and is a colourless liquid, with a slight menthol-like odour.

Bornyl ethyl ether, $C_{10}H_{17}OEt$, is obtained in a manner similar to the preceding compound, xylene being used as a solvent in place of toluene; it is a clear, colourless, viscid liquid, which boils at 97° under a pressure of 20 mm., and at 204—204·5° under a pressure of 750 mm. The yield is 98 per cent. of the borneol employed. All attempts to prepare dibornyl ether were unsuccessful.

Bornyl methylene ether, $CH_2(C_{10}H_{17}O)_2$, is formed by the action of methylene iodide on sodium bornyloxide; it crystallises from light petroleum in colourless, rhombic prisms, melts at 167—168°, and boils under reduced pressure without decomposition; when molten, it exhibits a bluish-yellow fluorescence.

Bornyl methyl ether is formed during the preparation of the preceding compound, and is separated by fractionation.

All attempts to obtain pure sodium camphor have been fruitless. Ethyl camphor, prepared according to Baubigny's method, combines with one atomic proportion of sodium if heated with it in xylene solution, and on treatment with ethyl iodide and subsequent rectification, a viscid liquid is formed, which boils at 156—168° under a pressure of 10 mm., and is probably *diethyl camphor;* it could not be completely purified from lack of material.

The action of sodium on camphor is stated by Baubigny to proceed according to the equation $2C_{10}H_{16}O + 2Na = C_{10}H_{15}NaO + C_{10}H_{17}ONa$; the yield of borneol is, however, considerably less than is indicated by this equation; a portion of the camphor is always recovered unaltered; these facts, as well as the behaviour of the ethereal salts of camphorcarboxylic acid (see below), seem to show that Baubigny's conclusions are incorrect; apparently camphor combines with 2 atoms of sodium, and the reaction which takes place is really represented by the equation $3C_{10}H_{16}O + 4Na = C_{10}H_{14}Na_2O + 2C_{10}H_{17}ONa$.

Camphocarboxylic acid is readily prepared by dissolving camphor (228 grams) in ether (1—1·5 litres), and adding sodium (46 grams) in the form of fine wire; the flask is fitted with a reflux apparatus, and a current of dry carbonic anhydride is passed through the solution; there is considerable development of heat, and the sodium is rapidly dissolved. As soon as the reaction is completed, powdered ice (1 kilo.) is added, the ether separated, and the aqueous solution allowed to remain for 24 hours, when a portion of the borneol separates in crystals, and the remainder is thrown down on heating the filtrate to 50°; the precipitated borneol, after recrystallisation from light petroleum, melts at 208—208·5°; the yield is theoretical. On acidifying the aqueous solution, camphocarboxylic acid is precipitated as a snow-white mass, which, on crystallisation from warm (not boiling) water, yields the pure acid in colourless needles; the yield is almost quantitative. This reaction may be explained by assuming that a disodium salt, $C_8H_{14}<\begin{matrix}C\cdot COONa\\ \|\\ C\cdot O\cdot COONa\end{matrix}$ is first formed, and this, on treatment with water, is decomposed, yielding the compound $C_8H_{14}<\begin{matrix}C\cdot COONa\\ \|\\ C\cdot OH\end{matrix}$, which then by intramolecular change gives sodium camphocarboxylate, $C_8H_{14}<\begin{matrix}CH\cdot COONa\\ \|\\ CO\end{matrix}$. In proof of the foregoing theory, it is found that ethyl camphocarboxylate reacts with sodium and ethyl chlorocarbonate to form a compound, $C_8H_{14}<\begin{matrix}C\cdot COOEt\\ \|\\ C\cdot O\cdot COOEt'\end{matrix}$ which on hydrolysis yields camphocarboxylic acid; further, on treating ethyl camphocarboxylate in toluene solution with sodium and carbonic anhydride, and subsequently adding water, the ethereal salt is recovered unchanged, showing that ethyl sodiocamphocarboxylate does not react with carbonic anhydride, or that the compound, if any is formed, is decomposed by water.

Camphocarboxylic acid melts at 127—128°, with evolution of carbonic anhydride. The sodium salt forms a crystalline powder readily soluble in water or dilute alcohol, insoluble in acetone, ether, and carbon bisulphide. The *calcium salt*, $(C_{11}H_{15}O_3)_2Ca$, crystallises from water or alcohol in needles; the *potassium*, *lithium*, and *ammonium* salts resemble the sodium salt. The *ethyl* salt is prepared by dissolving the acid in absolute alcohol, and saturating the solution with hydrogen chloride; it is a colourless, viscid liquid, and boils at 166·8—167·8° under a pressure of 21 mm.; the yield is theoretical.

Sodium acts on ethyl camphocarboxylate, hydrogen being evolved, and on treating the product with ethyl chlorocarbonate, a pale-yellow, viscid liquid, with an odour of pine-apple, is produced; this, after purification, boils at 179·6—181·5° under a pressure of 20 mm. Its physical and chemical properties prove that it has the formula $C_8H_{14}<\begin{matrix}C\cdot COOEt\\ \|\\ CO\cdot COOEt\end{matrix}$ (see above). The author suggests that the "ethyl methylcamphocarboxylate," $C_8H_{14}<\begin{matrix}CMe\cdot COOEt\\ \|\\ CO\end{matrix}$, recently

prepared by Minguin, by the mutual action of ethyl camphocarboxylate, methyl iodide, and sodium methoxide, is in reality ethyl camphocarboxylate methyl ether, $C_6H_{14}<\begin{matrix}C\cdot COOEt\\ \|\\ CO\cdot Me\end{matrix}$.

Ethyl camphocarboxylate readily combines with phenylhydrazine when the two are heated together at 100°; the product, after being washed with light petroleum and crystallised from dilute alcohol, is deposited in colourless, slender needles which melt at 132°. It is readily soluble in benzene and chloroform, and the solutions turn red even in the dark; ferric chloride, ammonia, and soda produce a similar change. The substance has the formula $C_{17}H_{20}N_2O + H_2O$, and appears to be a *pyrazolone*, $C_8H_{14}<\begin{matrix}CH\cdot CO\\ |\quad |\\ C:N\cdot NPh\end{matrix}$; it loses 1 mol. H_2O when heated at 100°.

Menthodicarboxylic acid, $C_{10}H_{16}O(COOH)_2$, is prepared in a similar manner to camphocarboxylic acid by the action of carbonic anhydride on menthone (3 mols.) and sodium (4 atoms); the product is treated with ice, in order to decompose the sodium mentholcarbonate, $C_{10}H_{19}O\cdot COONa$, the menthol is extracted with ether, and the aqueous solution, after saturation with sodium chloride, is acidified, and again shaken with ether. On allowing the ethereal solution to evaporate spontaneously, the dicarboxylic acid is obtained in small, colourless prisms; it melts at 128·5° with evolution of carbonic anhydride. It is very unstable, readily dissolves in methyl alcohol and acetone, but only very sparingly in water, chloroform, benzene, or carbon bisulphide. The salts of the alkali metals are exceedingly unstable; the *silver salt* is sparingly soluble, and readily decomposes on exposure to light.

The author discusses the camphor formulæ proposed by Kekulé and by Bredt, and points out that according to the former of these, camphor contains an asymmetric carbon atom; this fact appears to have been generally overlooked, although clearly stated by Van't Hoff.

The formation of a dicarboxylic acid by menthone, and of a monocarboxylic acid by camphor, is probably owing to the presence of the group $—CH_2\cdot CO\cdot CHMe—$ in the former compound, whilst the carbonyl group of camphor is only linked to a CH_2 group; menthodicarboxylic acid is therefore represented by the formula

$$CHPr^{\beta}<\begin{matrix}CH_2—CH_2—CMe\cdot COOH\\ |\qquad\qquad |\\ CH(COOH)\cdot CO\end{matrix}.$$

Camphoric acid must be regarded as *α-methyl-δ-isopropyl-$\Delta^{\alpha\beta}$-hydromuconic acid*, $COOH\cdot CHPr^{\beta}\cdot CH_2\cdot CH:CMe\cdot COOH$, or as a *methyl-isopropyltetramethylenedicarboxylic acid*, $\begin{matrix}CH_2\cdot CPr^{\beta}\cdot COOH\\ |\qquad\qquad |\\ CH_2\cdot CMe\cdot COOH\end{matrix}$, according to whether camphor is represented as having an ethylene linking (Kekulé) or a para-linking. Camphoric acid, which melts at 187°, is not oxidised by potassium permanganate, and is unaffected when heated with anhydrous cupric sulphate under pressure; it is known to be equally stable towards reducing agents and halogen hydrides. The

author confirms Menschutkin's observations on the low etherification value of camphoric acid. Diethyl camphorate is not acted on by bromine at the ordinary temperature, but yields ethyl bromide and camphoric anhydride when heated at 120°. Camphoric anhydride, ethyl chloride, and acetic acid are formed by the action of acetic chloride on ethyl hydrogen camphorate at 100°. All these observations point to camphoric acid as being a tetramethylene derivative, whilst the ease with which it forms the anhydride also tells in favour of its being regarded as a tetra-substituted succinic acid. Further, the hydromuconic acid formula only indicates the existence of three optically isomeric camphoric acids; four, however, are known with certainty, and two others are said to have been isolated; the tetramethylene formula requires six isomerides, four optically active, and two inactive.

The author concludes that camphor can only be accurately represented by the diagonal formula; in other words, he considers that it is derived from a double tetramethylene ring, $\begin{matrix}CH_2\cdot CH\cdot CH_2\\ |\quad\quad |\quad\quad |\\ CH_2\cdot CH\cdot CH_2\end{matrix}$.

J. B. T.

German and Turkish Rose-oil. By U. Eckart (*Arch. Pharm.*, **229**, 355—389).—Rose-oil consists of ethyl alcohol, which is distilled off below 100° and constitutes 5 per cent. of the oil, the elæoptene, which constitutes practically the whole of the liquid portion of the oil, and the stearoptene, which is the solid portion. The two latter are separated by dissolving the oil in 75 per cent. alcohol at 70—80°, and cooling to 0°, when the stearoptene separates; the alcoholic solution is then evaporated in a vacuum to obtain the elæoptene.

The elæoptene, from both Turkish and German rose-oil, has a composition corresponding with the formula $C_{10}H_{18}O$. Its physical constants vary, according to its source, between the following limits:—Boiling point, 216—217°; refractive index, 1·4710—1·4725; refraction equivalent, 48·97—49·28; dispersion 11·1—12·5; specific rotation, −2·7 to −2·8. The vapour density corresponds with the molecular weight 142·43 ($C_{10}H_{18}O$ = 154). Evidence of Markovnikoff's compound $C_{10}H_{20}O$ (Abstr., 1891, 219) was not obtained.

The author proposes the name *rhodinol* for the compound $C_{10}H_{18}O$. The following derivatives of it are described:—The *sodium* derivative, not prepared perfectly pure; the *chloride*, $C_{10}H_{17}Cl$, a yellowish-brown liquid which does not distil without decomposition; the *iodide*, $C_{10}H_{17}I$, a brown liquid with an odour of turpentine; the *cyanide*, a yellow oil. The *ether*, $C_{20}H_{34}O$, was obtained by acting on rhodinol with carbanil, whereby a crystalline *carbanilide* melting at 235° was formed; this was subsequently decomposed by water, when the ether separated as a yellow liquid. The *benzoate*, $PhCOO\cdot C_{10}H_{17}$, is a pale-yellow neutral liquid; the *acetate*, $MeCOO\cdot C_{10}H_{17}$, and the *thio-alcohol*, $C_{10}H_{17}\cdot SH$, were also obtained.

By oxidising rhodinol with potassium dichromate and sulphuric acid, the corresponding *rhodinaldehyde*, $C_{10}H_{16}O$, and the *silver* salt of the *acid*, $C_{10}H_{16}O_2$, *rhodinolic acid*, were prepared. When alkaline permanganate was used as the oxidising agent, a pentahydric

alcohol, $C_6H_{14}O_5$, and the following acids were obtained :—Valeric, butyric, acetic, formic, oxalic, and carbonic. When hydrogen peroxide was used, a monobasic *acid*, $C_6H_{12}O_6$, was formed, of which the *barium* salt, $(C_6H_{11}O_2)_2Ba$, was analysed.

Strong dehydrating agents act on rhodinol to form a hydrocarbon of the limonene group, namely, dipentene, $C_{10}H_{16}$, and a polyterpene, $(C_5H_8)_n$.

The stearoptene is colourless and odourless; its quantity varies in rose-oil between 20 and 68 per cent., and its melting point between 33·5° and 36·5°.

The author regards rhodinol as an unsaturated monhydric primary alcohol with an open-chain structure. Its optical activity shows the presence of an asymmetrical carbon atom, and by applying Brühl's method to the refraction equivalent, it would appear to contain two ethylenic linkings; the author therefore attributes to it the formula $CH_2{:}CPr{\cdot}CH{:}CH{\cdot}CHPr{\cdot}CH_2{\cdot}OH$, which would also account for its easy conversion into closed-chain compounds (compare Semmler, Abstr., 1890, 951). A. G. B.

Natural Resins. By M. Bamberger (*Monatsh.*, **12**, 441—463).—The resin from *Pinus laricio* (Poir) dissolves in alcohol, ether, methyl alcohol, amyl alcohol, acetone, and acetic acid; is partly soluble in benzene, chloroform, and turpentine, and is insoluble in light petroleum. It melts at about 100°; has a yellow colour which, on exposure to light becomes red, gives the phloroglucinol reaction, and, on distillation in a vacuum, furnishes a viscid, brown mass. As determined by Schmidt and Erban's method (*Monatsh.*, **7**, 655), the specimens examined had an acid equivalent of 116·6 and an iodine number of 51·9. The methoxyl number obtained by Benedikt and Grüssner's process varied from 49·6 to 54·8.

On boiling with water for a long time, or on blowing steam through an alcoholic solution, and exhausting with ether, the ethereal solution obtained gave, on evaporation, a crystalline mass which had an iodine number of 60·4. This was dissolved in alcohol, and allowed to crystallise. The first separation consisted of caffeïc acid, the diacetyl derivative of which formed slender, white needles, melted at 189°, and agreed in properties with the compound obtained by Tiemann and Nagai (*Ber.*, **11**, 656), who, however, give a slightly higher melting point, namely, 190—191°. On reduction of the acid with sodium amalgam, hydrocaffeïc acid, $C_9H_{10}O_4$, identical in crystalline [$a : b : c$ form = 2·5604 : 1 : 1·9676, $\eta = 108°$] and optical properties with the acid obtained by Hlasiwetz (*Annalen*, **142**, 354), was formed. The second separation was recrystallised from chloroform and from hot water, and proved to be ferulic acid. The mother liquor was then evaporated to dryness, dissolved in ether, the solution shaken with bisulphite, and finally treated in the way recommended by Tiemann (*Ber.*, **8**, 115), whereby vanillin was obtained.

On heating the resin (500 grams) left after boiling with water, with potash (2 kilos.) in an iron dish, a mixture of catechol and protocatechuic acid was obtained. Of these substances, the former is

probably derived from the latter, and the latter from ferulic acid, by the action of potash.

The resin from *Picea vulgaris* (Link) melts at about 100°, and the samples examined had an acid equivalent of 125—127·7, an iodine number of 61·2, and a methoxyl number of 33—34·9. The resin was treated in the same way as that obtained from *Pinus laricio*, and gave an aqueous extract which contained paracoumaric (naringenic) acid and vanillin. The resin, after boiling with water, had an acid equivalent of 99 and a methoxyl number of 34·8; and gave, on fusion with potash, a mixture of protocatechuic and parahydroxybenzoic acids.

G. T. M.

Substances contained in the Petals of Gentiana verna. By G. Goldschmiedt and R. Jahoda (*Monatsh.*, **12**, 479—485).—On evaporation of an alcoholic extract of 1 kilo. of the air-dried petals of *Gentiana verna*, a dark-red, viscid mass, containing solid, greenish-yellow, resinous lumps, is obtained. Water dissolves a reddish-violet colouring matter, dextrose, levulose, and another substance from the product, and leaves the resinous lumps unchanged. The resin dissolves in alcohol, and after treatment with charcoal forms a colourless solution from which three compounds may be separated by fractional crystallisation. That formed in greatest quantity is an amorphous, granular, white powder which melts at 215—219°. Elementary analysis and a determination of its effect in lowering the freezing point of phenol show that it has the formula $C_{30}H_{48}O_3$. It is without action on hydroxylamine and phenylhydrazine, but forms a triacetyl derivative, $C_{30}H_{45}(OAc)_3$, which is readily soluble in cold alcohol and melts at 175—180°, and, consequently, contains three hydroxyl groups, and has been named *gentiol* by the authors. It is readily soluble in hot alcohol, dissolves sparingly in ether and benzene, is insoluble in potash, and, on oxidation with chromic acid in acetic acid solution, gives a crystalline acid which melts at 127°. The two other fractions are only obtained in small quantity; one is soluble in alcohol, ether, and benzene, crystallises in beautiful, white plates, melts at 115—117°, and has the formula $C_{38}H_{64}O_3$; the other is a yellowish powder, which melts at about 240°. G. T. M.

Rind of Garcinia Mangostana. By P. R. Liechti (*Arch. Pharm.*, **229**, 426—439).—The author fully describes his method of preparing mangostin from the rind of *Garcinia mangostana;* it does not materially differ from that adopted by Schmid (*Annalen*, **93**, 83; *J. Chem. Soc.*, 1856, 190).

Pure mangostin, $C_{20}H_{22}O_5$, crystallises in bright-yellow, slender laminæ, melts at 173° (uncorr.), not at 190° (Schmid, *loc. cit.*), and is tasteless and odourless; it dissolves with a yellow colour in alcohol, ether, chloroform, glacial acetic acid, carbon bisulphide, xylene, acetone, strong sulphuric acid, and alkalis; it is sparingly soluble in benzene and solution of tannin, but not at all in light petroleum. Solutions of mangostin give a greenish-black colour with ferric chloride. Alkaline solutions of it fluoresce greenish, dissolve ferric hydroxide with a deep red-brown colour, and give an orange preci-

pitate with alkaline potassium iodide. Gold, silver, and platinum are reduced from their solutions by mangostin.

Mangostin is oxidised by nitric acid to oxalic acid. When it is heated with potassium hydroxide and a little water until the melt has a clear brown colour, and the melt subsequently dissolved in water, acidified, and extracted with ether, a small quantity of acid, resembling valeric acid in its odour and in its zinc salt, is obtained; if the melt is more strongly heated, carbonic anhydride and oxalic acid are produced.

When mangostin is reduced in alcoholic solution with sodium amalgam, and the solution filtered and acidified, a brick-red, amorphous precipitate is obtained which dissolves in alcohol; the solution gives a briliiant, green fluorescence when mixed with a little alkali. The absorption spectrum of this fluorescent solution contains a strong band between E and *b*, and a feeble band at F. This reduction product has the same percentage composition as mangostin, and is called *isomangostin* by the author, who regards it as a polymeride. It melts with partial decomposition at 127° (uncorr.); its solutions in alcohol and in ether are yellowish-brown, and are not further coloured by ferric chloride, nor will they reduce ammoniacal silver solution.

Schmid (*loc. cit.*) found that gamboge yielded a substance closely resembling mangostin when oxidised by nitric acid. The author prepared pure gambodic acid from gamboge by dissolving in absolute alcohol, filtering, precipitating with water, washing, dissolving in dilute ammonia, and precipitating with hydrochloric acid; it melts at 92—96° (uncorr.). This preparation was oxidised with nitric acid, and the product analysed; but in its composition and properties it bore no resemblance to mangostin.

Mangostin gives a white, crystalline acetate with acetic anhydride and sodium acetate, which is being investigated.

Some remarks on the anatomy of the rind of *Garcinia mangostana* conclude this paper. A. G. B.

Nicotenylamidoxime. By L. Michaelis (*Ber.*, **24**, 3439—3446). —*Nicotenylamidoxime*, $C_5NH_4{\cdot}C(NH_2){:}N{\cdot}OH$, is prepared by digesting equivalent quantities of β-cyanopyridine, hydroxylamine hydrochloride, and sodium carbonate in concentrated aqueous solution for eight hours at 70° in a closed vessel. The mixture is evaporated to dryness, extracted with absolute alcohol, the alcohol distilled off, and the product crystallised from hot chloroform. It melts at 128° without decomposition, is easily soluble in water, alcohol, acetone, alkalis, and acids, sparingly so in ether, chloroform, and benzene, and insoluble in light petroleum. With ferric chloride, it gives a red coloration; with Fehling's solution, a dirty brownish-green precipitate. The *hydrochloride*, $C_6H_7N_3O,2HCl$, is prepared by leading dry hydrogen chloride into a dry ethereal solution of the amidoxime. It forms very deliquescent needles, melts at 171°, and is soluble in water and alcohol. The *platinochloride* obtained by adding platinic chloride to a concentrated solution of the hydrochloride, crystallises in yellow scales, and is soluble in water and alcohol. Stannic chloride and

mercuric chloride cause no precipitate when added to an aqueous solution of the hydrochloride. The *copper* salt is obtained by adding copper acetate to an aqueous solution of the ammonium salt, and is soluble in ammonia and hydrochloric acid, insoluble in water. The *silver* salt is white, and blackens in the air.

Acetylnicotenylamidoxime, $C_5NH_4{\cdot}C(NH_2){:}NOAc$, is formed with development of heat on mixing finely-powdered nicotenylamidoxime with acetic anhydride. When the reaction is ended, the product is neutralised with sodium carbonate, filtered, and purified by crystallisation from chloroform. It melts at 143°, and is easily soluble in benzene, alcohol, acetone, chloroform, and acids, less so in water, ether, and light petroleum.

Nicotenylazoximethenyl, $C_5NH_4{\cdot}C\begin{matrix}<\\>\end{matrix}\begin{matrix}NO\\N\end{matrix}CMe$, is obtained as a sublimate by cautiously heating the preceding compound between watch-glasses on the sand-bath. It melts at 109°, and is soluble in water, ether, alcohol, benzene, acetone, chloroform, and acids, insoluble in alkalis. The *hydrochloride* forms small, white needles, and is soluble in water and alcohol. The *platinochloride* is obtained in beautiful yellow needles on adding platinic chloride to a solution of the hydrochloride, and is sparingly soluble in water, insoluble in alcohol. Mercuric chloride gives a white precipitate when added to a concentrated solution of the hydrochloride. Stannic chloride gives no precipitate.

Benzoylnicotenylamidoxime, $C_5NH_4{\cdot}C(NH_2){:}NO{\cdot}Bz$, is prepared by adding the calculated quantity of benzoic chloride to nicotenylamidoxime dissolved in the calculated quantity of sodium hydroxide. The mixture is shaken as long as the odour of benzoic chloride can be detected, a few drops of ammonia added, and the compound collected, washed with water, and crystallised from alcohol. It forms colourless scales, melts at 190°, is easily soluble in benzene, alcohol, and chloroform, very sparingly in ether and water, and insoluble in light petroleum. It dissolves in acids, and is reprecipitated by alkalis.

Nicotenylazoximebenzenyl, $C_5NH_4{\cdot}C\begin{matrix}<\\>\end{matrix}\begin{matrix}NO\\N\end{matrix}CPh$, is obtained as a sublimate by heating the preceding compound between watch-glasses or by boiling it for a long time with water. It melts at 139°, and is soluble in ether, benzene, light petroleum, alcohol, acetone, chloroform, and acids, and insoluble in water and alkalis. The *hydrochloride* is unstable. With platinic chloride and mercuric chloride, it yields sparingly soluble double salts.

Nicotenylazoximepropenyl-ω-carbonic acid,

$$C_5NH_4{\cdot}C\begin{matrix}<\\>\end{matrix}\begin{matrix}NO\\N\end{matrix}C{\cdot}CH_2{\cdot}CH_2{\cdot}COOH,$$

is obtained by heating a mixture of molecular proportions of nicotenylamidoxime and succinic anhydride at 100° to quiet fusion. The cold mass is extracted with dilute soda, filtered, and the filtrate saturated with dilute hydrochloric acid. The compound is obtained as a voluminous precipitate, and is purified by crystallisation from hot

water. It melts at 178°, is soluble in water, acetone, alcohol, acids, and alkalis, sparingly so in ether, chloroform, and benzene, insoluble in light petroleum, and reacts acid to litmus. The *silver* salt forms stellate groups of needles, blackens on exposure to light, and is soluble in ammonia. The *copper* salt is green, and dissolves in ammonia to a blue solution.

Nicotenylphenyluramidoxime, $C_5NH_4{\cdot}C(:NOH){\cdot}NH{\cdot}CO{\cdot}NHPh$, is obtained by mixing finely-divided nicotenylamidoxime with the calculated quantity of carbanil. It crystallises from chloroform in slender needles, melts at 167°, is easily soluble in hot water, alcohol, and chloroform, less so in benzene, ether, and acetone, and insoluble in light petroleum, acids and alkalis.

Ethyl nicotenylamidoximecarbonate, $C_5NH_4{\cdot}C(NH_2):NO{\cdot}COOEt$, is formed together with nicotenylamidoxime hydrochloride by adding ethyl chlorocarbonate (2 mols.) drop by drop to a saturated solution of nicotenylamidoxime (3 mols.) in absolute ether. It is purified by dissolving in benzene and precipitating with petroleum, melts at 136° and is soluble in water, alcohol, benzene, chloroform, acetone, and acids, insoluble in ether and light petroleum.

Nicotenylazosulphimecarbanilide, $C_5NH_4{\cdot}C{<}\overset{NS}{\underset{N}{>}}C{\cdot}NHPh$, is obtained on gently warming a mixture of finely-powdered nicotenylamidoxime and phenylthiocarbimide. The reaction takes place suddenly with much frothing, and the product is purified by several crystallisations from hot benzene. Although the experimental conditions were varied, the author could not obtain a nicotenylthiouramidoxime, but always obtained the condensation product. Nicotenylazosulphimecarbanilide is also obtained on heating to boiling nicotenylamidoxime (1 mol.) and phenylthiocarbimide (2 mols.) dissolved in chloroform. It crystallises in white needles, melts at 241°, is insoluble in water, soluble in alcohol, benzene, and chloroform, less so in ether and acetone, and is dissolved by acids and reprecipitated by alkalis.

Nicotenylamidoxime benzyl ether, $C_5NH_4{\cdot}C(NH_2):NO{\cdot}CH_2Ph$, is obtained by gently heating equivalent quantities of nicotenylamidoxime, sodium ethoxide, alcohol, and benzyl chloride in a reflux apparatus. It crystallises from light petroleum in needles, melts at 80°, is soluble in ether, alcohol, benzene, chloroform, and petroleum, insoluble in water, and dissolves in acids, but not in alkalis. E. C. R.

α-Pyridone (α-Hydroxypyridine). By H. v. Pechmann and O. Baltzer (*Ber.*, **24**, 3144—3153).—To prepare α-pyridone (α-hydroxypyridine), malic acid (500 grams) is converted into cumalic acid by heating it with sulphuric acid, and thence into the methyl salt; this is dissolved in ammonia, and boiled with sodium hydroxide, and on then adding hydrochloric acid, hydroxynicotinic acid is precipitated, which is dried and heated above its melting point until the evolution of carbonic anhydride slackens, when the temperature is raised and α-pyridone passes over. It melts at 107°, boils at 280—281°; the aqueous solution has a neutral reaction; the colour produced by ferric chloride is quite distinct from that obtained with phenol, and the observation that both the ethyl derivatives (see below) give the same

colour stands in harmony with this difference; it does not give Liebermann's phenyl reaction, and does not, under any circumstances, reduce permanganate solution instantaneously; when mercuric chloride is added to a concentrated solution, the *mercurochloride* separates, and this on crystallisation from water or dilute alcohol, forms long, colourless needles, and melts at 191—192°.

Ethyl-α-pyridone is obtained in theoretical yield by heating α-pyridone with an excess of ethyl iodide for five hours at 180°, adding hydrochloric acid, evaporating on the water-bath, redissolving in a little water, precipitating with an excess of potassium carbonate, extracting with chloroform, and rectifying. It is a colourless, almost odourless oil of strong basic properties, boils at 246—248°, is very sparingly volatile with steam, is miscible with water, and when heated at 290° in a sealed tube, undergoes partial decomposition, the residue being the unaltered compound; it behaves towards permanganate in a manner similar to α-pyridone; the *mercurochloride* crystallises from water or dilute alcohol in prisms, and melts at 112—113°; the *hydrochloride* is completely volatilised by protracted heating at the temperature of the water-bath; the *platinochloride* forms yellow needles, sinters at 98°, and melts at 105—108°. When ethyl-α-pyridone is heated in a reflux apparatus with an excess of 4 per cent. sodium amalgam, ethylamine is produced; the authors, therefore, believe it to have the constitution $CH\ll^{CH\cdot CO}_{CH:CH}\gg NEt$.

α-Ethoxypyridine is formed by shaking silver α-pyridone (prepared by adding the calculated quantity of silver nitrate to α-pyridone dissolved in the equivalent quantity of dilute soda) with ether and ethyl iodide at the ordinary temperature, until the precipitate has the colour of silver iodide, filtering, washing the precipitate with alcoholic hydrochloric acid, distilling off the alcohol and ether, mixing the residue with a little water, and precipitating the base with potassium carbonate; the yield is equal to the α-pyridone employed. It is a colourless oil, having a strong odour of pyridine and more feeble basic properties than its isomeride; it boils at 155—156°, is volatile with steam, and is much more stable than its isomeride, remaining unchanged when heated in a sealed tube at 230°, and being only very slowly attacked at the ordinary temperature by permanganate; the *mercurochloride* melts at 141—142°. When heated in dilute alcoholic solution with sodium amalgam, ammonia is evolved; it, therefore, probably has the constitution $CH\ll^{CH\cdot C(OEt)}_{CH=\!=CH}\gg N$.

Methyl-α-pyridone, C_5NH_4MeO, is a colourless, almost odourless liquid boiling at 240°; the *mercurochloride* melts at 127°.

α-Methoxypyridine, $C_5NH_4\cdot OMe$, closely resembles the ethyl derivative; the mercurochloride melts at 199—200°.

α-Chloropyridine [Cl = 2] is obtained by moistening α-pyridone with phosphorus oxychloride, mixing with 2½ times the quantity of phosphorus pentachloride, and heating the mixture for 3—4 hours in an oil-bath at 130°, adding water, and after rendering alkaline, driving over the new base with steam; it is a colourless oil having a pyridine-like odour, boils at 166° (714 mm.), and is insoluble in

water; the *platinochloride* crystallises in the monosymmetric system, $a : b : c = 1{\cdot}4348 : 1 : 2{\cdot}0380$; $\beta = 73^{\circ}\ 21{\cdot}4'$; observed forms ∞P, $-P\infty$, $0P$.

The concluding portion of the paper is devoted to a discussion on the constitution of pyridine by v. Pechmann, who considers that the general behaviour of pyridine, including the tautomerism of its hydroxy-derivatives (see also Haitinger and Lieben, Abstr., 1885, 966), is best explained by assigning to it a centric formula as suggested by Bamberger. A. R. L.

Piperazine. By A. Schmidt and G. Wichmann (*Ber.*, **24**, 3237—3248).—Majert and Schmidt (Abstr., 1891, 538) have already stated that piperazine passes unchanged through the human organism. The authors find that with a single dose of 3 grams the base can be detected in the urine even after 6 days, and although the chief portion is voided after a few hours, a certain amount remains in the blood for a long period. To detect piperazine in urine, the latter is rendered free from phosphates of the earth-metals by the addition of a few drops of sodium hydroxide solution, reacidified with hydrochloric acid, heated to 40°, and filtered after the addition of a solution of potassium bismuthoiodide, when crystals of the form already described (*loc. cit.*) separate from the filtrate after a time. In the detection of minute quantities of the base, the urine is evaporated, the residue being distilled with solid alkali and sand, and the distillate examined as above. Piperazine undergoes no change when directly injected into the blood, for example; by injecting 0·3 gram into the blood of a rabbit, the chief portion was found in the urine after 2 hours, but the presence of the base could still be detected at the end of $1\frac{1}{2}$ days.

When dry piperazine (1 gram) is heated for 14 hours at 270° with bromobenzene (11 grams), the product filtered from bromide, and distilled until the thermometer registers a temperature of 170°, alcohol extracts diphenylpiperazine (m. p. 160°) from the residue. Piperazine (8 grams) and bromobenzene (3 grams) heated in a similar manner give the same compound together with an oily substance, probably monophenylpiperazine.

Paranitrophenylpiperazine, $NO_2{\cdot}C_6H_4{\cdot}C_4H_9N_2$, is obtained when piperazine (8 grams) is heated with parachloronitrobenzene (3 grams) at 150° for 4 hours; the melt is triturated with dilute alkali, and the residue extracted with hydrochloric acid, when a small quantity of dinitro-derivative (see below) remains undissolved, together with chloronitrobenzene; the filtrate is freed from chloronitrobenzene by agitating it with ether, alkali added, and the precipitate which forms is dissolved in benzene; the pure compound separates from this solution on adding light petroleum; it melts at 129°, and is readily soluble in alcohol, chloroform, and benzene, but only very sparingly in water, ether, and light petroleum; the *hydrochloride* forms yellowish-red, lustrous prisms. *Paradinitrodiphenylpiperazine*,

$$C_4H_8N_2(C_6H_4{\cdot}NO_2)_2,$$

is almost exclusively formed when the previously mentioned re-

agents are heated together, in molecular proportion, for 3 hours at 150°; the product, after washing with water, is treated with boiling alcohol, when the dinitro-compound remains; it is very sparingly soluble in all solvents and melts at 248° with decomposition. *Diacetylpiperazine*, $C_4H_8N_2Ac_2$, is prepared by heating piperazine acetate with an excess of acetic anhydride in a reflux apparatus, distilling off to 300°, rectifying the residue in a vacuum, and crystallising the solidified distillate from benzene, when the compound separates in compact needles; it melts at 138·5°, boils with slight decomposition at 310°, and is readily soluble in water and alcohol. *Ethyl piperazyloxamate*, $C_4H_8N_2(CO{\cdot}COOEt)_2$, is formed when piperazine is heated at 100° for a short time with an excess of ethyl oxalate; it crystallises from water in needles, melts at 124°, and is readily soluble in solvents.

The *compound* $C_4H_{10}N_2,2PhOH$, which separates on mixing an alcoholic solution of piperazine with an ethereal solution of phenol in molecular proportion, crystallises from alcohol in large, lustrous prisms, melts at 99—101°, and develops the odour of phenol on keeping; whilst the *compound*, $C_4H_{10}N_2,C_6H_6O_2$, melting at 195°, with decomposition, separates in compact needles on mixing alcoholic solutions of piperazine and quinol.

The *benzylidene derivative*, $C_4H_8N_2{\cdot}CHPh$, produced by mixing piperazine with benzaldedyde, heating on the water-bath, and treating with boiling alcohol, is a white, amorphous substance almost insoluble in all solvents, and melts at 246—247°; whilst the compound $C_4H_{10}N_2CS_2$ separates as a greenish-white powder, on mixing alcoholic solutions of piperazine and carbon bisulphide; it decomposes at 260°.

Diazobenzenepiperazine, $C_4H_8N_2(N_2Ph)_2$, prepared by adding piperazine to an alkaline solution of diazobenzene, melts at 129°; a compound is also obtained with quinone.

Dichloropiperazine, $C_4H_8N_2Cl_2$, is best prepared by adding an aqueous solution of piperazine to one of freshly prepared sodium hypochlorite, collecting the precipitate and crystallising it from alcoholic ether; it has a sharp, tear-exciting odour, melts at 71°, detonates at 80—85°, is sparingly soluble in water, but is converted into piperazine hydrochloride by it, only slightly soluble in ether, and readily in alcohol. No analogous compound is formed by the action of sodium hypobromite, although the addition of bromine water to an aqueous solution of piperazine seems to produce it.

Dinitrosopiperazine (Ladenburg, Abstr., 1891, 1333) decomposes when distilled, and, on reduction with zinc and acetic acid, yields the *dihydrazine*, $C_4H_8N_2(NH_2)_2$, crystallising from alcoholic either in stout needles, melting at 100°, and boiling at 228°; the latter reduces Fehling's solution and ammoniacal silver solution on boiling; the *dibenzoyl derivative*, $C_4H_8N_2(NHBz)_2$, prepared by adding the calculated quantity of benzoic chloride dissolved in chloroform to a solution of the hydrazine in the same solvent, is a white, amorphous substance which does not melt at 310°, and is insoluble in solvents; whilst the *dibenzylidene derivative*, $C_4H_8N_2(N{\cdot}CHPh)_2$, obtained by adding benzaldehyde to a solution of the hydrazine in sodium acetate solution, melts at 205°, and is insoluble in water.

Dimethylpiperazine (Ladenburg, *loc. cit.*) boils at 153—158°, and does not solidify when cooled to −15°; the hydrochloride melts at 247—250° with decomposition. *Diethylpiperazine*, $C_4H_8N_2Et_2$, boils at 165°, and does not solidify at −15°; the *hydrochloride* crystallises from dilute alcohol in small, white needles, melts at 277° with decomposition; the *platinochloride* forms small, yellow plates.

A. R. L.

Quinolinehydrazines. By E. Böttiger (*Ber.*, **24**, 3276—3277).—A claim for priority. Dufton's researches on orthoquinolinehydrazine (Trans., 1891, 752) were not published until October, whereas the author had already, in August, applied for a patent concerning a method of preparation of quinolinehydrazines. He thinks he has at least an equal right with Dufton to be regarded as the discoverer of these compounds.

C. F. B.

μ-Phenylpentoxazoline. By S. Gabriel and P. Elfeldt (*Ber.*, **24**, 3213—3218).—The benzoyl derivative of γ-bromopropylamine, like the benzoyl derivatives of β-bromethylamine and β-bromopropylamine (Abstr., 1890, 1267), readily loses hydrogen bromide, forming a meso-substituted pentoxazoline,

$$CH_2<\begin{matrix}CH_2\cdot O\\CH_2\cdot N\end{matrix}>CPh,$$

which contains the same nucleus as trimethylenepseudocarbamide (Abstr., 1890, 472). The γ-bromopropylamine required was prepared according to Gabriel and Weiner's method (Abstr., 1888, 1292), and was freed from admixed trimethylenediamine hydrobromide by solution in absolute alcohol. The crude compound obtained on evaporating the solution was dissolved in water and treated with 2 mols. of sodium carbonate and 1 mol. of benzoic chloride; *γ-bromopropylbenzamide*, $CH_2Br\cdot CH_2\cdot CH_2\cdot NH\cdot COPh$, then separates as a white, crystalline compound, which is purified by triturating with dilute soda and recrystallising from benzene. It forms white, fascicular groups of needles melting at 62°. The crystals deliquesce in the course of a few weeks, and pass into the hydrobromide of *μ-phenylpentoxazoline*, $CH_2<\begin{matrix}CH_2\cdot O\\CH_2\cdot N\end{matrix}>CPh$; the free base separates on the addition of soda. It may be more quickly prepared by dissolving the benzamide in hot water, adding alkali, distilling in a current of steam, and extracting the distillate with ether. On evaporating the latter, the μ-phenylpentoxazoline remains as a yellowish oil, having a peculiar odour and pungent taste; it is sparingly soluble in cold, more readily in hot, water, and cannot be distilled under atmospheric pressure without decomposition. The *picrate*,

$$C_{19}H_{11}NO,C_6H_3N_3O_7,$$

forms yellow needles and melts at 151°; the *platinochloride*, orange-yellow, flat needles melting with decomposition at 185°; the *dichromate*, orange needles; and the *ferrocyanide*, a yellowish-green, crystalline precipitate.

Towards hot mineral acids the base behaves in a manner similar to the oxazoline bases previously described; with an excess of hydrobromic acid, it is reconverted into γ-bromopropylbenzamide, and with an excess of hydrochloric acid into *γ-chloropropylbenzamide*,

$$CH_2Cl\cdot CH_2\cdot CH_2\cdot NH\cdot COPh,$$

which crystallises from light petroleum in delicate needles, melts at 56—57°, and is much more stable than the bromine derivative. If, however, the base be boiled with an equivalent quantity of aqueous hydrobromic acid until the solution no longer forms a sparingly soluble dichromate, it is converted into the *hydrobromide* of *γ-amidopropyl benzoate*, $NH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot OBz$, which separates from acetic acid, on the addition of ethyl acetate, as a white, crystalline powder, melts at 134—135°, is readily soluble in water, and sparingly in light petroleum. The free *γ-amidopropyl benzoate* is a colourless oil easily soluble in water; its *picrate*, $C_{10}H_{13}NO_2,C_6H_3N_3O_7$, crystallises in yellow needles, and melts at 177—178°, and the *platinochloride*, $(C_{10}H_{13}NO_2)_2,H_2PtCl_6$, in yellowish-red needles melting with decomposition at 204—205°.

Corresponding with pentoxazoline is the compound pentathiazoline; this has not yet been prepared, but some of its derivatives are already known, namely, μ-mercaptopenthiazoline, $C_3H_6{<}\overset{S}{\underset{N}{>}}C\cdot SH$, and trimethylenepseudothiocarbamide (Abstr., 1890, 524). Other derivatives have been obtained by the action of trimethylene bromide on thioamides, and will shortly be described. H. G. C.

Oxazolines and Pentoxazolines. By P. Elfeldt (*Ber.*, **24**, 3218—3228).—In continuation of the work described in the previous abstract, the author has examined other derivatives of bromethylamine and bromopropylamine, and finds that these, like the acetyl and benzoyl compounds, readily yield oxazolines and pentoxazolines.

Metanitrobenzoic chloride acts on β-bromethylamine in presence of sodium carbonate, forming *β-bromethylmetanitrobenzamide*,

$$CH_2Br\cdot CH_2\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2,$$

which crystallises in needles melting at 116—117°, and is almost insoluble in cold water. It is converted by the calculated quantity of alcoholic potash into *μ-metanitrophenyloxazoline*,

$$\begin{matrix}CH_2\cdot O\\ |\\ CH_2\cdot N\end{matrix}{>}C\cdot C_6H_4\cdot NO_2,$$

which crystallises from water or dilute alcohol in long, narrow, rectangular plates melting at 118·5—119·5°. Of its salts, the *picrate*, $C_9H_8N_2O_3,C_6H_3N_3O_7$, melts at 145—146°, and the *platinochloride*, $(C_9H_8N_2O_3)_2,H_2PtCl_6$, at 195°; the *dichromate* forms a yellowish-red emulsion, and the *ferrocyanide* a yellowish-green, crystalline precipitate.

β-Bromopropylamine hydrobromide (which, after recrystallisation from acetic acid, melts at 156°) is readily acted on by metanitrobenzoic chloride and alkali, with formation of *β-bromopropylmetanitrobenz-*

amide, $CHMeBr{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}C_6H_4{\cdot}NO_2$, which crystallises from benzene in small needles melting at 84—85°, and is converted by alcoholic potash into *β-methyl-μ-metanitrophenyloxazoline*,

$$\begin{matrix} CHMe{\cdot}O \\ | \\ CH_2-N \end{matrix}\!\!>C{\cdot}C_6H_4{\cdot}NO_2.$$

This crystallises from water or dilute alcohol in long, silvery plates, melts at 85—86°, and is only slightly volatile in a current of steam; its *picrate*, $C_{10}H_{10}N_2O_3,C_6H_3N_3O_7$, crystallises in yellow needles, and melts at 152—153°, and the *platinochloride*, $(C_{10}H_{10}N_2O_3)_2,H_2PtCl_6$, forms flat, yellowish-red, quadratic crystals melting at 195—196° with decomposition.

γ-Bromopropylaminenitrobenzamide is obtained in a manner similar to the *β*-compound, and crystallises from benzene or chloroform in needles melting at 89—90°; by the action of alcoholic potash, it yields *μ-metanitrophenylpentoxazoline*, $CH_2<\begin{matrix} CH_2{\cdot}O \\ CH_2{\cdot}N \end{matrix}\!\!>C{\cdot}C_6H_4{\cdot}NO_2$, which separates from dilute alcohol or ether in long, silvery plates melting at 93—94°. The *picrate*, $C_{10}H_{10}N_2O_3,C_6H_3N_3O_7$, crystallises in tufts of needles, and melts at 123—124°, previously becoming plastic, and the *platinochloride*, $(C_{10}H_{10}N_2O_3),H_2PtCl_6$, forms an orange-red, crystalline powder which melts with decomposition at 196°.

β-Bromethylphenylacetamide, $C_2H_4Br{\cdot}NH{\cdot}CO{\cdot}CH_2Ph$, obtained from phenylacetic chloride and *β*-bromethylamine hydrobromide, crystallises from benzene in small, jagged plates, and melts at 84—85°. When treated with aqueous soda and distilled in a current of steam, it yields *μ-benzyloxazoline*, $\begin{matrix} CH_2{\cdot}O \\ | \\ CH_2{\cdot}N \end{matrix}\!\!>C{\cdot}CH_2Ph$, which may be extracted from the distillate with ether, and remains, on evaporating the solvent, as an oil having a feeble, penetrating odour. The *picrate*, $C_{10}H_{11}NO,C_6H_3N_3O_7$, melts at 130—131°. The larger quantity of the phenylacetamide is, however, converted into *amidoethyl phenylacetate hydrobromide*, $NH_2{\cdot}C_2H_4{\cdot}O{\cdot}CO{\cdot}CH_2Ph,HBr$, which is isolated by evaporating the solution of the amide to dryness, extracting the residue with water, and slowly evaporating the solution. The residue probably contains hydroxyethylamine hydrobromide, and is therefore treated with picric acid, which does not precipitate the latter, but yields the *picrate* of amidoethyl phenylacetate in small plates melting at 137—138°.

Phenylacetic chloride reacts with *β*-bromopropylamine much less readily than with the corresponding ethyl derivative; the *β-bromopropyl phenylacetamide*, $CHMeBr{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}CH_2Ph$, crystallises from light petroleum in delicate needles, melts at 45—46°, and when kept rapidly forms a syrup, which is partially soluble in water. The solution gives precipitates with picric acid and platinum chloride, the former having the composition $C_{11}H_{13}NO,C_6H_3N_3O_7$; the solution, therefore, in all probability contains *β-methyl-μ-benzyloxazoline*, $\begin{matrix} CHMe{\cdot}O \\ | \\ CH_2-N \end{matrix}\!\!>C{\cdot}CH_2Ph.$

γ-Bromopropylphenylacetamide, $C_3H_6Br{\cdot}NH{\cdot}CO{\cdot}CH_2Ph$, separates from light petroleum in tufts of slender needles, melts at 43—44°, and decomposes if kept, or by the action of alkalis, forming *μ-benzylpentoxazoline*, $CH_2<\begin{matrix}CH_2{\cdot}O\\CH_2{\cdot}N\end{matrix}>C{\cdot}CH_2Ph$, which is an oil having a pungent taste, but no odour in the cold. The *picrate*,

$$C_{11}H_{13}NO,C_6H_3N_3O_7,$$

crystallises well, and melts at 139—140°, whilst the *platinochloride* forms an orange-yellow, crystalline powder.

β-Bromethylcinnamylamide, $C_2H_4Br{\cdot}NH{\cdot}CO{\cdot}CH{:}CHPh$, obtained from cinnamic chloride and β-bromethylamine hydrobromide, crystallises from light petroleum in white plates melting at 90—91°. Alcoholic potash converts it into *μ-cinnamenyloxazoline*,

$$\begin{matrix}CH_2{\cdot}O\\|\\CH_2{\cdot}N\end{matrix}>C{\cdot}CH{:}CHPh,$$

which crystallises from light petroleum in transparent prisms containing light petroleum; this is evolved on exposure to the air or over sulphuric acid, and the substance then melts at 52—53°, becoming plastic at 48°. The *picrate*, $C_{11}H_{11}NO,C_6H_3N_3O_7$, forms yellow needles melting at 188—189°, and the *platinochloride*,

$$(C_{11}H_{11}NO)_2,H_2PtCl_6,$$

an orange-yellow, crystalline powder melting with decomposition at 193—194°.

β-Bromopropylcinnamylamide, $CHMeBr{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}CH{:}CHPh$, crystallises from benzene or light petroleum in white plates melting at 79—80°. The *β-methyl-μ-cinnamenyloxazoline*,

$$\begin{matrix}CHMe{\cdot}O\\|\\CH_2{-}N\end{matrix}>C{\cdot}CH{:}CHPh,$$

obtained from it, separates from light petroleum in crystals containing light petroleum, which is given off on exposure to the air, the compound then melting at 80—81°. The *picrate*, $C_{12}H_{13}NO,C_6H_3N_3O_7$, crystallises in delicate needles, and melts at 182—183°, and the *platinochloride*, $(C_{12}H_{13}NO)_2,H_2PtCl_6$, melts with frothing at 197—198°.

γ-Bromopropylcinnamylamide, $CH_2Br{\cdot}[CH_2]_2{\cdot}NH{\cdot}CO{\cdot}CH{:}CHPh$, forms hexagonal plates, melts at 74°, and is converted by alkalis into *μ-cinnamenylpentoxazoline*, $CH_2<\begin{matrix}CH_2{\cdot}O\\CH_2{\cdot}N\end{matrix}>C{\cdot}CH{:}CHPh$, which also contains light petroleum and melts, after removal of the latter, at 55—56°. The *picrate*, $C_{12}H_{13}NO,C_6H_3N_3O_7$, melts at 196°, and the *platinochloride*, $(C_{12}H_{13}NO)_2,H_2PtCl_6$, at 192—193° with decomposition. H. G. C.

Thiazole Compounds. By P. Spica and G. Carrara (*Gazzetta*, **21**, 421—432).—The authors have prepared the following compounds by Wöhler's method :—

Unsymmetrical dimethylthiocarbamide, $NH_2 \cdot CS \cdot NMe_2$, is obtained in colourless, hard, deliquescent crystals melting at 81—82°, and is very soluble in water and absolute alcohol.

Unsymmetrical diethylthiocarbamide, $NH_2 \cdot CS \cdot NEt_2$, is a colourless, deliquescent substance, which crystallises with difficulty, is soluble in water and absolute alcohol, and melts at 169—170°.

Unsymmetrical diisoamlythiocarbamide, $NH_2 \cdot CS \cdot N(C_5H_{11})_2$, is obtained in colourless scales, moderately soluble in water, easily soluble in absolute alcohol, and melts at 208—209°. It is very like camphor in appearance and in its behaviour when floating on water.

Unsymmetrical diisoamylselenocarbamide, $NH_2 \cdot CSe \cdot N(C_5H_{11})_2$, is obtained by the action of potassium selenocyanate on diisoamylamine in colourless scales melting without decomposition at 171—172°. By exposure to light or by heating, it turns first red and then green. It crystallises with 2 mols. H_2O, which it retains in a vacuum over sulphuric acid, but loses on heating at 100° in a current of air.

On condensation with halogen derivatives of ketones, the unsymmetrical bi-substituted thiocarbamides should behave analogously to the symmetrical derivatives, and yield thiazole derivatives of the constitution $\begin{matrix} S \cdot NR'_2 \\ | \\ CH:CR \end{matrix} \!\!> N$.

The authors endeavoured unsuccessfully to prepare these compounds by the use of chloracetone and bromacetophenone in the following cases:—

A mixture of unsymmetrical dimethylthiocarbamide with chloracetone in molecular proportion was heated on a water-bath until no further odour of chloracetone was observed. The residue was taken up with water, made alkaline with caustic soda, and the solution extracted with ether. The ethereal extract contains dimethylamine and an unknown base, the platinochloride of which contains 40·02 per cent. of platinum; the mother liquor, after complete extraction with ether, yields a yellowish precipitate when acidified with hydrochloric acid. This is partly soluble in alcohol and chloroform, sparingly in light petroleum, and sparingly and partially soluble in water; it contains sulphur but no chlorine, melts partially at about 90°, and decomposes above 100°; it is probably impure α-methylhydroxythiazole, but the quantity obtained was too small for purification and analysis.

The solution in absolute alcohol of equivalent quantities of unsymmetrical dimethylthiocarbamide and bromacetophenone is evaporated to dryness on the water-bath, the residue dissolved in absolute alcohol, and fractionally crystallised. On recrystallisation from dilute alcohol, long needles melting at 71—72°, and agreeing in properties with rhodanacetophenone, first separate; the mother liquor contains a deliquescent substance agreeing in properties with dimethylamine hydrobromide. When unsymmetrical diisoamylthiocarbamide and bromacetophenone are treated in the same manner, the substance melting at 71—72°, and a white, crystalline product, which seems to be diisoamylamine hydrobromide, are obtained. When the alcoholic solution of dibenzilethiocarbamide and chloracetone is treated in the manner indicated above, a product is obtained which, on solution in

alcohol and precipitation with light petroleum, yields dibenzylamine hydrochloride; the mother liquors contain a yellow substance, soluble in water and caustic alkalis, sparingly soluble in ether, insoluble in acids or ammonium carbonate solution, and melting at 96°. No analyses were made, but the substance is supposed to be methylhydroxythiazole. Similar results are obtained on heating unsymmetrical dibenzilethiocarbamide with chloracetone on the water-bath without any solvent, treating with caustic soda, and extracting with ether, as before indicated. Symmetrical diphenylthiocarbamide and chloracetone, treated in the same manner, yield the base melting at 138°, prepared by Taumann. Unsymmetrical dibenzilethiocarbamide and bromacetophenone, when heated together, give benzilamine hydrobromide and the substance melting at 71—72°. To show that this compound is really rhodanacetophenone, it was converted into carbaminethioacetophenone by boiling for a short time with strong hydrochloric acid; on prolonged ebullition, α-phenyl-μ-hydroxythiazole was obtained.

The general reaction between unsymmetrical bi-substituted thiocarbamides and halogen derivatives of ketones, is best represented by the following equation:—

$$R{\cdot}CO{\cdot}CH_2Cl + S{:}C(NH_2){\cdot}NR'_2 = N{:}C{\cdot}S{\cdot}CH_2{\cdot}R{\cdot}CO + NHR'_2{\cdot}HCl.$$

W. J. P.

Quinazolines. By S. Gabriel and R. Jansen (*Ber.*, **24**, 3091—3098; compare Abstr., 1890, 1442).—Orthamidobenzylacetamide, $NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH{\cdot}COMe$ [1 : 2], when distilled, yields a substance which must be β-methyldihydroquinazoline, $C_6H_4{<}\begin{matrix}CH_2{\cdot}NH\\ |\\ N{=}CMe\end{matrix}$, for when methylated it yields the same $\beta\gamma$-dimethyldihydroquinazoline, $C_6H_4{<}\begin{matrix}CH_2{\cdot}NMe\\ |\\ N{=}CMe\end{matrix}$, which is obtained by distilling orthamidobenzylacetomethylamide, $NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NMe{\cdot}COMe$. Hence, by analogy, the substance formed when orthonitrobenzylformamide,

$$NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NH{\cdot}COH,$$

is reduced with zinc and hydrochloric acid must be dihydroquinazoline, $C_6H_4{<}\begin{matrix}CH_2{\cdot}NH\\ |\\ N{=}CH\end{matrix}{\cdot}$

Orthonitrobenzylamine is best prepared by mixing orthonitrobenzyl chloride (24·5 grams) with potassium phthalimide (25·5 grams) in benzyl cyanide (35 c.c.), heating the whole on a water-bath until all the water is expelled, and finally keeping it for half an hour at 180°. The cyanide is then driven over with steam, and the residue purified by boiling with a little alcohol. Nitrobenzylphthalimide (31 grams = 75 per cent. of the theoretical yield) is left behind; it yields orthonitrobenzylamine when heated (15 grams) with hydrochloric acid of sp. gr. 1·19 (60 c.c.) for three hours at 185—190°. The hydrochloride is obtained by separating the phthalic acid and concentrating the filtrate. The *picrate*, $C_7H_8N_2O_2,C_6H_3N_3O_7$, forms sparingly soluble, yellow needles, and melts at 206—208°. *Ortho-*

nitrobenzylcarbamide, $NH_2{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}C_6H_4{\cdot}NO_2$, is obtained in needles melting at 150°, by concentrating an aqueous solution of potassium cyanate and orthonitrobenzylamine hydrochloride.

When orthonitrobenzyl chloride (10 grams) is allowed to remain in a closed flask with 10 per cent. alcoholic ammonia (100 c.c.) for 10 days at the ordinary temperature, crystals of *diorthonitrobenzylamine*, $NH(CH_2{\cdot}C_6H_4{\cdot}NO_2)_2$ (5·5 grams), are deposited. These can be crystallised from hot alcohol; they melt at 99—100°. The *hydrochloride*, $C_{14}H_{13}N_3O_4{\cdot}HCl$, melts above 220°, becoming charred. The *platinochloride*, $(C_{14}H_{13}N_3O_4)_2,H_2PtCl_6$, forms small, yellow needles, very sparingly soluble in water. The *nitrosamine*, $(NO_2{\cdot}C_6H_4{\cdot}CH_2)_2N{\cdot}NO$, is obtained in lustrous needles melting at 120°, when nitrous acid is added to an acetic acid solution of the base. The mother liquor from the diamine, on concentration, leaves a residue (4 grams), from which nitrobenzylamine hydrochloride (2 grams) can be obtained by extracting with alcohol a concentrated, filtered, aqueous solution of the residue.

When orthonitrobenzyl chloride (15 grams) is dissolved in alcohol (150 c.c.) and warmed for one hour in a stoppered flask in the water-bath with 33 per cent. aqueous methylamine (45 c.c.), and the residue left after evaporation of the alcohol is treated with water, it yields *diorthonitrobenzylmethylamine*, $NMe(CH_2{\cdot}C_6H_4{\cdot}NO_2)_2$, as an insoluble oil, which crystallises after a time; when recrystallised from methyl alcohol, it forms yellowish prisms melting at 62—64°. The aqueous solution is concentrated to a small bulk, treated with 33 per cent. aqueous potash, and extracted with ether. The brownish oil obtained on evaporating the ether is mixed with hydrochloric acid, and the solution evaporated. The *orthonitrobenzylmethylamine hydrochloride*, $NO_2{\cdot}C_6H_4{\cdot}NHMe,HCl$ (9·5 grams), thus obtained, crystallises from 95 per cent. alcohol in tables, and melts at 175—176·5°. When this salt (6 grams) is boiled for a quarter of an hour in a reflux apparatus with dry sodium acetate (3 grams) and acetic anhydride (12 c.c.), the mixture concentrated and treated with water, *orthonitrobenzylacetomethylamide*, $NO_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NMe{\cdot}COMe$, separates as an oil, which finally crystallises; from light petroleum, it can be obtained in small, lustrous, white crystals melting at 57—58°. This substance, finely powdered (1 gram), is mixed with water (15 c.c.) and concentrated hydrochloric acid, and treated with zinc. After remaining for a time, the clear solution is poured off, and treated with excess of aqueous soda; the *orthamidobenzylacetomethylamide*,

$$NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}NMe{\cdot}COMe,$$

is extracted with ether, and recrystallised from this solvent; it forms a fine powder melting at 94—95°. This was heated gently in a small distillation-flask until no more water was expelled, *βγ-dimethyldihydroquinazoline*, $C_6H_4<\begin{matrix}CH_2{\cdot}NMe\\ N=CMe\end{matrix}$, then distils over at 300—305° as a pale-yellow oil which solidifies on cooling. It crystallises from ether in small, white needles, softens at 70°, and melts at 75—77°. Its solution in water is alkaline, and has a bitter taste. It dissolves also in hydrochloric acid, and the solution forms double salts with platinum

chloride, potassium dichromate, and picric acid. The *picrate* softens at 210°, and melts at 215—217°.

β-Methyldihydroquinazoline unites with methyl iodide, forming colourless crystals of the methiodide. When these are dissolved in water, and the solution treated with potash, a yellow oil separates, which has all the properties of $\beta\gamma$-dimethylhydroquinazoline, described above.

Dihydroquinazoline, $C_6H_4<\begin{matrix}CH_2\cdot NH\\ |\\ N=CH\end{matrix}$, has now been obtained crystalline. From benzene it separates in small, yellowish crystals which soften at 115°, and melt at 127°. The *hydrochloride*, $C_8H_8N_2,HCl$, crystallises from alcohol. C. F. B.

Choline. By E. Schmidt (*Arch. Pharm.*, **229**, 467—486).—Choline platinochloride melts at 232—233° when heated in a narrow capillary tube, but generally at 240—241° with much frothing; Bode gives 233—234° (*Inaug. Diss., Marburg*, 1889), and Jahns gives 225° (Abstr., 1891, 94).

Gram (*Arch. exp. Path. Pharm.*, **20**, 116) says that neurine and choline platinochlorides are so similar in crystalline form as to be distinguishable only by their difference in colour. The author finds that choline platinochloride forms large, soluble, red, tabular, monoclinic crystals, arranged like steps; whilst neurine platinochloride crystallises in small, individual, sparingly soluble, orange-red, regular octahedra, and melts at 211—213°.

To convert choline into neurine, it is heated with fuming hydriodic acid at 140°, and the product is treated with moist silver oxide. To convert neurine into choline, it is heated with hydriodic acid, and the product then heated with silver nitrate in aqueous solution (compare Bode, *loc. cit.*).

Choline platinochloride is not converted into neurine platinochloride when heated with hydrochloric acid in the water-bath, as stated by Gram (*loc. cit.*).

Choline lactate is not converted into neurine lactate when heated in water, as stated by Gram, but a *lactocholine platinochloride*, $NMe_3Cl\cdot CH_2\cdot CH_2\cdot O\cdot CHMe\cdot COO\cdot CH_2\cdot CH_2\cdot NMe_3Cl,PtCl_4,2H_2O$, is obtained if, after the action has continued for six days, neutral platinic chloride is added in considerable quantity, and the mixture rapidly evaporated. This salt forms columnar crystals with bevelled ends, melts with decomposition at 220°, and dissolves easily in water, but more sparingly in alcohol.

An aqueous solution of choline does not contain any neurine after it has been kept for four months, whether the solution be concentrated or dilute. In two experiments with hay infusion, the author found that, under the influence of the organisms contained therein, choline is converted, to a small extent, into neurine; further experiments gave somewhat uncertain results. A. G. B.

Adenine. By M. Krüger (*Zeit. physiol. Chem.*, **16**, 160—172).—The knowledge of the nucleïn bases, derived from nucleïc acid, is of

importance, as the origin of uric acid in the system may probably be arrived at by their study, especially if adenine and hypoxanthine can be shown to belong to the uric acid group, which includes xanthine and guanine. Adenine was prepared from tea-extract, and estimated by the help of sodium picrate (Bruhns, Abstr., 1890, 534). It can be prepared free from water of crystallisation by adding excess of ammonia to concentrated solutions of its hydrochloride; four-sided pyramids are thus obtained. A 0·5 per cent. aqueous solution gives no precipitate with potassium ferrocyanide or ferricyanide until acetic acid is added, when thin, crystalline plates are obtained. Ferric chloride gives a red coloration unaltered by heat. Copper sulphate produces a greyish-blue, amorphous precipitate, containing 2 atoms of copper to 1 mol. of SO_3; it is, therefore, a mixture of copper-adenine and adenine-copper sulphate. With chromic acid, it forms a dichromate,

$$(C_5H_5N_5)_2,H_2Cr_2O_7;$$

this crystallises as six-sided plates. With chloracetic acid, it forms prismatic crystals of a chloracetate, $C_5N_5N_5,2CH_3ClO_2$. With hydrochloric acid at 135°, it is completely decomposed (Kossel), and it appeared of importance to determine the products formed. On carrying out the reaction in sealed tubes, it was found that the products were carbonic anhydride, carbonic oxide, and ammonium chloride. Four atoms of its nitrogen appear in the form of ammonia; consequently no methylamine group is present in adenine. Glycocine is also formed, and the following equation represents what occurs:—$C_5H_5N_5 + 8H_2O = 4NH_3 + CO_2 + 2CH_2O_2 + C_2H_5NO_2$. No formic acid is, however, found as such; the strong acid, the pressure, and the temperature break it up completely into carbonic oxide and water. Similarly treated, hypoxanthine undergoes the following reaction:—$C_5H_4N_4O + 7H_2O = 3NH_3 + CO_2 + 2CH_2O_2 + C_2H_5NO_2$. Comparing these results with those obtained by Schmidt (*Annalen*, **217**, 311) in relation to xanthine ($C_5H_4N_4O_2 + 6H_2O = 2CO_2 + CH_2O_2 + 3NH_3 + C_2H_5NO_2$), it is seen that xanthine and hypoxanthine yield qualitatively the same products; the quantitative difference is that the relation of $CO_2 : CH_3O_2$ is 1 : 2 in hypoxanthine, and 2 : 1 in xanthine. Uric acid, under the influence of concentrated hydriodic acid at 160—170°, also yields glycocine, carbonic anhydride, and ammonia (Strecker, *ibid.*, **146**, 142). W. D. H.

Adenine and Hypoxanthine. By G. Bruhns and A. Kossel (*Zeit. physiol. Chem.*, **16**, 1—12).—By Beckmann's method (*Zeit. physikal. Chem.*, **4**, 532) the molecular weight of adenine was found to be sufficiently near 135 to warrant the author's previous assumption that its formula is $C_5H_5N_5$.

On oxidation, uric acid, xanthine, and their derivatives yield products which show they contain an alloxan nucleus. Whether hypoxanthine and adenine contain this is uncertain, but by bringing acid groups into their molecule, it was hoped to obtain an answer to this question. For this purpose, the action of ethyl chlorocarbonate on hypoxanthine was investigated; 4 grams of hypoxanthine hydrochloride were mixed with 3 grams of sodium hydroxide and 5 grams of ethyl

chlorocarbonate, and after 24 hours, the precipitate which formed was collected, and was recrystallised from hot water, when tables about 7 mm. by 1 mm. were obtained, melting at 185—190°. They were sparingly soluble in alcohol, ether, and cold water, but readily in hot water, sodium hydroxide, and hydrochloric acid. Their composition was found to be $C_5H_3N_4O{\cdot}COOEt$, that is, the substance is the urethane of hypoxanthine. It was, however, found unsuitable for experiments on oxidation, and attention was then directed to the bromine derivatives of adenine. The action of bromine appears to take place in the following stages:—

(1.) $C_5H_5N_5 + Br_2 = C_5H_4N_5Br + HBr.$
(2.) $C_5H_4N_5Br + HBr = C_5H_4N_5Br,HBr.$
(3.) $C_5H_4BrN_5,HBr + 2Br_2 = C_5H_4BrN_5,Br_4,HBr.$

The final product, which is red, is *bromadenine tetrabromide hydrobromide.*

Bromadenine, $C_5H_4BrN_5$, crystallises in thin plates; it is sparingly soluble in water, but very readily in ammonia and fixed alkalis, and fairly soluble in mineral acids, with which it forms salts. The sulphate, $(C_5H_4BrN_5)_2,H_2SO_4 + 6H_2O$, hydrochloride, $C_5H_4BrN_5,HCl$, and nitrate, $C_5H_4BrN_5,HNO_3$, were prepared. The picrate,

$$C_5H_4BrN_5,C_6H_2(NO_2)_3{\cdot}OH + H_2O,$$

is very similar in its properties to adenine picrate. Bromadenine, like adenine, also gives metallic derivatives with silver nitrate, mercuric chloride, cadmium chloride, &c.

Attempts to obtain an oxyadenine or ethoxyadenine by the method adopted by Fischer in regard to caffeïne (*Ber.*, **14**, 637; **15**, 29, 453; *Annalen*, **215**, 253) failed. Difficulties were also found in an attempt to prepare chloradenine, but at last it was obtained by heating adenine with phosphorus pentachloride in a sealed tube at 160—170° for several hours. W. D. H.

Behaviour of Cupreïne and Quinine with Methyl Iodide. By O. Hesse (*Annalen*, **266**, 240—245).—When quinine is boiled with excess of methyl iodide in methyl alcoholic solution, it yields the methiodide, $C_{20}H_{24}N_2O_2,MeI + H_2O$, as sole product; if, however, the reaction is carried out at 80—100°, the dimethiodide, $C_{20}H_{24}N_2O_2,2MeI, + 3H_2O$ is formed. The *dimethochloride*, prepared from the methiodide, crystallises in pale-yellow needles, and is readily soluble in water. The *platinochloride*, $C_{20}H_{24}N_2O_2,Me_2PtCl_6 + 2H_2O$, is a dark-yellow, crystalline compound, sparingly soluble in cold water. The *aurochloride*, $C_{20}H_{24}N_2O_2,2MeAuCl_4$, is a yellow, flocculent substance, and decomposes at about 100°.

When a methyl alcoholic solution of cupreïne is boiled with excess of methyl iodide, the methiodide is formed, but if the mixture is heated at 80—100°, *cupreïne dimethiodide*, $C_{19}H_{22}N_2O_2,2MeI + 3H_2O$, is produced. This compound crystallises in prisms, melts at about 210° with decomposition, and is moderately easily soluble in hot water. The corresponding *methochloride* crystallises in pale-yellow needles, and is moderately easily soluble in water and alcohol; its *platino-*

chloride, $C_{19}H_{22}N_2O_2,Me_2PtCl_6$, is an orange, granular compound, very sparingly soluble in cold water.

When cupreïne is heated with methyl iodide and sodium methoxide in methyl alcoholic solution, it is converted into a mixture of the mono- and di-methiodides of quinine, as stated by Grimaux and Arnaud (Abstr., 1891, 1121). F. S. K.

Preparation of Homologues of Quinine. By E. Lippmann (*Monatsh.*, **12**, 512—514).—The yield of methylquinine obtained by Claus and Mahlmann's process (*Ber.*, **14**) is unsatisfactory, owing to a large quantity of the quinine methiodide escaping decomposition; the author finds that the following method gives much better results. The quinine methiodide is boiled with excess of silver oxide, the silver iodide filtered off, and the solution treated with a slight excess of dilute sulphuric acid, whereby the sparingly soluble sulphate is precipitated in the form of needles. The crystalline mass is dried on a porous plate, and heated in sealed tubes at 140° with excess of sodium hydroxide solution. Under these conditions, the quinine methohydroxide, $C_{20}H_{24}N_2O_2,MeOH$, loses water, and is converted into methylquinine, $C_{20}H_{23}MeN_2O_2$, which can be separated from the product by shaking with ether. G. T. M.

Isocinchonine. By O. Hesse (*Annalen*, **266**, 245—248).—This article is principally controversial; the author also describes experiments which point to the conclusion that commercial cinchonine sulphate may sometimes contain two isomeric alkaloïds, one of which yields isocinchonine, the other cinchoniline. F. S. K.

Isocinchonines. By E. Jungfleisch and E. Leger (*Compt. rend.*, **113**, 651—654; compare Abstr., 1891, 1121).—A continuation of the discussion with Hesse. They find that the isocinchonine of Comstock and Koenig is identical with cinchoniline. C. H. B.

Digitaleïne. By J. Houdas (*Compt. rend.*, **113**, 648—651).—The author has shown that the soluble digitalines of Schmiedeberg consist almost entirely of one glucoside, to which he gives Nativelle's name *digitaleïne*. It is characterised by the following properties:—When amyl alcohol is added to an aqueous solution of digitaleïne, the latter is rapidly precipitated in a crystalline form. If a hot mixture of amyl and ethyl alcohols is used, the solution, on cooling, deposits long, nacreous lamellæ, which contain amyl alcohol and water of crystallisation. If these crystals are dissolved in boiling water, the amyl alcohol expelled by prolonged ebullition, and the liquid mixed with its own volume of ethyl alcohol of 95°, long needles separate in stellate groups on cooling. The crystals contain ethyl alcohol and water, and are more soluble than those containing amyl alcohol. Similar results are obtained with methyl alcohol. It follows that when an alcohol of the ethyl series is added to a solution of digitaleïne, a crystalline compound of the alcohol and hydrated digitaleïne is obtained, and its solubility in water is greater the lower the molecular weight of the alcohol. Phenols seem to behave in a

similar manner, and ordinary phenol gives a well-crystallised compound which will be described subsequently. The crystals lose their alcohol and water at 110°. They dissolve somewhat slowly in cold water, but very rapidly in boiling water. Digitaleïne, however, has not yet been crystallised from aqueous solutions. When the liquid evaporates, the glucoside is left as a vitreous residue.

Digitaleïne is very slightly soluble in alcohol, and is practically insoluble in chloroform, ether, and light petroleum. In aqueous solution, it has a lævorotatory power; $[\alpha]_D = -49{\cdot}25°$. When heated, it shows no distinct melting point, but agglomerates at about 250°, intumesces at about 270°, and is completely caramelised at 280°. It seems to be unaffected by exposure to air, and its aqueous solution can be kept for a long time without undergoing any change. It is precipitated by tannin or ammoniacal lead acetate, and dissolves in cold hydrochloric acid without coloration; but if the solution is heated, it becomes violet-red, with a slight, greenish fluorescence. Sulphuric acid, diluted with its own volume of water, produces a yellowish coloration in the cold, changing to red, and finally to black, on heating.

The elementary composition is represented by the formula $C_{62}H_{52}O_{34}$, and agrees with that given by Schmiedeberg. When treated with very dilute sulphuric acid, digitaleïne yields two crystallisable glucosides without any glucose. C. H. B.

Hydrastine. By M. Freund and C. Dormeyer (*Ber.*, **24**, 3164).—The question as to whether the bromomethylhydrohydrastinine, $C_{12}H_{14}NO_2Br$, described by the authors (Abstr., 1891, 1518), is related to the compound obtained by Merlin (Abstr., 1884, 1385; 1887, 164) from dimethylpiperidine and bromine, and is, therefore, an ammonium bromide, has yet to be settled. A. R. L.

Lupanine: the Alkaloïd of the Blue Lupine. By C. Siebert (*Arch. Pharm.*, **229**, 531—546).—Hagen (Abstr., 1886, 163) ascribes the formula $C_{15}H_{25}N_2O$ to lupanine; this formula is contrary to the law of even atomicities, and should be doubled, except that Hagen's results do not exclude the formula $C_{15}H_{24}N_2O$.

The crushed seeds were extracted eight times with two successive quantities of alcohol containing hydrochloric acid; the extract was distilled, the residue made alkaline with potassium hydroxide, and extracted with ether; the ethereal solution was shaken with dilute hydrochloric acid, and the aqueous solution of the hydrochloride thus obtained was again treated with potassium hydroxide and ether to separate the pure base. The seeds yielded 0·33 per cent. of lupanine; Hagen obtained 0·19—0·22 per cent.

Lupanine is freely soluble in cold water to a clear solution, and also in cold alcohol (compare Hagen, *loc. cit.*). The hydrochloride, $C_{15}H_{24}N_2O,HCl + 2H_2O$, forms long, white, needle-shaped crystals, easily soluble in water, alcohol, and chloroform, but not in ether; when dried at 90°, it melts at 127°. The hydriodide, $C_{15}H_{24}N_2O,HI + 2H_2O$, forms yellowish crystals, and, when dried at 100°, melts at 184—185°. The *hydrobromide*, $C_{15}H_{24}N_2O,HBr + 2H_2O$, forms large, white,

tabular crystals, melts at 111°, and is soluble in water and alcohol. The platinochloride forms nodular crystals with 4 mols. H_2O. The aurochloride separates on addition of water to its alcoholic solution in long, prismatic crystals; it is anhydrous, dissolves in alcohol and water, and melts at 198—199°. The methiodide melts at 248—249° (Hagen gives 215°).

Lupanine is not changed by heating with fuming hydrochloric acid at 200°, or with concentrated aqueous or alcoholic sodium hydroxide solution at the ordinary pressure. When heated with soda-lime, the lupanine molecule is split up, 1 atom of nitrogen appearing as ammonia, and the other as a pyridine base; an unsaturated hydrocarbon is also obtained, and may be taken as evidence of a side chain in the molecule.

By oxidation with potassium permanganate in acid solution, lupanine yielded carbonic anhydride, a little ammonia, a neutral substance, $C_{15}H_{20}N_2O_3$, and a nitrogenous acid. A. G. B.

Nucleïns. By H. Malfatti (*Zeit. physiol. Chem.*, **16**, 68—86).—Nucleïns may be divided into two groups: the true nucleïns from cell-nuclei, which yield xanthine bases on decomposition, and the paranucleïns from egg yolk and milk, which do not. The question arises whether the artificial nucleïn of Liebermann, prepared by the addition of metaphosphoric acid to albumin, belongs to the first or second group. The preparation of nucleïc acid from nucleïn by Altmann (*Du Bois Reymond's Archiv, physiol. Abth.*, 1889, 514) gives a further means of distinguishing between the two groups. An artificial nucleïn, containing 6·1 per cent. of phosphorus, was prepared from serum-albumin; after dissolving in ammonia and reprecipitating by acetic acid several times, the percentage of phosphorus sank to 1·6. This is due to the separation of a nucleïc acid rich in phosphorus. This is soluble in ammonia; from this solution it is not precipitable by acetic acid, but it is by hydrochloric acid; it yields no trace of xanthine derivatives, and therefore belongs to the class of paranucleïc acids, and the nucleïn from which it originates to the class of paranucleïns. The opinion, however, is advanced that the nucleïns and paranucleïns are not so distinct as might be supposed, but that the true nucleïns are either simple additive or substitution compounds of paranucleïns and the xanthine bases in question.

After incineration and heating with potassium nitrate, phosphorus estimations were made, by titration with uranium acetate.

W. D. H.

New Proteïd from Human Blood Serum. By C. Chabrié (*Compt. rend.*, **113**, 557—559).—Serum, neutralised by acetic acid, is coagulated and evaporated at 100°. The mass is extracted by distilled water at 100°, the water being half the original bulk of the serum. The filtered liquid is somewhat cloudy; the addition of 89° alcohol gives a white, flocculent precipitate collecting together after some hours. The precipitate collected and dried in the air is soluble in water, from which it is reprecipitated by alcohol. It contains an organic substance resembling albumin, and yields 0·637 per cent. of ash consisting of phosphates, and not containing calcium or

chlorides. It is proved to be a new substance by the following reactions:—It is coagulated by alcohol, but not by heat, even in presence of acetic acid. Nitric acid gives a precipitate soluble in slight excess. Potassium ferrocyanide in presence of acetic acid gives a milkiness, increasing with time. Phosphotungstic acid yields a precipitate; ammonium phosphomolybdate gives a white precipitate on heating. Acid mercury nitrate gives a yellow precipitate; Millon's reagent a white one, becoming rose-coloured on heating. The substance yields no sublimate and no biuret reaction. No result follows the addition of a saturated solution of magnesium sulphate; sodium sulphate causes a white precipitate.

On account of its analogies with albumin, it is proposed to name the new substance *albumone*. It was found to the extent of 1/12,000 by weight in the blood of a healthy man. In that taken from a patient suffering from nephritis, it formed 0·087 per cent.

Albumone is strongly lævorotatory, but the opalescence of its solution prevents the determination of the amount of rotation with accuracy. It does not dialyse.

It differs from Béchamp's néphrozymase obtained from urine, this substance saccharifying starch at 60°, whereas albumone exerts no such action. W. T.

Physiological Chemistry.

Influence of Nutrition on the Composition of the Blood-ash. By K. Landsteiner (*Zeit. physiol. Chem.*, **16**, 13—19).—Verdeil states (*Annalen*, **69**, 89) that the salts of the blood vary with those of the food; an animal fed on flesh has in the blood alkaline phosphates, which are replaced by carbonates when a vegetable diet is given. Against this view we have the fact (Jarisch, *Wiener med. Jahrb.*, 1871, 435; 1877, 1) that the ash of the blood of different animals (men, dogs, horses, oxen) is practically the same, although their diet is different. In the present research, 15 young rabbits were dieted for three months and a half on hay, and another 15 on milk. The ash in the blood was in both cases practically the same, qualitatively and quantitatively; such differences as were noticed being explicable by differences in the relation of corpuscles to plasma. In animals with equal amounts of hæmoglobin in their blood, the corpuscular element was probably identical, and here, whatever the diet, the $Na_2O : K_2O$ quotient and the other analytical details obtained were also identical. W. D. H.

Bile during Inanition. By S. M. Lukjanow (*Zeit. physiol. Chem.*, **16**, 87—142).—The experiments were carried out on guinea pigs, and may be divided into five groups; the first group consisted of normal animals; the remaining four groups of animals in different stages of

inanition. Very complete analytical tables relating to each experiment are given.

The animals were found to lose on the average 1 per cent. of body weight in four hours four minutes. At the commencement of inanition, the relative weight of the liver is the smallest; in the middle period it rises, returning to the normal, and it continues to rise to the end. In the initial and middle stages, the liver is poor in water; in the final stage, the amount of water rises, first to the normal, and then above it. In the blood there is a progressive loss of water.

In the first stage (loss of body weight 5·53 per cent.), the amount of bile per hour per 10 grams of liver substance, and per 1 kilo. of body weight is rather greater than the normal; it then progressively sinks, but most rapidly in the middle periods (loss of body weight, 16 to 25 per cent.). This is represented in charts by means of curves. At first the bile is dilute, but, later, becomes more concentrated, soon, however, reaching a maximum at which it remains; this increased percentage of solids is chiefly due to the bile salts. The lessening found in the amount of bile secreted is not solely due to concentration, but also to a diminution in the solids secreted. The energy of secretion of bile during inanition is thus less than in normal animals; but the diminution in energy is most marked during the first half of the hunger period. W. D. H.

Carbohydrates of Putrefying Human Urine. By G. Treupel (*Zeit. physiol. Chem.*, **16**, 47—67).—The formation of fatty acids in normal urine when putrefaction sets in is due to the decomposition of its carbohydrates (dextrose and animal gum). In the present research, the furfuraldehyde and α-naphthol reaction was employed for the estimation of sugar (see Abstr., 1891, 1559), the results being controlled, in some cases, by Baumann's benzoic chloride method. It was found, that as putrefaction advanced the carbohydrate in the urine diminished, but a small quantity always remained, even after very prolonged periods (30 to 47 days). If the urine was exposed to the air, putrefaction and the diminution of carbohydrate occurred more rapidly than in closed vessels. Increase of the temperature to 35° also hastened the process. W. D. H.

Ethereal Hydrogen Sulphates in the Urine, and Disinfection of the Alimentary Canal. By A. Rovighi (*Zeit. physiol. Chem.*, **16**, 20—46).—From experiments on the author's person, on various patients, and on dogs, the following conclusions are drawn:—

1. The quantitative estimation of the ethereal hydrogen sulphates in the urine is a trustworthy criterion of the amount of putrefactive change in the intestine.

2. The amount of these substances passed varies with the time of day, so that it is necessary to examine a specimen of the mixed 24 hours' voidings.

3. In children, the amount passed is less than in adults.

4. Oil of turpentine and camphor in large doses lessen the putrefac-

tion in the dog's intestine, and, consequently, the output of ethereal sulphates in the urine.

5. In the human being, given either by mouth or rectum, these drugs have not the same efficacy.

6. Tannin clysters lessened, but only very slightly, the ethereal hydrogen sulphate of the urine in a case of enteroperitonitis, where their amount was excessive.

7. A saturated solution of boric acid injected into the intestine is more effective; but the absorption of the acid by the intestinal mucous membrane is dangerous.

8. The use of Carlsbad salts and Marienbad water is followed by an increased output of ethereal hydrogen sulphates for the first few days; this is followed by a very marked diminution.

9. Kephir ($1\frac{1}{2}$ litres per diem) is an excellent means of lessening intestinal putrefaction. Its action depends, in part at least, on the lactic acid it contains. W. D. H.

Physiological Action of Strontium Salts. By J. V. Laborde (*Compt. rend. Soc. Biol.*, 1890, 708—716; 1891, 562—566; compare Abstr., 1891, 99).—The action of the sulphate, normal tartrate, and orthophosphate of strontium was compared experimentally with that of the corresponding salts of potassium. The results again showed the innocuity of the strontium compounds; the lactate and tartrate have a slight diuretic action. Elimination takes place chiefly through the fæces. It is partly assimilated, being found in the liver and bones, and, to a small extent, is eliminated in the urine.

Further experiments with the bromide were confirmatory of the foregoing. W. D. H.

Physiological Action of Camphors, and of their Compounds with Chloral. By Schmitt (*Compt. rend. Soc. Biol.*, 1890, 678—683).—In a warm-blooded animal, camphor causes excitation of the central nervous system leading to general convulsions, an increase in the depth of respiration, a slowing of the heart, with increased force of its beats, and a marked elevation of blood pressure. Borneol and menthol, on the other hand, produce a sedative action on the nerve centres, borneol being the more powerful. Borneol, however, diminishes the frequency and depth of respiration, the number and force of the heart beats, and produces a fall of blood pressure; whilst menthol increases respiratory and cardiac activity, leading to a heightened intravascular pressure.

In experiments on rabbits, it was found that by giving borneol after chloral hydrate, the depressing action of the chloral was augmented by that of the borneol, whereas menthol in part counteracted this depression. Starting from this, the physiological action of compounds of chloral with the camphors was investigated.

Camphor dissolves in anhydrous chloral, but does not form definite compounds with it, whereas borneol and menthol do. The mixture of camphor and chloral produces the same effects as if the drugs were given successively, the convulsive effects of the camphor being masked by the sedative action of the chloral.

Chloral bornylate, $CCl_3 \cdot CH(OH) \cdot OC_{10}H_{17}$, forms white crystals insoluble in water, and melts at 45—55°. It is very toxic, producing a lowering of blood pressure and temperature to a greater extent than can be accounted for by the amount of chloral it contains.

Chloral menthylate, $CCl_3 \cdot CH(OH) \cdot OC_{10}H_{19}$, is a transparent, yellowish liquid, of the consistence of glycerol, insoluble in water, soluble in alcohol of 90°, and in oil. When distilled with water, it dissociates into menthol and chloral hydrate; an analogous dissociation in the body probably accounts for its physiological action. It irritates the mucous membranes when applied locally. Given subcutaneously or by the mouth, it leads to paralysis of the posterior limbs, and then to sleep; the soporific action is the same in its strength and duration as that produced by a corresponding dose of chloral hydrate, although its onset is somewhat delayed. The paralytic effects and lessening of reflex action are due to the menthol. The movements of respiration and of the heart are effected in the same way as with chloral; the depression of temperature is, however, not so marked. Blood pressure is first lowered, then rises, remaining stationary at a lower level than the original. Thus, to some extent, the menthol corrects the depression due to the chloral. W. D. H.

Toxic Action of Blood and of Various Tissues. By J. Héricourt and C. Richet (*Compt. rend. Soc. Biol.*, 1890, 695—696).—The blood of one animal is poisonous to that of another species; thus the toxic dose of dogs' blood, as tested in the rabbit, is 40—45 grams per kilo. of body weight. Birds' blood is more poisonous, its toxic dose being 7 grams. Mosso has previously shown, particularly with fishes' blood, that the poisonous effects of the serum are due to its proteïds (ichthyotoxin); and the present experiments confirm this conclusion, as the alcoholic extracts of the blood and spleen, which are, of course, free from proteïd, have lost their toxicity. The alcoholic extract of the muscles of some dogs was, however, poisonous, of others not. W. D. H.

Toxicity of Serum. By A. Charrin (*Compt. rend. Soc. Biol.*, 1890, 697).—A preliminary note regarding the toxicity of the serum from cases of uræmia, confirmatory of the conclusions in the preceding abstract. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Influence of Vegetable Poisons on the Germination of Seeds. By C. Cornevin (*Ann. Agron.*, **17**, 433—441).—The author's experiments are arranged under the following heads:—

A. *Action of a vegetable poison on the seeds of the species producing it.*—Seeds of *Agrostemma githago*, immersed for 6, 12, 18, 24, 36, and

48 hours in a solution of saponine, and then sown in sterilised soil, germinated sometimes as well as, and sometimes better than, untreated seeds. Similar results were obtained with seeds of *Cytisus laburnum* plunged in a solution of cytisine; in fact, more of the treated seeds germinated than of the untreated.

B. *Action of a vegetable poison not localised in the seed on the seeds of the plant producing it.*—Poppy seeds contain no poisonous alkaloïds, and tobacco seeds no nicotine. Seeds of *Nicotiana tabacum*, plunged for 38 hours in a concentrated decoction of tobacco, and then sown, did not germinate until 48 hours after untreated seeds. Seeds sown in soil watered with dilute nicotine (1 : 50) had their germination retarded by 10—23 days, and some refused to germinate. On the other hand, of 50 poppy seeds soaked for 38 hours in aqueous extract of opium, 48 germinated, whilst only 33 out of 50 untreated seeds germinated, and this, 24 hours after the others. Out of 50 poppy seeds sown in soil impregnated with opium, 49 germinated; out of 50 sown in soil watered with water only, 35 germinated a day in arrear of the treated lot. To ascertain which of the opium alkaloïds exercises this stimulating effect on germination, solutions of morphine, narceïne, codeïne, papaverine, narcotine, and thebaïne were tried separately, with the result that narcotine, codeïne, and narceïne stimulated or hastened the germination, whilst papaverine retarded it by 24 hours, and morphine and thebaïne were without influence.

C. *Action of a vegetable poison on seeds of species not producing it.*—Maceration of 30 hours in solutions of oleandrine and of andromedotoxin (from azaleas) had no injurious effect on the germination of peas, barley, wheat, and oats; but, whereas haricots were uninjured by oleandrine, their germination was retarded 9—10 days by andromedotoxin.

Colchicine was without effect on wheat, barley, and oats, but was fatal to the germination of haricots and very injurious to that of peas.

Cytisine prevented the germination of haricots, but was without effect on wheat, oats, barley, peas, and mustard.

Saponine and nicotine prevented the germination of haricots, but were without influence on wheat. Opium appeared to hasten the germination of oats.

D. *Influence of the duration of contact of the poison on the germination of seeds.*—Immersion of wheat in nicotine solution for 30 hours was without influence, but if the action was continued for 60 hours only a few seeds germinated, and that after a retardation of 7—8 days.

Three hours immersion of haricots in cytisine was without influence; 6 hours accelerated the germination; 9 hours prevented half the seeds from germinating; 12 hours immersion was fatal to all. Nicotine and saponine take 24 hours to destroy the germinating power of haricots. Wheat is more susceptible to injury from nicotine than from cytisine or saponine; the reverse is the case with haricots. J. M. H. M.

Direct Absorption of Ammoniacal Salts by Plants. By A. B. Griffiths (*Chem. News*, **64**, 147; compare Müntz, Abstr., 1890,

79, 287).—Bean seedlings, after immersion in copper sulphate solution to destroy nitrifying microbes, and washing with sterilised water, were allowed to grow under antiseptic conditions in a sterilised solution containing 0·1 per cent. of potassium chloride, 0·003 per cent. of ferrous carbonate, and 0·05 per cent. of sodium chloride, ammonium, calcium, and magnesium sulphates, and tricalcium phosphate.

At the end of four weeks, the ammonia in the culture solution had diminished to an amount corresponding with 0·027 per cent. of ammonium sulphate. There had been no direct absorption of atmospheric nitrogen, for nodules were not formed on the roots or rootlets, and there had been no nitrification, for at no time could any traces of nitric nitrogen be found in the culture solutions; hence the ammonium salts must have been directly absorbed by the plant. Jn. W.

Mineral Substance in Teak. By D. Hooper (*Zeit. Kryst. Min.*, **19**, 485, from *Nature*, **37**, 523).—The inorganic matter of teak (*Tectona grandis*) was formerly determined as $CaHPO_4$. The author finds that the inclusions of a tree from Nilambur have the following composition:—

$CaCO_3$.	$Ca_3(PO_4)_2$.	Quartz.	Organic matter.	H_2O.
70·05	2·89	9·76	14·33	3·00

B. H. B.

Composition of the Ash of Achyranthes aspera, Linn. By G. J. H. Warden (*Chem. News*, **64**, 161).—The ash, which is used in India as an alkali, for washing, dyeing, and medicinal purposes, contains potassium salts equivalent to 21·5 per cent. of potassium oxide in the leaves, to 38·0 per cent. in the stems, and to 28·6 per cent. in the roots. The author suggests the use of the plant as a cheap green manure. Jn. W.

Starch in the Fungus Boletus pachypus, Fr. By E. Bourquelot (*J. Pharm.* [5], **24**, 197—199).—The occurrence of starch has been very rarely detected in fungi. Thin sections of the foot and cap of *B. pachypus* stained with iodine solution give a blue coloration, due to the presence of starch in the tissue. The liquid pressed out of the fungus does not give the starch reaction. On boiling the fungus with water, the filtered solution gives a precipitate with alcohol, which, when redissolved in water, gives a blue coloration with iodine solution; a second portion mixed with fresh saliva (diastase solution) loses its property of becoming blue with iodine solution after a short time, whilst a third portion, treated with saliva and kept at the laboratory temperature for 10 hours, acquires the power of reducing alkaline copper solution. J. T.

Formation and Physiological Significance of Oxalic Acid in Fungi. By C. Wehmer (*Ann. Agron.*, **17**, 462—464; from *Bot. Zeit.*, 1891, **15**).—The author has experimented with pure cultivations of fungi in nutritive solutions. In doses of 1 per cent., oxalic acid is fatal to the growth of fungi, but in smaller quantities it is assimilated and decomposed by some as carbonaceous aliment in default of any

more suitable. Fungi form oxalic acid from any sort of carbonaceous compound which they can assimilate; its formation depends less on the nourishing medium and the species grown than on the degree of development which the fungus attains; it is, however, directly promoted by the presence of bases in the solution with which it can combine. The quantity formed is often many times greater than that of the fungus itself, and the weight of oxalic acid *plus* fungus corresponds nearly with that of the sugar consumed when sugar is used as nutritive medium. The author looks on oxalic acid as the product of incomplete respiration, and its persistence is, to a great degree, determined by the presence of bases. It is destroyed by further oxidation, with production of carbonic anhydride and water. J. M. H. M.

Organic Acids in Beet Juice. By E. O. v. Lippmann (*Ber.*, **24**, 3299—3306).—The presence of malic and tartaric acids in beet juice, hitherto asserted without proof by the text-books, has been proved. The chalk precipitate formed when unripe beets are treated in the evaporating apparatus contains, besides oxalic and citric acids, small quantities of lævomalic, dextrotartaric, and glutaric acids. Some deposits were also examined which had been formed in the preliminary warming of the juice after its treatment with chalk. One contained, besides oxalic acid, ordinary succinic and normal adipic acids. Another contained, besides oxalic, glycollic acid; about the same time as this was deposited, it was noticed in the factory that a white powder sometimes separated out during the filtration of the juice; this powder was shown to contain a polymeride of glyoxal. The author has once succeeded in obtaining glyoxylic acid from quite young beet plants. The presence in beet juice of the first five members of the oxalic acid series has now been proved, and also of glycollic, glyoxylic, malic, tartaric, and citric acids. C. F. B.

Constituents of Henbane Seed. By F. Ransom (*Pharm. J. Trans.* [3], **22**, 215—216).—The author obtained from the dried seeds of biennial plants of *Hyoscyamus niger*, grown at Hitchin, only 0·058 per cent. of alkaloïd. The seed is, therefore, not so rich in alkaloïd as some have asserted, and as it contains also much fixed oil, in which the alkaloïd is to some extent soluble, its use for galenical preparations seems undesirable. R. R.

Alkaloïds of the Solanaceæ. By W. Schütte (*Arch. Pharm.*, **229**, 492—531).—The author summarises the conclusions to be drawn from his paper, thus:—

(1.) The younger roots of wild belladonna contain only hyoscyamine, whilst the older roots contain atropine as well as hyoscyamine, but only in small proportion; the same was observed to be the case in the older cultivated roots.

(2.) The ripe berries of cultivated *Atropa belladonna nigra* contain atropine and hyoscyamine; those of the wild plant contain atropine only; the ripe fruit of *Atropa belladonna lutea* contains only atropine, and another base, perhaps identical with atropamine. The unripe

fruit of wild *Atropa belladonna nigra* contains hyoscyamine with only a small quantity of atropine.

(3.) The leaves of the yellow and black fruited, wild *Atropa belladonna* contain hyoscyamine and atropine, the latter being in small quantity only.

(4.) Fresh and old seeds of *Datura stramonium* contain chiefly hyoscyamine; small quantities of atropine and scopolamine are also present.

(5.) *Solanum tuberosum* contains, besides betaïne, an alkaloïd which causes mydriasis.

(6.) The mydriatic alkaloïd contained in *Lycium barbarum* and *Solanum nigrum* exists only in small quantities, and appears to be identical with the base contained in *Solanum tuberosum*.

(7.) The leaves of *Nicotiana tabacum* also contain traces of mydriatic alkaloïds.

(8.) In the seeds, leaves, and root of *Anisodus luridus*, gathered in autumn, hyoscyamine only has a pre-existence. A. G. B.

Toxic Principles of Amanita pantherina, D.C. By Inoko (*J. Pharm.* [5], **24**, 261—262; after *Pharm. Post*, **24**, 1891, 581; compare R. Böhm, Abstr., 1885, 1008).—The fungus, when dried, loses a portion of its poisonous activity. A dried sample yielded 0·1 per cent. of alkaloïds, consisting of choline with a little muscarine.

J. T.

Cicuta maculata, Linn. By R. Glenk (*Pharm. J. Trans.* [3], **22**, 69—70).—This paper contains the results of a complete analysis of the fruit of *Cicuta maculata*, with the chemical reactions of the volatile oil, resins, an aqueous extract, and the constituents of the ash. The author obtained an alkaloïd which, however, does not occur in the root also, but was unable to determine whether or no this was coniine, owing to insufficiency of material. At one stage of the operations a strong coniine-like odour was noticed. R. R.

Pollen of Pinus Sylvestris. By K. Kresling (*Arch. Pharm.*, **229**, 389—425; compare von Planta, Abstr., 1886, 91).—The methods adopted in the analysis of the pollen were those recommended by Dragendorf. Full details are given in the original paper; the results are summarised as follows:—

Moisture, 8·73 per cent.

Ash, crude ash, 5·51 per cent.; pure ash, 3·0 per cent., containing:—

K_2O.	Na_2O.	MgO.	CaO.	P_2O_5.	SO_3.	Cl.	Fe_2O_3.	Al_2O_3.	SiO_2.	Mn_2O_3.
37·16	1·62	4·94	4·63	28·70	4·38	1·35	4·08	1·86	10·51	trace.

(Compare Famintzin and Przybytek, *Bull. Acad. Imp. Sci. St. Pétersbourg*, **30**, 358.)

Fat, 11—12 per cent., melting about 40°, and containing:—glycerol, 5·24 per cent.; alcohols, chiefly cholesterol and myricyl alcohol, 6·16 per cent.; fatty acids, 87·85 per cent., of which 77·35 per cent. is oleïc acid, and 22·65 per cent. solid acids, chiefly palmitic.

Lecithin, 0·895 per cent.

Cane sugar, 12·75 per cent.

Starch, 7·4 per cent.

Total glucose, obtained by boiling with seminormal acid, 33·1 per cent., which is 11·7 per cent. more than can be accounted for by the cane sugar and starch; this remainder must be derived from the carbohydrates of the cell wall.

Cellulose, 19·06 per cent.

Mucilage, 0·196 per cent.

Organic Acids.—Tartaric and malic acids were isolated. Five grams of pollen gave sufficient acid to neutralise 17 c.c. of decinormal sodium hydroxide solution.

Nitrogenous Compounds.—Globulin, nucleïn, peptone, albumin, amines, and ammonia (0·094 per cent.) were detected. No peptonising ferments were found. Proteïds, soluble in water and precipitated by tannin, 1·61 per cent. By extraction with dilute hydrochloric acid and sodium hydroxide, 1·595 per cent. of proteïds was dissolved and precipitated by tannin. After this extraction there is still 0·681 per cent. of nitrogen, calculated on the original pollen, in the residue, and about half the total of nitrogen, namely, 1·34 per cent., remains in the extract, not being precipitated by tannin. Of bases, there were isolated: xanthine, 0·015 per cent.; guanine, 0·021 per cent.; hypoxanthine, 0·085 per cent., and a small quantity of a substance rich in nitrogen, vernine. A. G. B.

Rain as a Source of Nitrogen for Vegetation. By C. F. A. Tuxen (*Forsch. Gebiete Agr. Phys.*, **14**, 367—368; from *Tidsskr. f. Landökon.*, 1890, 325—350).—In connection with the question of the nitrogen compounds at the disposal of plants, the nitrogen compounds of rain in Denmark were investigated. The tables on the next page show (I) the amount of rain (from 1880 to 1885) and the ammonia and nitric acid per million; and (II) the amount of nitrogen as ammonia and as nitric acid in kilograms per hectare.

The ammonia is chiefly due to the decomposition of organic matter. The results are considered to be high, as the rain was collected near a rather large village, where the production of ammonia and nitric acid would probably be greater than in other parts of the country. N. H. M.

The Phosphoric Acid of the Soil. By P. P. Dehérain (*Ann. Agron.*, **17**, 445—454).—The author discusses the assimilation of phosphoric acid by different crops in the light of facts furnished by the experimental plots at Grignon.

The plots left unmanured since 1875 gave, of late years, very poor crops, and the author has attributed this result, in great measure, to the impoverishment of the soil in humus. As regards the direct elements of fertility, he has shown that the nitrogen is still easily nitrifiable, and that the total phosphoric acid is as much as 0·1 per cent. Yet a dressing of 200 kilos. mineral superphosphate on this plot raised the yield of wheat in 1890 from 8 to 22 metric quintals per hectare, whilst 200 kilos. of superphosphate with 200 kilos. of potassium chloride gave 24 metric quintals. Even then, as regards wheat,

the sterility is largely due to exhaustion of assimilable phosphoric acid, the total phosphoric acid, nevertheless, remaining abundant. The author long since proposed to treat samples of soil with acetic acid in order to distinguish the assimilable from the non-assimilable phosphates, on the assumption that the calcium phosphate of the soil is assimilable and entirely soluble in acetic acid, the ferric and aluminium phosphates being non-assimilable and insoluble. In point of fact, the soil of the unmanured plots yields only traces of phosphate soluble in acetic acid, whilst that of the manured plots yields notable quantities, as do other soils on which dressings of superphosphate produce no increase of crop. The soil of the unmanured plots contained, in 1879, 0·03 per cent. of P_2O_5 soluble in acetic acid, to-day, only traces; in 10 years, therefore, a layer of soil weighing 4000 tonnes per hectare has lost 1200 kilos. of assimilable P_2O_5. The crops removed during this time certainly contained less than 400 kilos. of P_2O_5 altogether, so that two-thirds of the assimilable P_2O_5 must have been washed out of the soil or converted into inert forms. The former alternative is improbable, drainage waters, especially from unmanured soils, containing mere traces of phosphoric acid. As regards the second alternative, Thénard concluded long ago, that a dressing of calcium phosphate (bone black) was converted, after a time, into ferric and aluminium phosphates by reaction with soil, and the same thing may be proved by a laboratory experiment. If a little calcium phosphate be mixed with soil and treated with carbonic acid water in a seltzogene, after a few days it is found that no phosphate is dissolved, although calcium phosphate by itself is soluble in carbonic acid water. The soil may be replaced by oxide of iron or alumina with the same result.

Although ferric and aluminium phosphates may be non-assimilable by wheat, they appear to stand on a different footing as regards oats, for whereas the plots manured every year gave, in 1888, 37·8 metric quintals of oats per hectare, the plots unmanured since 1875 gave as much as 31·1 metric quintals. Moreover, in 1891, whilst the manured plots gave 36 metric quintals of oats, and the unmanured plots 28, the addition of 200 kilos. of superphosphate to the latter only raised the yield to 30 quintals.

The author suggests, as a possible explanation, that the acid in the juice of the roots is carbonic acid, that the roots of oats may be more charged with this than those of wheat, and that the carbonic acid may withdraw alkali carbonate from its association with the clay of the soil to form bicarbonate, which is capable of dissolving the phosphates of iron and alumina, although carbonic acid itself will not do so. Even calcium carbonate, in conjunction with carbonic acid water, is capable of causing the solution of ferric phosphate.

It is probable that dressings of farmyard manure, containing as it does alkali carbonates, assist in the solution of these phosphates, and so render them assimilable by crops, and also liable to be washed out of the soil. J. M. H. M.

Analytical Chemistry.

The Application of Capillary Phenomena to the Analysis of Liquids. By E. Gossart (*Compt. rend.*, **113**, 537—540).—Every liquid may be caused to roll in drops upon itself, the drops being separated from the main body of the liquid by a thin stratum of vapour. A drop is allowed to fall from a height of 1 mm. upon the concave meniscus at the edge of the vessel containing the liquid. It is convenient to use a vessel with sloping sides, giving a meniscus of hyperbolic section. The liquid is rendered viscous by the addition of such substances as citric acid or glycerol. Using two pure liquids, the drops of the one never roll upon the other, owing to the immediate absorption of the separating film of vapour.

If the supporting liquid contains an impurity, test drops of the same liquid will roll upon the supporting liquid, provided that they contain the same percentage of the same impurity, or that this percentage only varies within fixed limits. These limits can, with care, be reduced so far that it becomes possible to find the amount of impurity present within $\frac{1}{500}$ of the total. Each impurity behaves as if it alone were present.

A general method for the detection and estimation of impurities in liquids hence becomes possible; it is particularly serviceable in the case of spirituous liquors. W. T.

Estimation of Free Hydrochloric Acid in the Stomach. By L. Graffenberger (*Landw. Versuchs-Stat.*, **39**, 455—459).—The best method for the estimation of the free hydrochloric acid in the contents of the stomach is that of Sjöquist (Abstr., 1889, 302), as modified by v. Jaksch; this modification consists in estimating the barium gravimetrically as barium sulphate.

In the present research, the applicability of the method was tried with various artificial mixtures, to which a known amount of hydrochloric acid was added; the mixtures contained chlorides; organic acids; organic acids and chlorides; peptone; peptone, chlorides and organic acids; starch; and lastly starch, peptone, pepsin, organic acids, and chlorides. The result in all cases was the same, or at least the error never exceeded 0·01 per cent. The method is thus an admirable one. Proteïds other than peptones in the mixture give rise to a loss of acid of from 3 to 4 per cent. W. D. H.

Estimation of Chlorates. By F. A. Gooch and C. G. Smith (*Amer. J. Sci.* [3], **42**, 220—223).—The authors communicate a rapid and easy but indirect process for the estimation of chloric acid, which is briefly as follows:—An accurately measured solution containing potassium iodide, sodium hydrogen arsenate, and dilute sulphuric acid is boiled in an Erlenmeyer's flask until the liberated iodine is expelled. The residue, after cooling, is first neutralised with soda, then mixed with excess of solution of sodium hydrogen carbonate,

and finally titrated with N/10 iodine. The experiment is now repeated, this time with the addition of a definite amount of a chlorate. As there is no reaction between hydriodic acid and arsenic acid, as long as there is a chlorate present, the amount of iodine used to reoxidise the arsenious acid will be considerably less. The amount of chloric acid may, therefore, be readily calculated. It is of great importance to have a good excess of potassium iodide. The test analyses are satisfactory. L. DE K.

Microscopic Detection of Sulphurous Anhydride. By G. DENIGÉS (*J. Pharm.* [5], **24**, 289—290).—A saturated solution of cadmium nitrate is diluted with 20 vols. of an aniline solution containing 20 to 25 grams per litre. Immediately before use a little of this is acidified with about 1 per cent. of acetic acid, taken up on the end of a glass rod, and held over the mouth of the vessel from which sulphurous anhydride is supposed to be escaping. In presence of this compound, a white film rapidly forms, which, under the microscope, is clearly seen to consist of regular, hexagonal plates. If the cadmium solution is not acidified, the test appears to be more sensitive, but, under the microscope, the hexagonal crystals are found to be almost completely replaced by far less characteristic radiating crystals. J. T.

New Method of Estimating Nitrogen. By E. BOYER (*Compt. rend.*, **113**, 503).—The method is founded on the complete reduction of nitric nitrogen to ammonia by oxalates and sulphur in presence of soda-lime. A reducing mixture is made, consisting of 1 part of sulphur, 2 parts of calcium oxalate, and 6 parts of soda-lime. A quantity of the dry substance containing not more than 0·5 gram of nitrate is intimately mixed with 50 grams of the reducing mixture. A combustion-tube, 55 cm. long and 1·7 cm. in diameter, is closed at one end, and is then charged by the successive introduction of 2 grams of calcium oxalate, 10 grams of powdered soda-lime, 10 grams of the reducing mixture, the substance mixed as above, 10 grams of the reducing mixture, 10 grams of powdered soda-lime, and a plug of asbestos. The combustion is carried on just as in an ordinary soda-lime combustion, and occupies about 40 minutes. It is necessary to boil the standard sulphuric acid, before titration, to expel the sulphuretted hydrogen and carbonic anhydride formed during the combustion.

The method may be employed to determine total nitrogen existing in the three states of organic, ammoniacal, and nitric nitrogen, and yields good results; for instance, an analysis of sodium nitrate gave 16·45 of nitrogen for 16·47 present; a mixture containing 0·1284 gram of organic and ammoniacal nitrogen yielded 0·1281 gram; a mixture containing burnt leather, ammonium sulphate, and sodium nitrate gave 0·1161 gram nitrogen out of 0·11655 gram; a similar mixture containing dried blood yielded 0·1624 gram out of 0·1627 gram of nitrogen present. W. T.

Estimation of Carbon in Steel. By A. A. BLAIR (*Chem. News*, **64**, 66—69; from *J. Anal. and Appl. Chem.*, **5**, 3).—A continuation

of the work of the International Steel Standards Committee; certain modifications are recommended in the ordinary combustion process.

The double chloride of copper and potassium is to be preferred to the analogous ammonium salt, as the latter is liable to contain organic impurities derived from the manufacture of the ammonia.

The air used for the combustion is best supplied from a pressure-cylinder, as the use of an aspirator facilitates the introduction of impurities from the atmosphere of the laboratory.

The products of combustion are best purified by cuprous chloride and anhydrous copper sulphate, the former absorbing the free chlorine, the latter the hydrogen chloride; the cuprous chloride, which is converted into a convenient granular form by heating the moistened powder and stirring until dry, is placed in the anterior limb of a Marchand U-tube, the posterior limb of which is occupied by the copper sulphate, guarded by a plug of asbestos. As anhydrous copper sulphate is a more efficient desiccating agent than the granular calcium chloride used in the guard-tube of the potash bulb, it is necessary to moisten the gases as they leave the purifying apparatus, and dry them again over calcium chloride before they enter the absorption apparatus. For this purpose, a plug of cotton wool placed in the bulb of a Marchand U-tube containing the calcium chloride is moistened at the commencement of each combustion.

In weighing the potash-bulbs, the use of capillary stoppers is recommended, as they allow the equalisation of pressure without permitting the introduction of any sensible amount of moisture.

Estimation of Thallium. By H. Baubigny (*Compt. rend.*, **113**, 544—547).—The estimation of this metal by precipitation as thallous iodide admits of accurate results, notwithstanding the remarks of previous observers. The inaccuracy of the method alleged by Willm is due to the final washing with distilled water. Werther's assertion that thallous iodide is insoluble in ammoniacal water is not borne out by the facts, but its solubility in dilute alcohol is less than that author indicates. The most accurate modification of the process is carried out as follows:—The thallous iodide is precipitated at 80—90°, it then collects together well without to any extent adhering to the glass. The whole is cooled; the orange precipitate, at first very finely divided, forms a dense, crystalline, yellow powder which may be readily filtered. The precipitate is washed with a 1 per cent. solution of potassium iodide, in which it is insoluble, until free from foreign salts; finally the potassium iodide is washed out by 82° alcohol, which, while readily dissolving potassium iodide, does not dissolve enough thallous iodide to yield even a coloration with ammonium sulphide after concentration of the washings to one-fifth their bulk. The precipitate is dried and detached as completely as possible from the filter, and in order to avoid the use of a tared filter, the thallous iodide adhering to the paper is dissolved by the aid of a little dilute nitric acid, and received in a tared porcelain crucible; the solution is then gently evaporated with a few drops of hydrochloric acid, precipitated by the addition of a drop of concentrated hydriodic acid, dried, the main quantity of the precipitate added, the whole heated for some hours at 170°,

and weighed. Although thallium and its salts are too volatile to allow of the incineration of the paper without loss, thallous iodide does not volatilise at 170°. Test analyses gave accurate results. (Compare Long, Abstr., 1891, 1295.) W. T.

Oxidation of Copper-glance by the Electric Current. By E. F. Smith and D. L. Wallace (*Ber.*, **24**, 2938—2939; see also *Ber.*, **23**, 2276).—It has been shown that metallic sulphides in alkaline solutions are decomposed by the electric current in such a way that the whole of the sulphur is oxidised to sulphuric acid. Copper-glance was the only exception. The authors have now succeeded in completely decomposing this mineral by the electric current.

Finely powdered copper-glance (0·1068 gram) and potassium hydroxide (35 grams) are mixed in a nickel crucible and submitted for 40 minutes to the action of an electric current producing 1 ampère of electrolytic gas per minute. Before stopping the current, it is reversed for a few minutes. The contents of the crucible are then washed out with water, filtered from the insoluble oxide, acidified with hydrochloric acid, and precipitated with barium chloride. The results are good: 20·80 and 20·91 per cent. of sulphur being obtained, as against 21·00 per cent. obtained by oxidation with nitric acid.

The essential conditions for success are the employment of a large quantity of potassium hydroxide and the prolonged action of the electric current. E. C. R.

Electrolytic Separation of Mercury from Copper. By E. F. Smith and A. W. MacCauley (*Ber.*, **24**, 2936—2938).—The authors have found that by carefully regulating the current, the separation of mercury from copper is complete, even when the latter is present in twice as large a quantity as the former. Moreover, the presence of zinc, nickel, or other metals in no way hinders the separation. A table of the results obtained is given. E. C. R.

A Reaction for Cerous Oxide. By P. C. Plugge (*Arch. Pharm.*, **229**, 558—561).—The most delicate reagent for cerous oxide is a solution of 1 part of strychnine in 1000 parts of concentrated sulphuric acid. The suspected solution is made alkaline with sodium hydroxide, evaporated on a piece of porcelain, and the dry residue brought in contact with 2 or 3 drops of the strychnine solution; in the presence of cerium, a bright-blue colour is developed which rapidly fades and gives place to a cherry-red or pale-red, according to the quantity of cerium present. As little as 0·01 milligram of cerous oxide can be detected in this way, the colour being a pale blue-violet which rapidly disappears.

This test was devised for the detection of cerium in the contents of a stomach, where the cerium was present in the form of oxalate, which is officinal in some pharmacopœias as a remedy for vomiting, dyspepsia, &c.; in such a case, the presence of sodium hydroxide is necessary to decompose the cerium oxalate. The test may also be applied directly to a precipitate produced by ammonia and contain-

ing zinc and aluminium as well, only ammonium sulphide or zinc sulphide must not be present. A. G. B.

Separation of Manganese and Nickel, Manganese and Cobalt, and of Manganese, Nickel, and Cobalt. By P. Jannasch and C. J. Franzek (*Ber.*, **24**, 3204—3205).—It has been previously shown by Jannasch and McGregory (Abstr., 1891, 963) that zinc and manganese may be quantitatively separated by means of hydrogen peroxide in strong ammoniacal solution and in presence of a large quantity of ammonium chloride. The separation of manganese from nickel may be readily carried out under similar conditions, but not that of manganese and cobalt. If, however, the hydrogen peroxide is added to these metals when in the form of double alkali cyanides, the manganese precipitate is completely free from cobalt; in the same way manganese may be separated from nickel, or, as would be expected, from a mixture of both these metals. The precautions necessary to ensure success will be published later. H. G. C.

Volumetric Estimation of Iron by Potassium Dichromate and Stannous Chloride. By R. Namias (*Gazzetta*, **21**, 473—476).—The author considers the ordinary method of estimating iron by dichromate, using potassium ferricyanide as an indicator, to be inconvenient and somewhat inexact. He finds the following method to give good results:—An excess of standard dichromate solution is run into the solution of the ferrous salt, acidified with hydrochloric acid; a few drops of iodine and starch solution are added, and the excess of dichromate determined by titration with standard stannous chloride solution.

It is convenient to use a potassium dichromate solution containing about 5 grams of the salt per litre; the stannous solution should be equivalent to this. W. J. P.

Colorimetric Estimation of Iron. By L. Lapicque (*Compt. rend. Soc. Biol.*, 1890, 669—671).—In view of certain observations by Krüss and Morath (Abstr., 1889, 124), in which they found the colorimetric estimation of iron led to variable results, the author has re-examined his former method (Abstr., 1890, 297) of estimating the iron in blood. He also finds certain variable factors, but by using a large excess of alkali thiocyanate in constant proportion, and then acidifying strongly with sulphuric acid, these are reduced to a minimum. Among the circumstances leading to variation, temperature must be mentioned; to obviate this, it is suggested that every time a series of estimations is to be made, the thiocyanate should be previously titrated with a ferric salt in order to determine the constant K. W. D. H.

Decomposition of Chrome-Iron Ore by Hydrochloric Acid under Pressure. By P. Jannasch and H. Vogtherr (*Ber.*, **24**, 3206—3208).—The method already recommended by one of the authors for decomposing silicates, namely, by heating with hydrochloric acid under pressure in a platinum apparatus (Abstr., 1891,

619), may also be adopted with advantage in decomposing chrome-iron ore for quantitative analysis. The most suitable acid is a mixture of 4 vols. of concentrated acid of sp. gr. 1·119 and 1 vol. of water, and it should be saturated with ammonium chloride; the tubes must be heated for 8—10 hours at about 250°, the decomposition being then at least as complete as with the methods usually adopted.

H. G. C.

Estimation of Molybdic and Tungstic Acids. By E. F. Smith and R. H. Bradbury (*Ber.*, **24**, 2930—2936).—The authors have made experiments to determine if molybdic and tungstic acids can be estimated by means of their barium, calcium, strontium, lead, silver, cobalt, bismuth, or cadmium salts. The following results were obtained:—

Barium molybdate is precipitated on adding barium chloride to a cold solution of sodium molybdate. It dissolves completely in acids, is more soluble in a dilute solution of ammonium nitrate than in water, and dissolves in 17,200 parts of water at 23°. The quantitative estimation was carried out as follows:—A measured quantity of sodium molybdate solution containing 0·1144 gram of molybdenum was made up to 200 c.c., heated to boiling, precipitated with a boiling solution of barium chloride, allowed to remain until cold, filtered, washed with cold water, and the precipitate separated from the filter-paper, and ignited. The results obtained were good. If the precipitate be filtered while the solution is hot, a small quantity of molybdenum will be found in the filtrate.

Barium tungstate is a heavy, white precipitate, which is decomposed by warm acids with formation of yellow tungstic acid, and is more soluble in dilute ammonium nitrate than in water. The quantitative estimation, which gives good results, is carried out in a similar way to the molybdate, but in this case the precipitate is collected while hot, and washed with hot water.

Strontium molybdate resembles the barium salt in appearance, is practically insoluble in water, dissolving in 9600 parts at 17°. It is easily decomposed on heating, and is, therefore, not suitable for quantitative estimations.

Strontium tungstate behaves in the same way as the molybdate.

Calcium Molybdate.—The addition of calcium chloride to a cold, dilute solution of sodium molybdate does not cause a precipitate. On adding alcohol, or on heating the solution to boiling, a white, granular precipitate is at once obtained, which is somewhat soluble in water, and insoluble in alcohol. The quantitative estimation was carried out in the same way as for the barium salt, but although the filtrate contained molybdenum, the results were always too high. The following method was then employed:—The calcium molybdate was precipitated in boiling solution, and boiled until the precipitate became granular, cooled, one-third the volume of alcohol added, the mixture allowed to remain for some time, filtered, and the precipitate washed with dilute alcohol (1 : 3). The filtrate contained no molybdenum. On heating the precipitate in a platinum crucible to a strong, yellow heat, it loses weight, and, unless the heating is sufficient, high results are obtained.

Calcium tungstate resembles the preceding salt, but the quantitative results varied considerably.

Lead molybdate is a white, granular precipitate, in a moist condition soluble in nitric acid and sodium hydroxide; on heating, it acquires a yellow colour, and then is not attacked by the above reagents. With regard to the quantitative results, the authors confirm the results of previous observers.

Lead tungstate is a white, flocculent, finely-divided precipitate, extremely hard to filter, and insoluble in water. It is quite insoluble in ammonium nitrate, and the addition of this salt renders the filtration much easier. The quantitative results were good.

Silver tungstate and molybdate are at once precipitated on adding silver nitrate to solutions of the sodium salts. Silver tungstate is more finely divided and more difficult to filter than the molybdate. The latter is a white precipitate resembling silver chloride, distinctly soluble in water, easily soluble in nitric acid, potassium cyanide, and sodium hydroxide; on heating, it turns purple, and melts at a low temperature to a clear, yellow liquid. Silver tungstate is yellow, less soluble in water, melts at a higher temperature, and, on heating, turns dark-purple. These salts are not suitable for quantitative experiments, as they are soluble in water, and decompose on heating.

Cadmium molybdate is a heavy, granular salt, insoluble in water, and, when moist, soluble in ammonia, acids, and potassium cyanide, and, after heating, is still soluble in acids. Good quantitative results are obtained as follows:—The solution is precipitated with cadmium nitrate, collected on a Gooch's porcelain crucible, and, after drying, carefully heated.

Cadmium tungstate is obtained in a fine state of division, but is not difficult to filter. It resembles the molybdate, but, after heating, is not soluble in acids. The quantitative estimation is carried out in the same way as for the molybdate.

The authors point out that probably an estimation of molybdic and tungstic acids when mixed could be obtained by dividing the solution into two parts: in one part estimating the mixed acids as cadmium salts, and in the other part also precipitating as cadmium salts, then dissolving in potassium cyanide, and determining the cadmium electrolytically.

The bismuth salts are insoluble in water.

Cobalt molybdate is not formed either in cold dilute or concentrated solutions. By heating a concentrated solution of sodium molybdate with cobalt nitrate, a small quantity of a bluish-white precipitate is formed, which dissolves again on cooling.

Cobalt tungstate is violet-red, and is at once formed on adding cobalt nitrate to a solution of sodium tungstate. E. C. R.

Estimation of Antimony and its Condition of Oxidation. By F. A. Gooch and H. W. Gruener (*Amer. J. Sci.* [3], **42**, 213—220).—When antimonious oxide is treated with iodine in an alkaline solution, it passes into the higher state of oxidation. If, on the other hand, an acid solution of antimonic oxide is boiled with hydriodic

acid, iodine is liberated, and the antimony is reduced to the lower state of oxidation.

On these principles the authors have based the following process for the determination of antimony:—A weighed quantity of the antimony salt, corresponding with about 0·2 gram of Sb_2O_3, is titrated in presence of 1 gram of sodium tartrate and 20 c.c. of a saturated solution of sodium hydrogen carbonate, with N/10 iodine solution standardised against tartar emetic. The result of this titration gives the amount of Sb_2O_3. 4 grams of tartaric acid is then added to the liquid, and, if still alkaline, dilute sulphuric acid is added until the mixture is neutral. 10 c.c. of 50 per cent. sulphuric acid is now added, and also a little over a gram of potassium iodide. The liquid is diluted to 100 c.c., and boiled in an Erlenmeyer flask until the volume is reduced to 50 c.c. In order to prevent bumping, a platinum spiral is introduced, and to obviate mechanical loss, also a trap made of a two-bulb drying tube, cut short, and hung, large end downward, in the mouth of the flask. The faint colour still remaining after concentration is bleached by means of centi-normal sulphurous acid, and the solution nearly neutralised with sodium hydroxide; 20 c.c. of solution of sodium hydrogen carbonate is again added, and the liquid once more titrated with the standard iodine solution in the presence of starch. This titration gives, of course, the entire amount of antimony present. The difference between the indications of the two titrations gives the antimony in the higher state of oxidation. The process is accurate and rapid, as shown by many test analyses, and also extremely simple as regards manipulation. L. DE K.

Carbazole Method for Estimating Nitrates in Water Analysis. By W. P. MASON (*Chem. News*, **64**, 197).—The author, who is slightly disappointed with the delicacy and uniformity of results obtained by this process, points out the fact that cold solutions darken much more slowly than the warmer ones. In applying the process, the same precaution must be taken as when nesslerising for ammonia, namely, the standards and the solutions of unknown strength must be operated on at the same temperature. After the addition of strong sulphuric acid, the tube may be cooled immediately, or gradually, before the carbazole solution is added. The latter solution, which in a stoppered flask keeps for about 48 hours, acts best when its colour has changed to an olive-green. L. DE K.

Estimation of Nitrates in Water. By A. HAZEN and H. W. CLARK (*Chem. News*, **64**, 121—122, and 162—164).—The authors have examined the phenolsulphonic acid process of Grandval and Lajoux (Abstr., 1885, 1093), and find that it is not trustworthy, as the various nitrophenols which may be formed have colouring powers differing in intensity.

The aluminium process, however, yields more satisfactory results. 50 c.c. of the water is treated with 2 c.c. of 40 per cent. sodium hydroxide solution and 0·4 gram of aluminium foil, 0·12 mm. thick, and the whole is allowed to remain at the ordinary temperature for 24 hours. If the free ammonia is high, it must be distilled off before

adding the aluminium. A portion of the solution, varying from 1 to 25 c.c., according to the amount of nitrates present, is now diluted to 500 c.c. with water free from carbonic anhydride (prepared by passing steam through distilled water), and nesslerised in the usual way. It is found unnecessary, in most cases, to distil before nesslerising, as the water is sufficiently decolorised and clarified by the action of the hydrogen. The diluent water must be free from carbonic anhydride, as otherwise the liquid will become turbid with precipitated aluminium hydroxide. A correction is made for the volume of the sodium hydroxide solution, the ammonia carried off by the hydrogen, and the ammonia converted into nitrogen, the factor being 0·88 when the above quantities are used. The authors have experimentally determined the amount of ammonia carried off by the hydrogen, and find it to agree with the amount calculated from the gaseous laws. Albuminoïd matter is attacked by the hydrogen, part of it being converted into an amount of ammonia varying from 2 to 4 per cent. of the albuminoïd ammonia, but the quantity is negligible unless the latter is very high. JN. W.

Estimation of Volatile Oil in Copaiba. By R. A. CRIPPS (*Pharm. J. Trans.* [3], **22**, 193—194).—In a small weighed flask, 0·5 gram of copaiba is placed with about 5 c.c. of water. A regulated jet of steam is sent through the mixture, and, as the exit tube from the flask leads into a test tube immersed in cold water, any turpentine present can be immediately recognised by its odour. The exit tube is provided with a bulb, in which any resin mechanically carried over is arrested. In half an hour, the loss of weight, after drying the flask at 100°, represents all the volatile oil. R. R.

Examination of Spirits for Secondary Constituents. By A. H. ALLEN and W. CHATTAWAY (*Analyst*, 1891, 102—115).—The authors have devised the following process (a modification of Marquardt's method) for the estimation of fusel oil in commercial spirits, such as whisky:—As a preliminary step, any fixed matters must be removed, and any ethers and furfuraldehyde destroyed. 100 c.c. of the spirit is taken, 20 c.c. N/10 soda added, and the whole heated in a reflux apparatus for an hour. The contents of the flask are then distilled in the following manner:—A volume of 90 c.c. is allowed to pass over, the flame is then removed, and 30 c.c. of water is introduced into the distilling flask. The distillation is conducted until 20 c.c. more has been collected. The flask is allowed to cool, and 10 grams of sodium sulphate washed into it with 20 c.c. more water. If now the distillation be continued until another 20 c.c. has passed over, all the amyl alcohol will have been volatilised. The entire distillate is now diluted with brine until the density of the liquid is about 1·1, when it is shaken four times successively with carbon tetrachloride, using 40 c.c. the first time, then 20 c.c., and lastly, 10 c.c. The carbon tetrachloride now contains the amyl alcohol (and other fusel constituents), and, probably, some ethyl alcohol, which may be removed by agitation, first with brine, afterwards with a strong solution of sodium sulphate. The oxidation of the fusel oil may be

conducted in a closed bottle, or, more conveniently, using a reflux condenser. The oxidising mixture consists of 5 grams of potassium dichromate, 2 grams of strong sulphuric acid, and 10 c.c. of water. When a flask is used attached to a reflux condenser, the carbon tetrachloride should be kept in active ebullition for eight hours, the source of heat being a water-bath. After oxidising, the product is diluted with 30 c.c. of water and distilled over a naked flame until only 20 c.c. remains in the flask. 80 c.c. of water is now added, and the distillation continued until only 5 c.c. remains in the flask. The distillate will now contain the whole of the valeric acid, a portion being dissolved in the carbon tetrachloride, and the remainder in the aqueous fluid. The entire distillate is now titrated with N/10 barium hydroxide, using methyl orange as an indicator, and shaking thoroughly after each addition. If the carbon tetrachloride has, before use, been well purified by treatment with the oxidising mixture and redistillation, no more than 2 c.c. of the baryta solution ought to be required. Phenolphthaleïn is now added, and the titration continued, with frequent shaking, until the neutral point is again reached. Each c.c. of N/10 alkali used in the second stage of the titration corresponds with 0·0102 gram of valeric acid or 0·0088 gram of amyl alcohol. The neutralised aqueous fluid is now carefully separated from the carbon tetrachloride (which can be used again), evaporated to dryness at 130°, and the residual barium salt is weighed. After allowing for any barium chloride, which may be calculated from the alkali used in the first stage of the titration, the mean combining weights of the organic acids can be found as follows:—

$$\frac{\text{Milligrams of organic barium salt}}{\text{c.c. of N barium hydroxide}} \times 67{\cdot}5 = \text{combining weight of organic acid.}$$

The process gives very accurate results, providing the following points are rigidly observed:—

1. The carbon tetrachloride must be previously purified by treatment with chromic acid mixture and subsequent distillation over barium carbonate, and must be free from chloroform.

2. All corks used in distilling the spirit must be kept distinct from those employed in the distillation of the products of oxidation. They must be always carefully covered with tin-foil.

3. A few small fragments of pumice-stone should be added, in each case, to the contents of the distilling flasks. They should be treated with the chromic mixture before use.

4. The brine should be made from clean table salt, and rendered distinctly acid with sulphuric acid.

Qualitative and Quantitative Estimation of Furfuraldehyde.—Furfuraldehyde in spirits can be detected, and its proportion roughly guessed at, by the reaction of the sample with a solution of aniline in glacial acetic acid. Ten drops of aniline are dissolved in 2 c.c. of the acid, and the mixture added to 10 c.c. of the spirit to be tested. A red coloration, which increases in intensity after a time, shows the presence of furfuraldehyde. If a quantitative estimation is required, the authors proceed as follows:—

200 c.c. is distilled to about 20 c.c., when 50 c.c. of water is added, and the distillation continued until all but 10 c.c. has passed over. The distillates are mixed and divided into two equal parts, A and B. One portion, A, is titrated with N/10 soda, using phenolphthaleïn as indicator, and the free acid thus found calculated to acetic acid. The neutral liquid is treated with 20 c.c. of N/10 soda and boiled in a reflux apparatus for one hour, when the excess of alkali is ascertained by titrating with N/10 hydrochloric acid. The other portion, B, is treated with 1 c.c. of aniline and 1 c.c. of phosphoric acid of 1·442 sp. gr., and boiled in a reflux apparatus for at least two hours. It is then distilled to a low bulk, and the distillate neutralised and treated with 20 c.c. of N/10 soda, exactly as was done with the other portion. The difference between the alkali added and that found by titration represents that consumed by the saponification of the ether in 100 c.c. of the spirit; each c.c. represents 0·0088 gram of ethylic acetate.

The difference between the amounts of alkali required for the saponification of portions A and B represents the alkali which has reacted with furfuraldehyde, acetaldehyde, &c. Assuming only the first to be present, 1 c.c. of N/10 soda represents 0·0192 gram of furfuraldehyde.

One of the authors very much questions whether the presence of even an excess of amyl alcohol in whisky constitutes a danger to health. L. DE K.

Estimation of Glycerol, Astringent Acids, and Colouring Matter in Wine. By F. JEAN (*Analyst*, 1891, 56—57).—*Estimation of the Glycerol.*—250 c.c. of the sample is evaporated to the volume of 100 c.c., agitated with lead oxide, and then rendered slightly alkaline with baryta-water. The filtrate is neutralised with dilute sulphuric acid, concentrated to about 50 c.c. in a flat porcelain dish, and mixed with 5 grams of lead oxide, 10 grams of sand, and 20 grams of barium sulphate. The mass is cautiously dried at 100°, and the powdered residue extracted with a mixture of equal parts of alcohol and ether until the liquid measures 60 c.c. 30 c.c. is placed in a tared glass capsule, and 20 grams of dry litharge having been added, the whole is evaporated on the water-bath, and then dried to a constant weight at 105—106°. The other 30 c.c. is evaporated in a tared glass capsule of 6 cm. diameter, and finally dried in an air-bath at 160—170°. The difference in weight between residue No. 1 (after allowing for the litharge) and No. 2, multiplied by 8, and divided by 1·243, gives the number of c.c. of glycerol in 1 litre of wine.

Estimation of Astringent Acids.—(*a.*) *Œnontannin.* 250 c.c. of the sample is concentrated down to 100 c.c., shaken with excess of freshly precipitated arsenious sulphide, and then filtered. The filtrate is concentrated to 50 c.c., mixed with 10 grams of silica and 20 grams of barium sulphate, and finally dried at 100°. The residue is powdered and extracted with warm ether; the latter is evaporated, and the residue is dissolved in a little alcohol. Into this solution is now introduced a weighed quantity of dry, prepared, powdered hide, which will take up all the tannin in about half an hour. After

washing it with spirit, it is dried at 100° and reweighed. The increase in weight, multiplied by four, equals the œnontannin in 1 litre of the wine. (*b.*) *Œnogallic Acid.* The alcoholic filtrate is diluted with distilled water up to 100 c.c., and in 20 c.c. of this, the acid is estimated by means of a solution of iodine, previously standardised with gallic acid, as follows :—Two solutions are prepared, one containing 0·2 gram of iodine per litre, the other 0·125 gram of gallic acid in 250 c.c. of distilled water. Into a beaker, marked 50 c.c., is put 10 c.c. of the gallic acid solution and 3 c.c. of a saturated solution of sodium hydrogen carbonate. Iodine solution is now added from a burette until a drop of the mixture, tested on thick filter-paper dressed with powdered starch, leaves a stain surrounded by blue. Water is now added up to the mark, and iodine again added until a similar stain is obtained. Having thus standardised the iodine, it is used in a similar manner on the 20 c.c. of the alcoholic liquid, mixed with 3 c.c. of solution of sodium hydrogen carbonate. (*c.*) *Colouring matter.* 250 c.c. of the sample is slowly evaporated down to 100 c.c., rendered alkaline with ammonia, and shaken up with freshly-precipitated arsenious sulphide. After filtering, a slight excess of acetic acid is added, and the liquid once more filtered. The two filters containing the arsenious sulphide are, after washing, heated with spirit slightly acidified with acetic acid, which gradually dissolves out the colouring matter. The alcoholic solution is evaporated in a tared capsule, desiccated at 105°, and the residual colouring matter is weighed. L. DE K.

Estimation of Pentoses in Vegetables. By W. E. STONE (*Ber.*, **24**, 3019—3021).—The material under examination is heated in a retort with hydrochloric acid (sp. gr. 1·06) so that not more than 10 c.c. of distillate is obtained in five minutes, fresh acid being added from time to time. As soon as the distillate ceases to react with aniline acetate, the heating is suspended, and the distillate neutralised with soda, slight excess of acetic acid added, and the liquid diluted with water to a known volume. Portions of 25 c.c. are then mixed with phenylhydrazine solution, quickly boiled, rapidly cooled, and filtered, the filtrate being tested with alkaline copper solution; if it contains excess of phenylhydrazine, less is added in subsequent titrations; after three or four experiments, it is possible to determine the exact quantity of phenylhydrazine required, within 0·1 c.c.

The phenylhydrazine solution is made by dissolving 1 gram of phenylhydrazine hydrochloride, and 3 grams of sodium acetate in 500 c.c. of water, and is standardised by titration with a solution containing 1 gram of pure furfuramide and a little acetic acid in 1 litre of water. The phenylhydrazine solution changes after 24 hours.

Although this method does not give results which are theoretically correct, since part of the material is decomposed during distillation with the acid, the numbers obtained for the same substance are uniform, and the percentages of pentoses contained in different alimentary substances can be readily compared. J. B. T.

Estimation of Mixtures of Saccharose, Invert Sugar, and Dextrose or Levulose. By G. Wiechmann (*Analyst*, 1891, 15—33).—A direct estimation of saccharose in presence of dextrose and levulose has been proposed by Winter. This process, the accuracy of which is much doubted by the author (but which wants further investigation), is carried out as follows:—The sugar solution is mixed with a solution of lead acetate, to which ammonia has been added until a permanent precipitate threatens to form. An abundant white precipitate is formed, which is then digested with a large amount of water. The filtrate contains the sugar as a lead compound, from which the lead may be readily separated by a current of carbonic anhydride. The insoluble portion is suspended in water, and also treated with carbonic anhydride to liberate the dextrose. The insoluble mass, which still contains the levulose, will yield the latter on treatment with hydrogen sulphide.

Indirect processes, based on polarisation, do not always yield accurate results, as the polarimetric observations are too much influenced by a small change in temperature.

The author, who has made a large number of test analyses (without making any important alteration in the process), has proved the accuracy of the method proposed by Sieben, which is based on the following principle:—

The saccharose and dextrose + levulose are calculated from the copper-reducing power before and after inversion. Any levulose, whether naturally present, or formed from half the quantity of the saccharose during inversion, may be readily destroyed by prolonged boiling with excess of hydrochloric acid, and subequently determined from the diminished copper-reducing power. L. de K.

Estimation of Maltose, Dextrose, and Dextrin in Beer-wort and Beer by means of Ferment Organisms. By H. Elion (*Chem. Centr.*, 1891, ii, 281; from *Centr. Bakteriologie u. Parasitenkunde*, **9**, 525—528).—The author refers again to this method (Abstr., 1891, 368), and in proof of its validity, he points out that the reducing power of the sugar which disappears during fermentation and the amount of dextrose formed by hydrochloric acid from the same, almost exactly corresponds with the amount of maltose. At the same time, he admits that under the term "maltose" he includes also any other sugar which may have undergone fermentation, still the result is sufficiently exact for technical purposes. The author also objects to the use, as in Bau's experiments (*loc. cit.*), of *Saccharomyces apiculatus*, since its nature and fermenting qualities have not as yet been sufficiently examined. J. W. L.

Estimation of Cholesterol. By K. Obermüller (*Zeit. physiol. Chem.*, **16**, 143—151).—In the estimation of cholesterol in mixtures containing neutral fats, the sodium ethoxide method of saponification (Abstr., 1890, 1474) is found to cause no loss of cholesterol.

W. D. H.

Carbohydrates. By B. Tollens and others (*Landw. Versuchs-Stat.*, **39**, 401—453).—In the analysis of vegetable products by the usual

method, the fat, proteïds, insoluble fibre, and ash are estimated directly, and the difference between the sum of these components and 100 is returned as "extractive matter free from nitrogen." This extractive matter consists for the most part of carbohydrates, which can be estimated directly by means of Fehling's solution, after previous treatment with dilute acids; it contains, however, in many cases, a considerable proportion of substances which cannot be estimated in this manner, and for the detection and estimation of which suitable methods are greatly needed.

In the present paper, the author reviews the most important reactions of various carbohydrates, with reference to the analysis of vegetable products in general.

The levulinic acid reaction is first discussed, and it is stated that the formation of this acid, on boiling a substance with hydrochloric acid of sp. gr. 1·09—1·10 for 20 hours, may be considered as strong evidence of the presence of a true carbohydrate* (compare Wehmer and Tollens, *Annalen*, **243**, 315; Abstr., 1888, 535). The following substances give the levulinic acid reaction:—Cane sugar, dextrose, levulose, inulin, gum-arabic, filter-paper, fir-wood, starch, Carragheen moss, levulin, lactose, galactose, raffinose, irisin, mannose, sorbin, the glucosides salicin and amygdalin, potato-juice, and chondrin. It must be borne in mind that even in the case of a true carbohydrate only a small quantity of levulinic acid is formed, and that the isolation of the acid is by no means an easy matter; consequently an unsuccessful attempt to obtain the levulinic acid reaction only shows the absence of any considerable quantity of a true carbohydrate.

Having ascertained in this way the presence of a true carbohydrate, its isolation and identification have next to be considered.

In the case of dextrose, or of substances such as lactose, raffinose, salep-juice, &c., which yield dextrose, the presence of this sugar can be easily proved by oxidising the substance with nitric acid (compare Gans and Tollens, *Annalen*, **245**, 215; Abstr., 1888, 1059); the formation of saccharic acid under these conditions is a proof of the presence of dextrose, or of dextrose-groups. Inulin, sorbin, arabinose, galactose, mannose, and quince-juice† do not give the saccharic acid reaction.

The formation of mucic acid on oxidation with nitric acid (compare Creydt and Tollens, Abstr., 1886, 582) may be taken as a proof that a substance contains galactose or galactose groups; it has been shown that this acid is obtained from galactose, lactose, raffinose, and Carragheen moss, and also from the "sulphite-liquors" of the wood-cellulose process (compare Weld, Lindsay, Schnelle, and Tollens, Abstr., 1891, 43). The quantity of raffinose in molasses can, in fact, be determined by estimating the mucic acid produced on oxidation (compare Creydt, Abstr., 1887, 307). There is no reaction by which the presence of levulose, or of levulose groups, in a vegetable product

* *Note by Abstractor.*—The term "true carbohydrate" seems to apply only to the hexoses, and to compounds such as starch, inulin, &c., which yield hexoses on hydrolysis.

† *Note by Abstractor.*—Quince-juice, according to Bauer (see p. 128), yields dextrose on hydrolysis.

can be satisfactorily determined; the readiness with which this sugar undergoes decomposition on heating with sulphuric acid, or dilute hydrochloric acid, yielding brown solutions, may, however, serve as a means of distinguishing it from dextrose; Seliwanoff's colour reaction (Abstr., 1887, 459) is also to be recommended in particular cases.

Mannose can be readily detected by warming a dilute solution of the substance under investigation with phenylhydrazine acetate; its presence is shown by the formation of a crystalline hydrazone (m. p. about 188°). As this sugar is usually present in vegetable products in a combined form, the substance must first be heated with 3 per cent. hydrochloric acid for some hours. The presence of mannose in the "sulphite-liquors" from the wood-cellulose process is easily proved by means of the phenylhydrazine reaction; the sugar can be conveniently prepared by decomposing the hydrazone with concentrated hydrochloric acid.

The pentoses, arabinose, and xylose, although closely related to the hexoses, differ from the latter in possessing certain characteristic properties by which their presence in a given vegetable product can be easily proved. They do not give the levulinic acid reaction, but when distilled with hydrochloric or sulphuric acid they yield a distillate which contains furfuraldehyde; the presence of this compound can be easily ascertained by the red coloration which is produced on the addition of aniline or xylidine (compare Schiff, Abstr., 1887, 571). As, however, the hexoses give traces of furfuraldehyde under the same conditions, the presence of pentoses must not be regarded as definitely established unless the reaction is very marked, or unless the furfuraldehyde is determined quantitatively by means of phenylhydrazine (compare Chalmot and Tollens, Abstr., 1891, 768). The pentoses also give a characteristic red colour with phloroglucinol and with orcinol, in presence of hydrochloric acid. It must be borne in mind that glycuronic acid and its derivatives give all the reactions of the pentoses.

A very complete account of the occurrence, properties, and methods of estimation of the pentoses is given, but all the principal facts dealt with have formed the subject of previous papers by the author and others (compare Abstr., 1891, 43, 659, 768). F. S. K.

Valuation of Oil of Cloves. By H. Thoms (*Pharm. J. Trans.* [3], **22**, 450, 451).—Assuming that the quantity of eugenol in oil of cloves can be taken as a measure of the value, the author proposes to separate the eugenol directly from the oil in the form of benzoyleugenol, by mixing the oil with solution of sodium or potassium hydroxide, and then adding an equivalent of benzoic chloride. Crystalline benzoyleugenol separates as the mixture becomes cold, is recrystallised several times from hot alcohol, washed with alcohol at 17°, and weighed dry on a filter, allowance being made for its solubility (0·55 gram in 25 c.c. of 90 per cent. alcohol). From the weight of benzoyleugenol, the quantity of eugenol present in the oil can be calculated. R. R.

Examination of Vinegar. By W. J. Sykes (*Analyst*, 1891, 83—87).—The author thinks that considerable information may be gathered from an examination of the nitrogenous constituents of a vinegar, as to whether it is genuine or not; but the fixing of limits must naturally be reserved until a long series of experiments have been performed in this particular direction.

Albumoses may be estimated by precipitation with a saturated solution of ammonium sulphate. Peptone may be precipitated in the filtrate by the cautious addition of a solution containing 4 grams of tannin in 190 c.c. of proof spirit mixed with 8 c.c. of dilute acetic acid. Pure malt vinegar should also give a turbidity with phosphotungstic acid, or potassium bismuthoiodide, or potassium mercuroiodide. L. de K.

Adulteration of Beeswax. By A. and P. Buisine (*Bull. Soc. Chim.* [3], **5**, 654—660).—Amongst the substances used to adulterate beeswax, the most conspicuous and common are those indicated in the accompanying table. Although the influence of some of these on the physical character of the wax is extremely marked, others, by judicious selection, can be so combined as to imitate it, not only in its physical characteristics, but also in its behaviour under the methods of analysis at present in use.

The authors propose, in addition to the usual estimation of free and combined fatty acids, to determine the unsaturated fatty acids, the free hydrocarbons, and the alcohols present in the sample, as well as its melting point and density.

The sample, dried at 110°, at which temperature it should not lose more than 1 per cent. of its weight, should leave no residue of mineral adulterants on treatment with hot chloroform or turpentine. The melting point and density of the original sample should correspond with those of beeswax. Any serious adulteration will be rendered evident by this procedure, and will necessitate further examination to determine its nature and amount. To estimate the soluble fatty acids, an excess of which indicates the presence of vegetable waxes, and to detect soluble colouring matter such as turmeric and annatto, 20 grams of the sample is extracted with hot water. The dried residue is utilised for the determination of the free and total fatty acids, the unsaturated acids (by iodine absorption), the alcohols (by the amount of hydrogen liberated by alkalis), and the free hydrocarbons.

The nature and approximate amount of the adulterants are then determined, in the manner already indicated, by reference to the appended table (see next page), which embodies the results obtained by the examination of the various adulterants known to be in use.

General and Physical Chemistry.

Measurement of Light Intensity by the Expansion of Chlorine. By A. Richardson (*Phil. Mag.* [5], **32**, 277—284).—The author has confirmed Budde's observation (*Phil. Mag.*, 1871) that when chlorine is exposed to sunlight an expansion of the gas occurs, which is independent of direct heating effects due to the light; and that the volume to which the gas first expands is maintained during exposure, provided that the intensity of the light remains constant, contraction to the original volume taking place when the gas is shaded.

In order to compare the expansion obtained in this way with the light intensity, as determined by means of a Bunsen and Roscoe's pendulum actinometer, a differential apparatus was constructed, consisting of two tubes of 55 c.c. capacity and 10 cm. in length, which were connected with a graduated horizontal gauge, provided with a small bulb at each end. The gauge and bulbs contained strong sulphuric acid, a short column of air serving as index. The tubes to be exposed were suspended in a box, which could be placed at any required angle to face the sun, and when filled with dry air were found to be equally heated. One tube was then filled with dry chlorine, and the acid, up to the index, was saturated with this gas. The bulbs containing the acid were in all cases protected from the light. When the maximum expansion of the chlorine was reached at any one time, as shown by the index remaining stationary, the light intensity was measured. A comparison of the numbers thus obtained showed that the change in volume of the chlorine is very nearly proportional to the actinic intensity of the light, as given by the actinometer.

Experiments were also made with mixtures of chlorine and air. The effect of dilution with air is at first very marked, diminishing after a time, but finally increasing when only a small proportion of chlorine remains. It was found that the expansion of chlorine by light is unaffected by change of temperature within a range of from 14° to 138°.

The author finally constructed an automatic registering apparatus for measuring light intensity. This was done by suspending a differential apparatus on the beam of a balance in such a manner that the flow of acid from one arm to the other produced a movement of the beam, which was communicated by means of a lever to a pen, and was recorded on a rotating drum. This instrument will record continuously the actinic intensity of the light under all conditions of weather throughout the year. J. W.

The Application of Ketteler's Formulæ to Optical Chemistry. By R. Nasini (*Rend. Acad. Linc.*, **6**, ii, 324—331).—The author compares Ketteler's formula, $M = (n^2 - 1)(v - \beta)$ (Abstr., 1889, 326),

with those of Lorenz and Lorentz, Gladstone and Landolt, and points out that the constants β and M vary much in value under different conditions of temperature and pressure. Thus, for α-bromonaphthalene, the value of β between 16·5° and 28·1° is 0·03226, between 28·1° and 77·6° 0·15966, and the mean value between 16·5° and 77·6° is 0·13620, the numbers being for infinite wave-length. A small change in the index of refraction makes an enormous difference in the values of β and M, and as the index of a substance varies somewhat with different samples, each as pure as possible, the values calculated for β and M are very discordant, and hence of little value in optical chemistry. Ketteler's formulæ, although of great theoretical interest from a purely physical point of view, cannot be advantageously applied to optical chemistry, simply because the experimental data are not sufficiently exact. W. J. P.

Rotatory Power of Silk. By L. Vignon (*Compt. rend.*, **113**, 802—804).—Silk may be expected to act on polarised light, as it readily yields leucine and tyrosine on hydrolysis. Attempts to find a suitable solvent for the material as a whole proving unsuccessful, the two chief constituents were examined separately.

The colouring matter of the silk of *Bombyx mori* having been extracted by repeated treatment with hot alcohol acidified with hydrochloric acid, the skein is plunged into cold 3 per cent. aqueous soda solution, which dissolves the enveloping material, but leaves the matrix or fibroïn untouched. The rotatory power of a yellowish, limpid solution thus obtained was $[\alpha]_j = -39·2°$.

To prepare the fibroïn for examination, the silk is boiled twice with 10 per cent. soap solution, the soap being washed away with water after each boiling; it is then washed with acidified water (0·1 per cent. of hydrochloric acid), and finally with alcohol. The white substance thus obtained is dried and dissolved in moderately strong hydrochloric acid. A clear, dilute solution prepared in this way showed a rotatory power of $[\alpha]_j = -40°$, which was not materially altered by further dilution, or by the addition of excess of ammonia.

The rotatory powers of the two chief constituents of silk are, therefore, practically identical, and are of the same sign as those of the proteïds. Jn. W.

Changes of Voltaic Energy of Alloys during Fusion. By G. Gore (*Phil. Mag.* [5], **32**, 27—31).—Regnauld (*Chem. News*, **38**, 33) observed that liquid gallium is electropositive to solid gallium in a neutral solution of gallium sulphate. The author has made corresponding observations with various alloys. A glass dish and a tobacco pipe with a wide bowl were partially filled with a conducting liquid (solution of hydrogen chloride or sodium chloride), and connected by means of a siphon. A rod of the solid alloy was placed in the cup, and a second portion was melted in the bowl of the pipe. Connection was made through a galvanometer by means of iron wires. The alloy in the bowl was alternately heated and cooled, the galvanometer being observed in order to ascertain if there was any deflection of unusual magnitude when the temperature passed the melting point

of the alloy. As most of the alloys employed did not melt sharply, no very sudden deflection was noted, but in the case of an amalgam of 1 part of cadmium and 4 parts of mercury in a solution of sodium chloride, there was a sudden reversal of the current when the amalgam completely liquefied, the liquid being electronegative to the solid at this point. J. W.

Electromotive Forces of Metallic Salts. By C. L. Speyers (*Amer. Chem. J.*, **13**, 472—486).—In continuation of previous work (Abstr., 1890, 843), the difference of potential between mercury and copper, iron, and tin has been measured in various electrolytes in ten different states of concentration, varying from molecular proportion (gram-litre) to $\frac{1}{512}$ molecular proportion, each solution having one-half the concentration of the preceding. The metals were used in the state of amalgam wherever practicable. In the case of copper, the electrolytes were hydrochloric, nitric, acetic, and sulphuric acids, alone and in pairs; the copper salts of these acids, with the exception of the chloride, which attacked the mercury; pairs of these salts, namely, nitrate with acetate and sulphate, and acetate with sulphate; mixtures of the salts with acids, namely, the nitrate, acetate, and sulphate with nitric, acetic, and sulphuric acids; and, finally, the zinc salts of the same acids. In the case of iron, the same series of electrolytes was used, with the addition of the metallic chlorides, ferrous and ferric salts being substituted for copper salts. In the case of tin, the electrolytes used were the above acids, alone or in pairs; the chlorides, alone, or mixed with acids; the above-mentioned zinc salts, and the corresponding ferric salts.

The general conclusions which the author deduces from the numerous data thus obtained are: That the electromotive force increases, as a rule, with dilution; that in solutions containing hydrochloric acid it is lower than in those containing the other acids, and is not materially affected by the admixture of those acids or of metallic salts; that in solutions containing different pairs of metallic and acid radicles it is only slightly greater than in the solutions of the pair yielding the lower value; and that it is lessened by substituting copper, stannous tin, or, in the case of chlorides, ferrous iron for hydrogen, but is practically unaffected by the substitution of stannic tin.

The increase of electromotive force with dilution may be explained by means of the dissociation hypothesis, if the assumption is made that the mean free path of the ions is increased by dilution, so that the ions have less influence on one another, and give up, therefore, more electricity to their respective electrodes.

A theory of chemical affinity, which is proposed, is based on the non-conductivity of the non-metals. The atoms of these are supposed to contain a constant amount of negative electricity, neglecting artificial surface charges, whilst the metallic atoms contain positive, or both positive and negative, electricity, the total quantity, however, being constant. When an atom of a non-metal comes in contact with a metal, its charge attracts the positive charge of the latter, and, as it cannot unite with it, a portion of the metal is detached, and a com-

pound formed, the stability of which depends on the completeness of the internal insulation of the negative ion and the magnitude of the positive charge of the positive ion. This explains the weakness of the combinations of metals with metals, and non-metals with non-metals, and the strength of those of metals with non-metals.

The lowering effect produced on the electromotive force by stannous tin, and to a less general extent by ferrous iron, may be explained in accordance with the above hypothesis, by supposing that the negative electricity in the non-conducting ion is inextricably entangled with the matter. The initial action of the ion on the metal is to dislodge and combine with a portion of the latter containing unit positive charge, and a molecule of an *ous* compound is formed; this, however, meets with more negative ions, and gives up part of its positive charge to one of them, so that 2 molecules of the *ic* compound are formed. Since the negative electrode is charged with negative electricity by the negative ions, and partially discharged by the positive ions, it follows that when the *ic* compound is present, the charge removed is less, and the potential of the electrode numerically greater than when the *ous* compound is present. Jn. W.

Influence of Boric Acid on the Electrical Conductivity of Aqueous Solutions of Organic Acids. By G. Magnanini (*Gazzetta*, **21**, ii, 215—228).—It has been previously shown (*Gazzetta*, **20**) that the electrical conductivity of solutions of tartaric acid is sensibly increased by the addition of boric acid and is to some extent dependent on the dilution and the quantity of boric acid used; this behaviour was explained by assuming the formation of a combination of the two compounds which has electrolytic properties and is partially dissociated by water. In the present paper, the results of a series of experiments on the influence of boric acid on the electrical conductivity of aqueous solutions of acetic, benzoic, butyric, succinic, crotonic, salicylic, lactic, glyceric, gallic, amygdalic, and glycollic acids are described. There is a marked difference between the behaviour of hydroxy- and other acids, the conductivity of solutions of the former being materially increased by the addition of boric acid even in very dilute solutions; this increment rises with the quantity of boric acid added, but falls on dilution; it varies considerably with the nature of the acid under observation. Solutions of hydroxyisobutyric, pyrocatechuic, malic, and citric acids similarly show an increase of conductivity on the addition of boric acid, whilst pyruvic, dehydracetic, formic, oxalic, valeric, monochloracetic, levulinic, camphoric, and aspartic acids, which do not contain the hydroxyl group in their acid radicles, exhibit no such increase. This behaviour may possibly be of use in deciding as to the presence of an hydroxyl group in organic acids.

The electrical conductivity of aqueous solutions of resorcinol, quinol, phenol, ortho- meta- and para-cresol, guaiacol, and phloroglucinol is only very slightly increased by the addition of boric acid; on the other hand, that of solutions of catechol, and more especially of pyrogallol, is considerably increased. The author believes this to be due to the presence and position of the hydroxyl

group in these compounds, and proposes to investigate the behaviour of polyhydric phenols containing two hydroxyl groups in ortho-position in this respect. S. B. A. A.

Some Points on Electrolysis. By J. Swinburne (*Phil. Mag.* [5], **32**, 1—9).—The author considers a one-fluid reversible cell, with its external circuit closed through a resistance so high that, in comparison, the internal resistance is negligible. A coulomb passing through the cell has work done on it numerically equal to the electromotive force E. At the electrodes p and n there is chemical action, c, and local heating, h, so that as there is assumed to be no work done in overcoming the resistance of the electrolyte, $E = E_{pc} + E_{nc} + E_{ph} + E_{nh}$. The seat of E.M.F. is here supposed to be in the cell and not at the metallic junction outside.

If the chemical work is assumed to be independent of the temperature of the cell, it can be shown from the above equation that $E = E_{nc} + E_{pc} + \theta \frac{dE}{d\theta}$, when θ is the temperature (Helmholtz's equation). The author further shows how the Peltier effect at each contact in the cell can be obtained separately. When there is any secondary or "non-adjuvant" action, the cell is not reversible. The formation of lead sulphate on both plates of a secondary battery is considered by the author to be a primary reaction (that is, there is no intermediate formation of lead monoxide) and the cause of the activity of the cell.

His views of nascent action are as follows:—Sodium amalgam in dilute acid gives off hydrogen, and will reduce a ferric salt to the ferrous stage. This reduction he does not attribute to the action of "nascent" hydrogen. A better explanation would be that the metal can dissolve if it *either* reduces the ferric salt *or* evolves hydrogen. "Evolution of hydrogen and reduction of the salt are thus alternate, not consecutive, results. Similarly, in an engine, the steam either works the engine or comes out at the safety-valve; it does not begin to lift the safety-valve, and then change its mind and work the engine in a nascent state." J. W.

Relation of E.M.F. to Latent Heat, Specific Gravity, &c., of Electrolytes. By G. Gore (*Phil. Mag.* [5], **32**, 157—168).—In order to ascertain whether, in cases where the mixture or dilution of electrolytes is attended by a heat-effect, a change in the power of exciting electromotive force occurs, the author took various pairs of solutions (or one solution and pure water) at the same temperature, measured the E.M.F. of a cadmium-platinum couple in each liquid separately, then mixed the liquids, observed the temperature of the mixture, and, after allowing the liquid to acquire the former temperature, measured the E.M.F. of the couple in it. This E.M.F. he then compared with the mean value of the E.M.F. in the liquid before mixture. The results are contained in the following table. The solutions of the chlorides of sodium and potassium were measured with a zinc-platinum couple:—

Mixture.	Change of temperature in degrees centigrade.	Change in E.M.F.
Na_2SO_4 solution + dil. H_2SO_4	− 0·66	+0·0401
CH_3·COOH + water.....	− 0·9	+0·0730
Tartaric acid solution + water	− 0·16	+0·1923
NH_4NO_3 ,, ,, ...	− 4·44	+0·0400
$NaNO_3$,, ,, ...	− 1·42	+0·1228
$Sr(NO_3)_2$,, ,, ...	− 1·08	+0·0741
NaCl ,, ,, ...	?	+0·0668
Na_2SO_4 ,, ,, ...	− 0·14	+0·0359
$(NH_4)_2SO_4$,, ,, ...	− 0·14	+0·0402
Na_2CO_3 ,, ,, ...	− 0·28	−0·0445
KNO_3 ,, ,, ...	− 0·54	+0·0715
NH_4Cl ,, ,, ...	− 0·19	+0·0345
CH_3·COONa ,, ,, ...	+ 0·14	+0·0360
$MgSO_4$,, ,, ...	+ 0·22	+0·0787
KCl ,, ,, ...	+ 0·04	+0·1219
NaOH ,, ,, ...	+ 7·14	+0·0298
HCl ,, ,, ...	+ 2·38	+0·2872
H_2SO_4 ,, ,, ...	+11·00	+0·2375
KOH ,, ,, ...	+ 0·02	+0·0150
NH_3 ,, ,, ...	+ 0·10	+0·0040

Special experiments were also made on the contraction of salt solutions and water. The author concludes that "in cases of mere physical mixture, the changes of mean specific gravity and of mean electromotive force of electrolytes are probably related to each other as concomitant effects of the same cause, change of molecular motion."

J. W.

Specific Inductive Capacity and Latent Heat of Vaporisation. By E. Obach (*Phil. Mag.* [5], **32**, 113—127).—From a consideration of the specific inductive capacities published by Tereschin (*Ann. Phys. Chem.* [2], **36**, 792) and the heats of vaporisation observed by Schiff (*Annalen*, **234**, 338), the author finds a relation between these two magnitudes for members of various homologous series. In any one series, the quotient of the latent heat of vaporisation, λ, by the specific inductive capacity, K, is practically constant. Thus, for the ethereal salts of acetic acid the following values of λ/K are obtained :—

	Methyl.	Ethyl.	Propyl.	Isobutylyl.	Amyl.
$\frac{\lambda}{K}$	12·0	12·8	12·3	12·1	12·8

The mean value of the ratios for the corresponding formates is 9·83, and that of the benzoates, 10·33. Monatomic alcohols give a mean ratio of 7·56, and ethyl salts of the acetic series, 12·42.

The relation thus obtained in homologous series may be combined with other similar relations. For example, Trouton gives $\lambda = C\frac{T}{M}$,

where T is the boiling point in the absolute scale, M the molecular weight, and C a constant. If we make $\lambda = \gamma K$ and introduce this value in the equation, then $\gamma K = C\frac{T}{M}$, or $KM = CT$; that is, in any series the boiling points in the absolute scale are proportional to the molecular inductive capacities. Similarly, by making use of De Heen's results, it follows that the coefficient of expansion at 0° is inversely proportional to the molecular inductive capacity.

The ratio λ/K for ethyl oxide is 20·8; for carbon tetrachloride, 21·0; for carbon bisulphide, 33·0; and for oil of turpentine, 31·1.

J. W.

Change of the Empirical and Theoretical Isothermals of Mixtures of two Substances with the Temperature. By A. Blümcke (*Zeit. physikal. Chem.*, **8**, 554—565).—The method which the author has employed in a former paper (Abstr., 1891, 375) for tracing the connection between the empirical and theoretical isothermals of mixtures is still further extended, the effect of change of temperature on the relation between the isothermals of mixtures of two substances being here considered. H. C.

Thermal Expansion of Liquid Bismuth. By C. Cattaneo (*Rend. Acad. Linc.*, **7**, ii, 88—93).—Vincentini (*Atti R. Ac. Torino*, **22**, 1886) stated that liquid bismuth has a maximum density at its point of solidification. This was contested by Lüdeking (Abstr., 1888, 790), who found the temperature of maximum density to be a few degrees above the melting point. The author confirms Vincentini's statement by observing the expansion of an amalgam of bismuth prepared by dissolving the metal in an equal weight of mercury. The experiments were conducted in dilatometers holding about 220 grams of the amalgam, those used by previous experimenters being much smaller. The saturation temperature of the amalgam was 162·7°, and the density was measured between 236° and 279°. On examining the curve obtained by plotting densities against temperatures, no breaks could be detected, the curve being practically a straight line. The author therefore concludes that liquid bismuth has a maximum density at its solidifying point. The density of liquid bismuth at various temperatures is given below:—

t.	Density of liquid Bi.	*t.*	Density of liquid Bi.
235°	10·248	260°	10·224
240	10·243	265	10·219
245	10·239	270	10·214
250	10·233	275	10·209
255	10·229	280	10·205

W. J. P.

Calculation of the Boiling Points of Normal Isomeric Ethereal Salts of the Fatty Series. By G. Hinrichs (*Compt. rend.*, **113**, 798—800).—The boiling points of the normal fatty ethereal salts having the general formula $C_pH_{2p+1}\cdot C_qH_{2q-1}O_2$ are plotted out in curves, the ordinates of which are proportional to the logarithms of the maximum moments of inertia of the molecules (*Compt. rend.*, **76**, 1592; **112**, 1128), and the abscissæ proportional to p, that is, to the length of the alkyl chains. Four different curves are thus obtained, corresponding to the four values 6, 7, 8, 9 of $p + q$, and the actual boiling points fall very fairly on them (compare Abstr., 1891, 1406, 1408, 1441; this vol., p. 2). Jn. W.

Calorimetry. By P. Mahler (*Compt. rend.*, **113**, 774—776).—The author has devised a cheap, efficient, and durable modification of Berthelot's calorimetric bomb, suitable for use in industrial and ordinary laboratories. The chief alteration is in the combustion chamber, which, instead of consisting of platinum, is made of mild steel, forged and turned to a suitable shape, and enamelled inside. The mouthpiece is closed by a screw stopper packed with a lead washer. The substance under examination is supported and ignited by apparatus attached to the stopper, and the oxygen for the combustion is supplied at a pressure of 25 atmospheres from an ordinary pressure cylinder through a stopcock screwed into the stopper. The calorimeter and agitator are constructed on the original model, with slight modifications to reduce the cost. Trial determinations of the heat of combustion of naphthalene gave good results. The apparatus is adapted for the study of furnace and other gases. Jn. W.

Thermal Constants of Active Malic Acid and Potassium and Sodium Malates. By G. Massol (*Compt. rend.*, **113**, 800—801).—The heat of solution of anhydrous malic acid is −3·31 Cal., whilst that of the monopotassium and dipotassium salts is −5·78 Cal. and +1·55 Cal., and that of the corresponding sodium salts −1·66 Cal. and +1·78 Cal. respectively.

The heat of neutralisation of the acid and of the hydrogen alkali salts is +26·23 Cal. and +12·85 Cal. with potash, +24·86 Cal. and +12·46 Cal. with soda.

The heat of formation of the solid salts from the solid acid and base, as calculated from the above data, allowing for the formation of solid water, is +29·74 Cal. and +49·15 Cal. for the monopotassium and dipotassium salts, and +22·02 Cal. and +42·12 Cal. for the corresponding sodium salts.

Dipotassium and disodium malates, prepared by neutralising the anhydrous acid with alcoholic alkali, and heating the dried products at 120° in a current of hydrogen, may be crystallised, contrary to the assertion of Kammerer (*J. prakt. Chem.*, **88**, 321), by dissolving in water, evaporating to a syrup, powdering the surface with a little of the anhydrous salt, and keeping over sulphuric acid for some months. *Dipotassium malate* crystallises in small needles, which are scattered through a firm, pasty mass. *Disodium malate* forms long, prismatic needles containing $\frac{1}{2}$ mol. H_2O. *Monopotassium and monosodium*

malates crystallise readily with 1 mol. H_2O, which is slowly lost at 120°. JN. W.

Heat of Formation of Hydrazine and Hydrazoic Acid. By BERTHELOT and MATIGNON (*Compt. rend.*, **113**, 672—679).—Hydrazine sulphate, N_2H_4,H_2SO_4, prepared by Curtius, was employed. Heat of dissolution at 10·8° = −8·7 Cal. The heat of neutralisation was determined (1) by exact precipitation with barium hydroxide, and (2) by direct addition of dilute hydrochloric acid to the solution of the free base left after separation of the barium sulphate.

H_2SO_4 diss. + N_2H_4 diss. = N_2H_4,H_2SO_4 diss.	develops	+11·1 Cal.
H_2SO_4 sol. + N_2H_4 diss. = N_2H_4,H_2SO_4 cryst.	,,	+36·0 ,,
2HCl dil. + N_2H_4 diss. = N_2H_4,2HCl. diss.	,,	+10·4 ,,

Hydrazine is a feeble base, like ferric oxide, and its heat of neutralisation is less than that of ammonia (+12·4 Cal. per equiv.) or even hydroxylamine (+9·3 Cal.).

The heat of combustion was determined in the calorimetric bomb, the salt being mixed with a known weight of camphor.

N_2H_4,H_2SO_4 cryst. + O_2 + Aq = H_2SO_4 dil. + N_2 + $2H_2O$	develops	+127·7 Cal.

and consequently—

S (octah.) + O_4 + H_6 + N_2 = N_2H_4,H_2SO_4 cryst.	,,	+220·3 ,,
N_2 + H_4 + Aq = N_2H_4 diss.	,,	− 9·5 ,,

The formation of hydrazine is endothermic; its conversion into ammonia by loss of hydrogen and nitrogen is exothermic, and so likewise is its direct conversion into ammonia by combination with hydrogen.

N_2H_4 dil. = NH_3 dil. + N + H	develops	+25·75 Cal.
$3N_2H_4$ dil. = $4NH_3$ dil. + N_2	,,	+32·75×3 ,,
N_2H_4 dil. + H_2 = $2NH_3$ dil.	,,	+51·5 ,,

It is clear that the direct conversion of ammonia into hydrazine is not possible without the intervention of oxidising actions; but, on the other hand, the compound may be obtained by the carefully regulated oxidation of hydrogen compounds of nitrogen and the amides and nitrates derived from them, or by the reduction of oxygen compounds of nitrogen and nitro- or azo-derivatives.

It is noteworthy that the endothermic character of the nitrogen hydrides diminishes as the saturation with hydrogen becomes more complete, and this has already proved to be the case with the oxy-acids of nitrogen and the hydrides of carbon, thus: HNO dil. −28·7 Cal., HNO_2 dil. −4·2 Cal., HNO_3 dil. +14·3 Cal., and C_2H_2 −60·4 Cal., C_2H_4 −14·8 Cal., C_2H_6 +25·2 Cal.

Hydrazoic Acid.—The experiments were made with the ammonium salt supplied by Curtius. Heat of dissolution (N_3H,NH_3) at 11° =

−7·08 Cal. Heat of neutralisation by baryta +10·0 Cal., by ammonia +8·2 Cal. Hydrazoic acid is therefore comparable to amidobenzoic acid in the energy of its acid function. Heat of combustion (in the calorimetric bomb, both with and without camphor) at const. vol. = +163·8 Cal.; at const. press. +163·3 Cal.

$N_4 + H_4 = N_3H,NH_3$ cryst.	develops	−25·3 Cal.
$N_4 + H_4 = N_3H,NH_3$ diss.	„	−32·3 „
$N_3 + H + Aq = N_3H$ diss.	„	−61·6 „

Hydrazoic acid is the most endothermic of the nitrogen hydrides. It is most probably ammonia in which two atoms of hydrogen have been displaced by a molecule of nitrogen, $NH{:}N_2$, the substitution of the electronegative nitrogen for the hydrogen conferring upon the compound its acidic properties. C. H. B.

Formation of Salts in Alcoholic Solution. By C. M. van Deventer and L. T. Reicher (*Zeit. physikal. Chem.*, **8**, 536—542; compare Abstr., 1890, 553).—Continuing their investigations on the heats of formation of metallic salts in alcoholic solution, the authors have measured the heats of neutralisation of sodium and potassium ethoxides by a number of acids in the presence of an excess of alcohol. The salts formed, with the heat evolved in each case, are given in the following table:—

Sodium acetate....	7·3 Cal.	Sodium chloride ..	11·2 Cal.
Potassium acetate .	7·5 „	Sodium bromide...	12·4 „
Potassium biacetate	7·8 „	Sodium iodide.....	11·2 „
Sodium benzoate ..	6·45 „		

The authors propose to continue their investigations with other acids and bases. H. C.

Critical Temperatures of Mixed Liquids. By G. C. Schmidt (*Annalen*, **266**, 266—292).—The author has determined the critical temperatures of a number of mixtures of two liquids in order to test the validity of Pawlewski's formula $\vartheta m = \frac{n\vartheta + (100 - n)\vartheta'}{100}$ (compare *Ber.*, **15**, 460 and 2460).

In the place of the air-bath described by Galitzine (*Ann. Phys. Chem.* [2], **41**, 623), the author employed a beaker, 250 mm. in height and about 60 mm. in diameter, which was half filled with paraffin; the liquid was contained in a small sealed tube which was attached to a thermometer placed in a paraffin-bath; the temperature at which the liquid completely disappeared and the temperature at the moment of the reappearance of the meniscus were both noted. Very good results are obtained with this apparatus, but it can only be employed for temperatures below 260°, as the paraffin darkens very rapidly when heated more strongly.

The experimental values obtained in this way were in some cases rather greater, in others rather less, than those calculated by Pawlewski's formula, the maximum difference being 3·9°; as, in the

case of any particular mixture, the differences were, as a rule, either all positive or all negative, it would seem that Pawlewski's formula is not quite accurate; it is possible, however, that the deviations from the calculated values are due to a slight decomposition of one or both liquids.

The observed and the calculated critical temperatures of the mixtures are given in tables. F. S. K.

Vapour Pressure of Aqueous Solutions of Cobalt Chloride. By G. Charpy (*Compt. rend.*, **113**, 794—795).—The curve showing the variation of the vapour pressure of 32 per cent. aqueous cobalt chloride with the temperature comprises two approximately rectilinear portions, one ranging from 20° to 40°, and corresponding with the red solution, the other ranging above 75° and corresponding with the blue solution. The intermediate portion is curved. These facts point to the existence of two stable modifications of the salt, perhaps hydrates or other molecular aggregates. The curve is similar to that obtained by Étard from a consideration of the solubility of the chloride, but the intermediate limiting temperatures are not the same, those observed by Étard being 35° and 50°; this, however, is probably accounted for by the fact that he dealt throughout with saturated solutions. Jn. W.

Pressure and Specific Volume of Saturated Vapours. By C. Del Lungo (*Rend. Acad. Linc.*, **7**, i, 141—145).—The equation $\log p = k - \frac{a}{T} - b \log T$, where p is the pressure, T the absolute temperature, and a, b, and k are constants, is derived by Bertrand (*Thermodynamique*, 1887, 93) from Boyle's law and equations given by Clapeyron, Clausius, and Regnault. From the same sources the author derives the equation $\log s = k' + \frac{a'}{T} + b' \log T$, where s is the specific volume of the saturated vapour. The specific volumes of carbon bisulphide vapour at different temperatures calculated by this formula agree well to the third decimal place with the values given by Hirn. The function $p = 0$ when $T = 0$, and then increases until the critical temperature is reached, when $T = a/b$, after which it decreases indefinitely, and has no further physical significance. Similarly s is infinite when $T = 0$, and decreases to a minimum at the critical temperature, when $T = a'/b'$. For the same vapour, therefore $a/b = a'/b'$.

Zeuner's equation, ps^n = constant, where n is a constant such that $a = na'$ and $b = nb'$, may be at once deduced from the above two equations. W. J. P.

The Freezing Points of Aqueous Solutions of Boric Acid and Mannitol. By G. Magnanini (*Gazzetta*, **21**, ii, 134—141).—A study of the electrical conductivities of aqueous solutions of boric acid and mannitol has already enabled the author to determine the composition of the compound of the two substances which exists in solution (Abstr., 1890, 1357); no clue was, however, obtained to the amount of the compound produced.

An investigation of the solutions by the cryoscopic method shows that the number of molecules existing in an aqueous solution containing both boric acid and mannitol is about 5·4 per cent. less than it would be if no combination occurred, the cryoscopic constant of the solvent for water (18·5) being diminished by 5·4 per cent. in solutions containing both constituents, whilst for solutions only containing one of the substances, the constant is considerably increased in value.

The author has also determined the electrical conductivity at different temperatures (20—50°) of solutions containing boric acid and mannitol in varying proportions, and finds that the conductivity decreases by about 6 per cent., with a rise of temperature of 30° (20—50°); the rate of decrease is almost the same for differently constituted solutions. The author considers that this abnormal change in the conductivity of such solutions is only apparent, the diminution in conductivity with rise of temperature being due to increased hydrolytic dissociation. The true temperature coefficient of the electrical conductivity is, therefore, most probably positive. As a rise in temperature causes a decrease in the amount of the compound of boric acid and mannitol in the solution, the formation of this substance is probably accompanied by development of heat.

W. J. P.

The New Theories of Solution. By J. Walker (*Phil. Mag.* [5], **32**, 355—365).—This paper contains a reply to some of the objections advanced by Pickering against the theories of osmotic pressure and of electrolytic dissociation. The author doubts if Pickering's determinations of the freezing point of sulphuric acid solutions (Trans., 1890, 331) have the degree of accuracy claimed for them, and gives an example to show that the "potential dissociation" advocated by Lodge is insufficient to explain the known facts of electrolysis.

J. W.

Change of Volume on Dissolution. By J. A. Wanklyn, W. Johnstone, and W. J. Cooper (*Phil. Mag.* [5], **32**, 473—477).—When a solid dissolves in water, one of three things may happen with respect to the volume. The volume of the solution may be equal to the sum of the volumes of the dissolved substance and the water, or it may be greater, or it may be less, as is usual. When there is contraction, the authors measure it by the weight of water, which, instead of overflowing from a vessel of 100 c.c. capacity filled with water, is retained when 1 gram of salt dissolves so as to give 100 c.c. of solution. This constant they term the "condensate." In the case of sugar there is no condensate, as there is no change of volume. With some ammonium salts there is expansion, and the condensate is consequently negative. The authors state that, "in the case of very many salts, the condensate bears an atomic relation to the gram of salt which occasions it" (compare Abstr., 1891, 1412). J. W.

Mutual Solubility of Salts in Water. By J. E. Trevor (*Phil. Mag.* [5], **32**, 75—78).—With reference to Nicol's paper under the above title (this vol., p. 8), the author draws attention to the fact that the problem therein discussed has received a theoretical solution, with experimental confirmation for many cases, from the work of Nernst, Noyes, and himself. J. W.

Solubility of Mixed Crystals, especially of two Isomorphous Substances. By H. W. B. Roozeboom (*Zeit. physikal. Chem.*, **8**, 504—530).—According to the rules laid down by Gibbs for equilibrium between three phases, two of which are solid salts and the other their solution, the composition of the saturated solution at constant temperature will be dependent on the pressure. Experiment up to the present has confirmed the above for a number of solutions of mixed salts, but there are a number of exceptions where the salts taken are capable of forming a double salt or an isomorphous mixture. The exception has been shown to be only an apparent one in the case of double salts by the author's investigation of the behaviour of astracanite (Abstr., 1888, 1164). Rüdorff's researches on the solubility of mixtures of isomorphous salts have, however, placed it beyond doubt that the composition of their solution is variable, and not constant, for constant pressure, even when excess of both salts is present. The explanation of this behaviour must be sought in the fact that the isomorphous salts combine with one another to form homogeneous mixed crystals, the equilibrium conditions being thus altered. This difference between isomorphous and other mixed salts is of importance, as it is evident that the solubility of mixed salts becomes a criterion of their isomorphism, but, before this property can be made any extensive use of, it will be necessary to establish the conditions of equilibrium existing between isomorphous mixtures and their solutions.

If, with Van't Hoff (Abstr., 1890, 1044), we regard isomorphous mixtures as solid solutions, the dissolution of the mixed crystals may be compared with the evaporation of a liquid made up of two components, both of which are volatile. Osmotic pressure then takes the place of vapour pressure, and, in place of the concentration of the liquid solution, that of the solid solution must be taken. If there are N molecules of the one salt, and n molecules of the second with osmotic pressure p, in the solid solution, then we get, as the expression for the law of Henry, $kp = n/(N + n)$, or, since saturation is complete when the osmotic pressure of the solid is equal to that of the solution, if the second salt is present in the solid in the molecular proportion x per cent., and if in the saturated solution the concentration is represented by c_2 molecules, then $kc_2 = x$. This, of course, assumes the absence of electrolytic dissociation. It also assumes the identity of the solid and liquid molecule, but if this is not the case, and n of the latter combine to form one of the former, the formula becomes $kc_2 = x^{\frac{1}{n}}$.

If x becomes smaller during solution and greater during the separation of the mixed crystals, the solution will be richer in the component x than the crystals. Hence, if the osmotic pressure of a saturated solution of mixed crystals increases or decreases with increasing proportion of one of the components of the mixed crystals, the ratio of this component to the other in the solution will in the one case be greater, and in the other less, than in the mixed crystals. This enables a distinction to be made of the possible cases during solution or crystallisation of mixed crystals.

If the mixed crystals are miscible in all proportions, three cases

are possible. The osmotic pressure of the saturated solution is a continuous function of the concentration, and may either increase continuously with the concentration, it may increase to a maximum and then fall, or it may fall to a minimum and then rise. In the first case, on evaporation of a solution of the two constituents, the crystals separating out would contain increasing quantities of that component the saturated solution of which had the greatest osmotic pressure, until at length nothing but a solution of this component was left. In the second case, the crystals would be of varying composition, until a point is reached corresponding with the maximum, when the composition of the crystals would be the same as that of the solution. The third case would be similar in character to the second.

If the mixed crystals are not miscible in all proportions, the osmotic pressure is no longer a continuous function of the concentration. The curve for the pressure as a function of the concentration will then be represented for a certain portion of its length by a straight line, parallel to the abscissæ axis, and terminating at one end with a certain limiting value of the concentration of the one constituent, and at the other end with a certain limiting value of the other constituent in the mixed crystals. From these end points to the points representing the pressures of the saturated solutions of the pure components, the curve may take various forms. Some of these are considered by the author, and he points out that isodimorphous mixtures probably all give a discontinuous curve of the above form.

H. C.

Solubility of Mixed Crystals of Potassium and Thallium Chlorates. By H. W. B. Roozeboom (*Zeit. physikal. Chem.*, **8**, 531—535).—The author has determined the solubility of mixtures of potassium and thallium chlorates in varying proportions. He finds that these salts present one of the cases considered in a former paper (preceding abstract) of mixed crystals which are not miscible in all proportions, and obtains results which generally confirm his theoretical conclusions.

H. C.

Affinity Coefficients of Organic Acids and their Relation to Chemical Constitution. By P. Walden (*Zeit. physikal. Chem.*, **8**, 433—503).—The author has determined the affinity coefficients of a large number of dicarboxylic acids from the conductivities of their aqueous solutions (see Ostwald, Abstr., 1889, 818). The values obtained for $K = 100k$ are given in the following tables:—

I. Malonic Acid and its Derivatives.

Dimethylmalonic acid...	0·076	Ethylmethylmalonic acid	0·161
Methylmalonic acid.....	0·086	Malonic acid	0·163
Isobutylmalonic acid....	0·090	Diethylmalonic acid	0·74
Butylmalonic acid	0·103	Diallylmalonic acid	0·76
Propylmalonic acid	0·112	Benzylethylmalonic acid.	1·46
Isopropylmalonic acid...	0·127	Dibenzylmalonic acid ...	4·1
Ethylmalonic acid	0·127	Chloromalonic acid.....	4·0
Benzylmalonic acid	0·151	Benzyltartronic acid	0·55
Allylmalonic acid.....	0·154		

II. Succinic Acid and its Derivatives.

(*a.*) *Mono-substitution Compounds.*

Succinic acid.....	0·0068	Isobutylsuccinic acid..	0·00882
Isopropylsuccinic acid..	0·0075	Propylsuccinic acid ...	0·00886
Ethylsuccinic acid.....	0·0085	Benzylsuccinic acid ...	0·0091
Methylsuccinic acid....	0·0086	Allylsuccinic acid.....	0·109

(*b.*) *Di-substitution Compounds.*

Antidimethylsuccinic acid	0·0123	Parabenzylmethylsuccinic acid	0·0219
Paradimethylsuccinic acid	0·0191	μ-Benzylmethylsuccinic acid	0·0247
μ-Ethylmethylsuccinic acid.....	0·0201	Parabenzylethylsuccinic acid.....	0·0262
Parethylmethylsuccinic acid	0·0207	μ-Benzylethylsuccinic acid	0·0414
Paradiethylsuccinic acid	0·0245	Paradiphenylsuccinic acid	0·0200
Antidiethylsuccinic acid	0·0343	Antidiphenylsuccinic acid	0·026
Diethylsuccinic acid (3)	0·0386	Antidihydroxysuccinic (inactive tartaric) acid	0·060
Parallylethylsuccinic acid	0·0269	Paradihydroxysuccinic (tartaric) acid	0·097
μ-Allylethylsuccinic acid	0·0359	Dextrotartaric acid	0·097
μ-Phenylmethylsuccinic acid	0·0233	Lævotartaric acid.....	0·097
Paraphenylmethylsuccinic acid	0·0372		

(*c.*) *Tri-substitution Compounds.*

Trimethylsuccinic acid .	0·0307	Propyldimethylsuccinic acid.....	0·0551
Benzyldimethylsuccinic acid	0·0455	Ethyldimethylsuccinic acid	0·0556

III. Glutaric and Pimelic Acids and their Derivatives.

Glutaric acid.....	0·00475	Benzylmethylglutaric acid	0·0059
α-Methylglutaric acid .	0·0052	Pimelic acid:	
Paradimethylglutaric acid	0·0055	From suberone, Schorlemmer.....	0·0032
Antidimethylglutaric acid	0·0055	From castor-oil, Hell..	0·00348
Metapropylmethylglutaric acid	0·0054	From pentanetetracarboxylic acid, Perkin..	0·00345
Paradiethylglutaric acid	0·0055	Of unknown origin, Ostwald.....	0·00357
Metethylmethylglutaric acid	0·0056	β-Pimelic acid, Arth...	0·00420
β-Methylglutaric acid .	0·0059	Pimelic acid from amylene bromide:	
Parethylmethylglutaric acid	0·0059	(*a.*) Bauer.....	0·0097
Parapropylmethylglutaric acid	0·0059	(*b.*) Hell	0·0091

IV. Unsaturated Dibasic Acids.

Methylitaconic acid	0·0095	Fumaric acid	0·093
Ethylmethylmaleïc anhydride	0·0097	Methylmesaconic acid...	0·094
Pyrocinchonic anhydride	0·0108	Ethylmesaconic acid	0·093
Itaconic acid	0·0120	Isopropylmesaconic acid .	0·093
Benzylglutaconic acid..	0·0153	Methylcitraconic acid....	0·238
Glutaconic acid	0·0183	Citraconic acid	0·340
Mesaconic acid	0·0794	Maleïc acid	1·17

It will be seen that, with the exception of dimethylmalonic acid, all the di-substitution compounds of malonic acid have higher affinity coefficients than malonic acid itself. The mono-alkyl derivatives, on the other hand, have smaller coefficients than the parent acid. In the cases of succinic acid, the mono-alkyl derivatives are better conductors than the free acid, the di-derivatives better than the mono-derivatives, and the tri-derivatives better than the di-derivatives. When succinic anhydride is dissolved in cold water, the electrolyte obtained is identical with ordinary succinic acid, and no evidence of the existence of a second succinic acid is obtained. The author points out that the antidihydroxy-, antidimethyl-, and μ-ethylmethyl-succinic acids have smaller coefficients than the corresponding para-acids. It would, therefore, appear possible, although in opposition to the accepted view, that the first contain the maleïnoïd, and the second the fumaroïd, grouping. H. C.

Chemical Action at a Distance. By W. Ostwald (*Phil. Mag.* [5], **32**, 145—156).—A short glass tube of about 2 cm. diameter, closed below with parchment paper, is introduced into a small beaker. Both these vessels are filled with a solution of potassium sulphate, care being taken that the level of the liquid in the tube is higher than the level in the beaker. A rod of pure zinc is dipped into the solution in the tube, and connected electrically with a piece of platinum wire, which reaches to the bottom of the beaker. A few drops of a solution of sulphuric acid specifically heavier than the potassium sulphate solution are then carefully brought with a pipette upon the bottom of the outer vessel, so as not to come into contact with the parchment diaphragm. Hydrogen is at once evolved on the platinum, and a subsequent investigation of the solution in the inner vessel shows that a quantity of zinc has dissolved in the potassium sulphate solution as zinc sulphate. Such an action as this, where the specific solvent for a metal (here zinc) is applied at a place where it can have no direct action and yet exerts its solvent power, is termed by the author a chemical action at a distance. Many instances of similar phenomena are given. For example, gold may be dissolved in a solution of common salt, by bringing the platinum with which it is connected into contact with a salt solution saturated with chlorine. Again, if two beakers—one containing a solution of ferrous chloride, the other a solution of common salt saturated with chlorine or bromine—are connected by means of a siphon filled with salt solution and closed at

both ends with parchment paper, then on introducing platinum electrodes into the beakers and connecting them through a galvanometer, a current is at once indicated, and the ferrous chloride becomes oxidised to ferric chloride in the neighbourhood of the electrode, as may be shown by the previous addition of a little potassium thiocyanate solution.

All such reactions receive a ready explanation from the theory of electrolytic dissociation, the author laying emphasis on the fact that the description of many of the experiments made by him was completely worked out at his writing table, on the basis of this theory, before he had seen any of the phenomena in question; and that after the experiments had been performed, nothing in the description required to be altered. J. W.

Chemical Action at a Distance. By S. U. Pickering (*Phil. Mag.* [5], **32**, 478).—The author holds that a simple explanation of Ostwald's experiments (see preceding abstract) may be obtained without having recourse to the theory of free ions in solution, and that, therefore, these experiments cannot be accepted as proofs of this theory. S. U. P.

Artificial Colouring of Crystals. By O. Lehmann (*Zeit. physikal. Chem.*, **8**, 543—553).—Senarmont discovered that salt crystals may be coloured by certain organic dyes without any change in the form or homogeneity of the crystal. The author has on former occasions made similar observations with other inorganic and organic compounds, and in order to ascertain something more with reference to the conditions under which this phenomenon takes place, has now made a large number of experiments on the artificial coloration of crystals. The crystals made use of were those of certain organic acids, such as succinic, protocatechuic, and phthalic acids, and these were coloured by means of different organic dyes. The author summarises his results as follows:—

The crystals always become darker in colour than the solution from which they separate. They are usually observed to be surrounded by a lighter coloured, or even quite colourless, layer, the colouring matter being deposited with such rapidity upon the growing crystal that the slow diffusion of the dye from the more distant parts of the solution is not sufficient to make up for the decreasing concentration in the neighbourhood of the crystal.

The colouring of the crystals is in nearly all cases dichroic, a proof that the colouring matter actually enters in some way into the structure of the crystal. The remarkable rule is observed that only one of the two rays produced by double refraction is coloured, whilst the other appears to be perfectly white, the colourless ray being always the one which has undergone the least refraction.

If two colouring matters are present in the solution, the presence of the one often hinders the absorption of the other. In some cases, however, the reverse takes place, and a colouring matter which alone would not be absorbed may become so when some second colouring matter is added. Change of the solvent, or the addition of other solid or liquid foreign matter, may act in a similar manner.

Different crystals are only capable of taking up certain organic dyes, so that two compounds of perfectly similar appearance may be capable of combining the one only with one, and the second only with some other dye. This fact may obviously be made available in distinguishing crystals one from another. It may also perhaps be applicable for the purification of certain dye stuffs. H. C.

Rapid Weighing on Precision Balances by means of a Scale read by a Microscope. By A. Collot (*Bull. Soc. Chim.* [3], **6**, 98—100).—The needle of a balance carries a scale illuminated from behind the balance, and viewed by a small microscope containing a scale in the focal plane of the eye-piece. The centre of gravity of the beam may be lowered considerably, and thus the rapidity of oscillation of the beam increased materially by the aid of this device. The value of each division of the scale carried by the needle being known in centigrams and milligrams, the position of rest of the indicator is ascertained by the method of oscillations, and from its deviation from the central point the weight to be added to that in the pan is known. With a little care, weighings only take one-fourth or one-fifth as long by this method as they usually do. W. T.

A Siphon for Hot Liquids or for those Evolving Gases or Vapours. By J. C. Essner (*Bull. Soc. Chim.* [3], **6**, 19—21).—Between the two arms of the siphon a reservoir is interposed; this is filled with some of the liquid to be siphoned, and hermetically closed. When the long arm of the siphon is opened, the fall of the liquid determines a diminution in the pressure of the reservoir, and a continuous flow results. T. G. N.

Inorganic Chemistry.

Preparation of Pure Hydrogen Peroxide Solution. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 24—25).—The solution of hydrogen peroxide which results from the action of hydrochloric acid (sp. gr. 1·1) on barium dioxide is extracted by shaking with ether, and the ethereal solution is agitated with distilled water, to which it yields the dissolved hydrogen peroxide. By repetitions of this process, a pure, neutral solution corresponding with 0·8—0·9 per cent of hydrogen peroxide is obtainable, from which the dissolved ether may be eliminated by distillation under reduced pressure. T. G. N.

Preparation of Hydrobromic Acid. By G. S. Newth (*Chem. News*, **64**, 215).—By means of the following arrangement a large quantity of bromine can be rapidly converted into hydrobromic acid:—A glass tube, 7 inches long and $\frac{5}{8}$ inch in diameter, is fitted at each end with a cork carrying a piece of small tubing and a piece of stout wire. The ends of these pieces of stout wire, within the longer tube,

are joined by a spiral of platinum wire 1 inch long, and after expelling the air the spiral is heated to bright redness by an electric current; a stream of hydrogen, impregnated with bromine by bubbling through that liquid, which may be heated at 60°, is passed through the longer tube, and, as long as a slight excess of hydrogen is maintained, hydrobromic acid quite free from bromine issues from the other end, and is collected in water. There is very little danger of explosion, but to render it impossible, the small supply tube may be plugged with a little glass wool. D. A. L.

Solubility of Gases in Water. By L. W. Winkler (*Ber.*, **24**, 3602—3610; compare Abstr., 1891, 384).—In this paper the author gives in tabular form the results of experiments on the solubility of nitrogen and of oxygen in water, at temperatures ranging from 0° to 80°; the calculated values for the solubility of the two gases at temperatures ranging from 80—100° are also given. As regards the solubility of nitrogen, the author's values are considerably larger than those given by Bunsen. F. S. K.

The Densities of Sulphuric Acid Solutions. By S. U. Pickering (*Chem. News*, **64**, 311).—Lunge's doubts as to the accuracy of the author's density determinations are, in the opinion of the latter, due to a misapprehension as to the method employed to determine the strength of the acid, and as to the experimental error involved. S. U. P.

The Contraction on Mixing Sulphuric Acid and Water. By S. U. Pickering (*Chem. News*, **64**, 14—15).—From his own results the author has calculated the strength at which the maximum contraction occurs, and finds that this maximum, when calculated for unit weight of solution, shifts from 67 per cent. at 8° to 70·1 per cent. at 38°, whereas the maximum contraction calculated per unit volume remains practically constant at 76 per cent. throughout this range of temperature. Neither of these maxima occurs at the composition of the dihydrate (73·1 per cent.) or of that of any other hydrate of which indications have been obtained. The rate at which the amount of contraction is influenced by the temperature varies irregularly with the actual value of the temperature; thus with solutions from 64 to 80 per cent. strength, the contraction diminishes at nearly the same rate for the intervals 8° to 18°, and 28° to 38°, whereas for the intermediate interval, 18° to 28°, the rate of diminution is about 25 per cent. smaller. S. U. P.

Density and Composition of Dilute Sulphuric Acid. By A. W. Rücker (*Phil. Mag.* [5], **32**, 304—313).—Pickering (Trans., 1890, 64) deduced the existence of various hydrates in sulphuric acid solutions from sudden changes of curvature in the curves representing the variation of the density, &c., of such solutions with the composition. The author considers the "first differential" curve for 18° between 46 per cent. and 80 per cent., in which there are supposed to be four breaks, and shows that it is possible to find an equation, and, therefore, a continuous curve, which will represent the results within the limits of the experimental error. The equation is of the form

$$u\ 2$$

$$y = a + bx - cd^x + \frac{m}{n^x + n^{-x}},$$

and contains seven arbitrary constants. The author thus doubts the value of "differentiation" or of the bent ruler, as used by Pickering, in discovering changes of curvature in curves drawn to represent experimental numbers. J. W.

The Densities of Sulphuric Acid Solutions. By S. U. Pickering (*Phil. Mag.* [5], **33**, 132).—The curve used by Rücker (see preceding abstract) to bridge over four of what the writer considered to be breaks in the figure formed by the first differentials of the densities of the acid can, he maintains, prove nothing about one of these breaks, and very little about another, for it extends too short a distance beyond them. The formula for the curve suggested by Rücker consists of a combination of an exponential curve and a straight line, on to part of which (as this curve did not agree with the results) a hump was engrafted by means of a complex fourth term, the whole forming a curve for which, as an expression of physical facts, there would seem to be no precedent. The points, moreover, at which the term expressing the hump begins to be appreciable and again becomes inappreciable correspond exactly with the positions assigned by the author to two of the breaks, thus confirming, rather than disproving, the existence of these as points where some new conditions in the solutions become sensible. The only break which Rücker's curve does successfully bridge over is that particular one which the author pointed out to be especially doubtful: and even in favour of this break the evidence is not thereby entirely negatived.

The author maintains that even the most successful attempt to offer an alternative explanation of a small portion of some of his results could not upset his conclusions which were based entirely on the cumulative evidence derived from many sources, and of which he here gives a summary. S. U. P.

Boron Phosphides. By H. Moissan (*Compt. rend.*, **113**, 726—729).—*Boron phosphide*, PB, is obtained by reducing the phosphoiodide in hydrogen at 450—500°. The product is powdered, and again heated in hydrogen at the same temperature in order to remove excess of iodine, and the process is repeated two or three times if necessary, care being taken that the temperature does not exceed 500°. It is a very light, amorphous, maroon-coloured powder, insoluble in the chlorides of arsenic, phosphorus, carbon, and antimony, and in all solvents, organic and inorganic, that were tried. It is not volatile in a vacuum at 500°. At 200°, in presence of oxygen, it burns and yields boric and phosphoric anhydrides; when thrown into fused alkaline nitrates, there is incandescence and deflagration; fused sulphur has no action, but sulphur vapour converts it into boron and phosphorus sulphides. Chlorine converts boron phosphide into boron trichloride and phosphorus pentachloride, with incandescence; bromine has no action in the cold, but combination takes place if the temperature is raised. Vapour of iodine, arsenic, or

phosphorus has no action at a dull-red heat. When heated at 500° in a current of nitrogen, boron phosphide yields no nitride, and, although at higher temperatures it loses phosphorus (as it does in a vacuum), no nitride is formed. When a mixture of boron phosphide and sodium is gently heated in a current of hydrogen, it rapidly becomes incandescent, with formation of sodium phosphide and boride. Potassium yields the same products at a lower temperature. A mixture of the boron phosphide with powdered magnesium becomes incandescent at about 500°, but aluminium has no action, except at a much higher temperature. Finely-divided silver, copper, and platinum react with the phosphide when gently heated, but mercury has no action at its boiling point. When boron phosphide is thrown into the strongest nitric acid, it takes fire, even in the vapour, and burns brilliantly on the surface of the liquid; on slightly heating, it dissolves immediately and completely. Concentrated solutions of hydrochloric and hydriodic acids have no action on the phosphide, and sulphuric acid has no action in the cold, but is reduced on heating. Concentrated hot solutions of potash and soda dissolve it slowly, whilst fused potash dissolves it completely with formation of hydrogen phosphide and potassium borate. Gaseous hydrogen fluoride attacks it below dull redness, with formation of boron fluoride, hydrogen, and phosphorus. Gaseous hydrogen chloride behaves similarly at a higher temperature. Boiling water has no action on the phosphide, but water vapour decomposes it at 400° with production of boric acid and hydrogen phosphide. Hydrogen sulphide at a dull-red heat yields boron sulphide and hydrogen phosphide. In ammonia at about 300° the phosphide burns, with formation of boron nitride and liberation of phosphorus.

Boron phosphide, B_5P_3, is obtained by heating the preceding compound at 1000° in a current of hydrogen. It has a paler colour than the phosphide PB, does not inflame in chlorine or nitric acid, and is not attacked by the latter, even when boiling. It is insoluble in all inorganic and organic solvents, burns with some difficulty in oxygen, and is attacked by fused nitrates with incandescence, but only with difficulty by metals and non-metals. It does not burn in chlorine below a dull-red heat.

If the hydrogen used for reduction contains water or oxygen, a white phosphoboric acid, also known as boron phosphate, is formed, and the same compound is obtained by the action of nitrogen oxides on a mixture of the phosphides. C. H. B.

Boron Phosphide. By A. Besson (*Compt. rend.*, **113**, 772—773).—The author draws attention to his previous note on the subject (Abstr., 1891, 1418), and describes an additional property of the phosphide. It is oxidised by dilute nitric acid to a substance, probably phosphoboric acid, which is left in nacreous plates on evaporating the solution to dryness, is soluble in water, and gives a white, gelatinous precipitate with excess of ammonia.

Moissan (*ibid.*, 787—788), commenting on this and the previous note, draws attention to the absence of numerical data justifying the formula BP attributed to the phosphide, and claims priority in the

systematic study of boron phosphides (*Compt. rend.*, **112**, 717, and **113**, 19). Jn. W.

The Influence of Steam and other Gases on the Combustion of Carbonic Oxide and Oxygen. By N. Békétoff (*Chem. Centr.*, 1891, ii, 449—450; from *Bull. Acad. St. Pétersbourg* [2], **2**, 175—179).—Having repeated Dixon's experiments (Trans., 1885, 94), the author has obtained the same results, namely, that a mixture of carbonic oxide and oxygen, when dried by means of phosphoric anhydride, is not exploded by the passage of an electric spark, and further, that if the gases be dried by sulphuric acid, which appears to leave a trace of moisture in the gas, the combustion proceeds so slowly that it may be followed with the eye. The presence of other gases, sulphurous anhydride, or nitrous oxide, had not a similar effect. Cyanogen, on the other hand, when present to the extent of 10 per cent., exerted an influence similar to that of steam, and caused an immediate explosion on the passage of the spark. Békétoff suggests that the action of cyanogen may be explained on the assumption that the heat liberated in the decomposition of the cyanogen is added to the heat of combustion of the carbon, and he further assumes that the dissociation temperature of the water molecule being lower than that of the oxygen molecule is the proper explanation of the fact that the presence of water in a mixture of carbonic oxide and oxygen assists the combustion of the latter gases. J. W. L.

Reactions of Carbonic Anhydride at High Pressures. By A. d'Arsonval (*Compt. rend. Soc. Biol.*, 1891, 320—321).—Liquefied carbonic anhydride is a powerful antiseptic. It does not coagulate albumin. At high pressures it can displace both organic and mineral acids. When urine is subjected to a pressure of 40 atmospheres of carbonic anhydride, crystals of uric acid are deposited. A dilute solution of potassium silicate similarly treated becomes solidified from the deposition of silicic acid. Carbonic anhydride at the same pressure is also able to liberate hydriodic and hydrobromic acids from solutions of potassium iodide and bromide respectively.

W. D. H.

Reduction of Cæsium. By N. Békétoff (*Chem. Centr.*, 1891, ii, 450—451; from *Bull. Acad. St. Pétersbourg* [2], **2**, 169—170).—The author has prepared considerable quantities of cæsium by reducing the hydroxide with aluminium. The reaction proceeds well, and is as readily carried out as the reduction of rubidium. The author refers to the results, which Winkler has recently published, on the heat of combination of the alkali metals, and points out that the deductions which Winkler has made are diametrically opposed to his own. The author finds that the combining heat of the alkali metals varies inversely with their atomic weights. He further urges that Winkler has not employed the oxides, but the hydroxides and carbonates, for his determinations, which are not suitable for the purpose.

J. W. L.

Properties of Cæsium and its Hydroxide. By N. Békétoff (*Chem. Centr.*, 1891, ii, 451; from *Bull. Acad. St. Pétersbourg* [2], **2**,

171—173).—The author has used a very pure specimen of cæsium sulphate as material on which to work. A determination of the sulphuric acid gave almost the theoretical amount, and by means of the spectroscope only a trace of rubidium could be detected.

The hydroxide was obtained from the sulphate by precipitation with barium hydroxide, and concentration of the filtrate in a silver dish, which was placed in a metal retort. In this manner carbonic anhydride was excluded. After concentration in the retort, the solution was transferred to a small silver dish, the remainder of the water evaporated, and the hydroxide finally fused. The silver dish was slightly attacked, and the silver oxide dissolved in the fused cæsium hydroxide; it was again precipitated, however, as the latter cooled. The quantity of silver oxide was inconsiderable. Cæsium hydroxide has a sp. gr. 4·0178, compared with water at 4°; the molecular volume = 37·3 (sodium hydroxide = 18; potassium hydroxide = 27; rubidium hydroxide = 32 ?). The molecular volume of the hydroxide corresponds with a very considerable diminution of volume during its formation from the elements. The heat of solution of the hydroxide in water is 15,876, which is higher than for all other alkali hydroxides. The heat of neutralisation of the hydroxide with hydrogen chloride (dilute) is 13,790, or nearly the same as that found by Thomsen for potassium hydroxide, or, indeed, for the other alkali hydroxides. Metallic cæsium was obtained by heating 114 grams of the hydroxide in a nickel retort with 27 grams of aluminium, and collecting the distilled metal in glass receivers; 20—25 grams of the metal were thus obtained.

The heat of combination of cæsium with water was found to be from 50 to 52 Cal. J. W. L.

Action of Sodammonium and Potassammonium on Metals. By Joannis (*Compt. rend.*, **113**, 795—798).—Sodammonium and potassammonium are decomposed by mercury, lead, and antimony, but are not affected by aluminium, silver, zinc, or copper. When a solution of sodammonium in liquefied ammonia is allowed to fall drop by drop on mercury, it is decomposed with the formation of a crystalline amalgam, Hg_8Na, which can be washed free from excess of the reagent with liquefied ammonia. Potassammonium under similar conditions yields an amalgam of the composition $Hg_{18}K$.

When pure lead is brought into contact with sodammonium, the reddish-brown liquid turns blue, and then green, and a little hydrogen is disengaged, owing to the spontaneous decomposition of the sodammonium. Finally, however, the metal is partially converted into an indigo-blue mass, which dissolves in liquefied ammonia to a bottle-green solution, and has the composition $Pb_4Na,2NH_3$. This substance decomposes at ordinary pressures, leaving a grey mass resembling spongy platinum, and oxidises rapidly on exposure to air, with evolution of heat. When thrown into water, the first portion dissolves completely, owing to the combination of the lead with the dissolved oxygen, and the subsequent solution of the oxide in the sodium hydroxide simultaneously formed, but as soon as the oxygen is used up, metallic lead is thrown down as a black, curdy precipitate.

Jn. W.

Influence of Ammonia on the Solubility of Ammonium Chloride. By R. Engel (*Bull. Soc. Chim.* [3], **6**, 17).—The presence of ammonia diminishes the solubility of ammonium chloride in water at 0° at first, but as the quantity of ammonia is increased, a corresponding increase in the chloride dissolved obtains. This result is probably due to the formation of compounds of ammonium chloride and hydroxide. Tables of values are given. T. G. N.

Precipitation of Copper by Iron and the Action of Iron on Ferric Solutions. By J. C. Essner (*Bull. Soc. Chim.* [3], **6**, 147—148).—In the wet method of copper extraction, very mixed qualities of scrap iron are employed. The reduced copper occurs in powder, grains, and filaments which cannot be readily washed free from the mud of ferric hydroxide formed. The author finds that the structure of the iron used exerts a marked influence on that of the copper obtained. By selecting the iron to be used, it is possible to obtain the reduced copper in a fibrous or granular condition, when it admits of being readily washed free from ferric hydroxide.

The occurrence of the mud of ferric hydroxide is due to the formation of a basic ferric sulphate, $Fe_2(OH)_4SO_4$. This salt is decomposed by iron as follows:—$6Fe_2(OH)_4SO_4 + Fe_2 = 6FeSO_4 + 4Fe_2(OH)_6$. On reduction with iron, dilute solutions of ferric sulphate give ferrous sulphate only.

The addition of a little sulphuric acid to the copper solution prevents the formation of the mud, and enables a clean deposit of copper to be obtained. W. T.

Mercurammonium Compounds. By E. Balestra (*Gazzetta*, **21**, ii, 294—305).—The author has examined some of the ammoniacal mercury compounds prepared by Millon (*Ann. Chim. Phys.* [3], **18**), and also described by Gmelin.

A. $NH_2HgCl,HgCl_2$.—This compound was obtained by Millon by adding small quantities of ammonia to a large excess of corrosive sublimate. The author succeeded in preparing a compound having the same physical and chemical characteristics by gradually adding to a solution of corrosive sublimate half the quantity of dilute ammonia required for the complete precipitation of the mercury. It does not evolve ammonia when boiled with potash, but a large quantity is given off on treating it with a cold concentrated solution of ammonium bromide, according to Pesci's reaction (Abstr., 1890, 1211), showing that the nitrogen is wholly contained in the mercurammonium radicle. Its composition was found to be $NHg_2Cl,2HCl$. When it is suspended in water and exactly neutralised with potash, it is converted into dimercurammonium chloride, NHg_2Cl.

B. $4NH_2HgCl,NH_2(Hg_2O)Cl$.—Millon obtained a yellow powder of the above composition by pouring a boiling solution of corrosive sublimate into a large excess of ammonia and thoroughly washing the product. Under these conditions, however, the author finds that a white precipitate is formed which loses ammonium chloride, on repeatedly washing with water, gradually acquiring a yellowish tinge; it then approximates in composition to dimercurammonium chloride.

The unaltered product has the composition of infusible white precipitate, NHg_2Cl,NH_4Cl.

C. $NH_2HgCl,2NH_2(Hg_2O)Cl_2$.—This compound was obtained by Millon in two ways: (1) by washing A completely with water, and (2) by adding small quantities of ammonia to a large excess of a boiling solution of corrosive sublimate. By washing A with water, the author, however, obtained a bright yellow powder of the composition $2NHg_2Cl,HgCl_2,H_2O$, which loses $\frac{1}{2}$ mol. H_2O at 105—110°.

By Millon's second method (the author added to a boiling 7 per cent. solution of corrosive sublimate half the quantity of ammonia required for neutralisation); a pale-yellow, amorphous powder was obtained having the composition NHg_2Cl,HCl. On neutralising this compound with potash, dimercurammonium chloride is formed. When it is washed with water, it is converted into the compound

$$2NHg_2Cl,HgCl_2,H_2O.$$

S. B. A. A.

Solubility of Glass in Cold Water. By F. Kohlrausch (*Ber.*, **24**, 3560—3575).—The author has made experiments on the solubility of various kinds of glass by measuring the electrical conductivity of the solutions obtained on treating the glass with distilled water at 18°. He finds that the quantity of glass dissolved increases with the time, but not proportionately, the solvent action being more rapid at first; in the case of some of the best samples of glass, no appreciable action takes place even on prolonged contact. It was also found that of two solutions, prepared in like manner from two kinds of glass having approximately the same composition, the one may have almost twice the conductivity of the other; this result may be due to the two samples having undergone different treatment in their manufacture. The composition of the various kinds of glass employed and the numerical results of the experiments are given in tables.

The author also points out that the best and most rapid test for inorganic salts in distilled water is a measurement of its electrical conductivity; the presence of carbonic anhydride can be ascertained in the same way.

F. S. K.

Reaction between Potassium Permanganate and Hydrogen Peroxide Solution. By R. Engel (*Bull. Soc. Chim.* [3], **6**, 17—19).—It often happens that when potassium permanganate solution is added to hydrogen peroxide solution, decolorisation does not at once ensue, but that when once the reaction has begun, decolorisation proceeds rapidly. Brodie attributed this result to the degree of dilution of the hydrogen peroxide, and Schöne to the action of light on this compound. The author regards neither of these hypotheses as tenable, and shows that the onset of the reaction is determined by the presence of a trace of a manganous salt in the mixed solutions; this results from the action of traces of sulphurous or nitrous compounds in the hydrogen peroxide solution on the permanganate; the manganous salt is then oxidised to manganic sulphate, which is unstable in presence of hydrogen peroxide. The addition

of a trace of manganous sulphate to the hydrogen peroxide solution before running in the permanganate solution determines decolorisation at the onset. T. G. N.

Action of Ferric Chloride on Metallic Sulphides. By CAMMERER (*Chem. Centr.*, 1891, ii, 525; from *Berg. Hütten Zeit.*, **50**, 295—298).—(For the first part of this work, see this vol., p. 18.) Ferric chloride reacts with stannic sulphide forming stannic chloride, sulphur, and ferrous chloride. Mercuric sulphide is converted into mercuric chloride, sulphur and ferrous chloride being formed at the same time. The mercuric chloride at first formed reacts again with two more molecules of mercuric sulphide, with production of Heumann's double salt, $2HgS,HgCl_2$. This is a white substance, which is blackened by alkalis, but appears to be regenerated by the subsequent action of nitric acid.

With silver sulphide, ferric chloride reacts, forming silver chloride, sulphur, and ferrous chloride. With the sulphides of lead, bismuth, cobalt, and manganese, ferric chloride reacts, the corresponding chloride of the metal is formed together with ferrous chloride, and the sulphur is set free. Most of the reactions take place readily and completely. J. W. L.

Coloration of Solutions of Cobalt and the State of the Salts in the Solutions. By A. ÉTARD (*Compt. rend.*, **113**, 699—701).—Cobalt iodide yields red, green, and blue solutions. Its solubility at various temperatures is as follows:—

t	−22°	−8°	−2°	+9°	14°	25°	34°	46°
Sol...	52·4	56·7	58·7	61·4	61·6	66·4	73·0	79·0

t	60°	82°	111°	156°
Sol...	79·2	80·7	80·9	83·1

Cobalt chloride yields rose-coloured or blue solutions, and its solubilities are as follows:—

t	−22°	−4°	+7°	11°	12°	25°	34°	41°
Sol...	24·7	28·0	31·2	31·3	32·5	34·4	37·5	39·8

t	45°	49°	56°	78°	94°	96°	112°
Sol...	41·7	46·7	48·4	48·8	50·5	51·2	52·3

The garnet-red, hexahydrated cobalt iodide yields a dull red solution between −22° and about +20°, the solubility between these limits being represented by a right line. Above 20°, the liquid becomes brown, then olive, and finally at 35° deep chrome-green, this colour persisting even up to 320°. The deep green liquid yields green, lamellar crystals of the composition $CoI_2,4H_2O$. The formation of this salt begins at 20°, and since it is more soluble than the red salt, and the two solubilities are superposed, there is a gradual increase in the total solubility between 20° and 35°, the curve being convex towards the axis of temperature. Above 35°, the green salt alone exists in solution, and its solubility is represented by a right

line. If it were possible to make experiments above 320°, it is probable that the green liquid would become blue, and would contain a lower hydrate analogous to $CoCl_2,2H_2O$. Such a blue solution is obtained when a solution of the cobalt iodide is poured into a saturated solution of magnesium chloride.

In the case of cobalt chloride, the hydrate, $CoCl_2 + 6H_2O$, dissolves without change between −22° and +25°, the solution has a pure rose colour, and the solubility is represented by a right line. At 25°, dissociation begins, and the more soluble blue hydrate, $CoCl_2 + 2H_2O$, is formed, the colour of the solution changing to purple, and finally, at 50°, to blue, this colour persisting up to 300°. Between 25° and 50°, the curve of solubility is convex towards the axis of temperature, but beyond 50°, it again becomes a right line.

The changes of colour are not due to the presence of free acid or an acid salt, for they can be observed in presence of calcium carbonate or precipitated cobalt carbonate. C. H. B.

Oxidation of Nickel Carbonyl. By Berthelot (*Compt. rend.*, **113**, 679—680).—Nickel carbonyl can be kept under water in a flask without undergoing any alteration, provided that air is excluded, but in presence of air, green nickelous hydroxide, free from carbon, separates, and, at the same time, some of the nickel carbonyl escapes into the air and is oxidised to a white powder which, in mass, has a pale greenish tinge. It has the composition C, 5·3; NiO, 53·3; H_2O, 40·1 = 98·7, whilst the formula $C_2O_3Ni_3,10H_2O$ requires C, 5·6; NiO, 52·5; H_2O, 41·9 = 100. The compound would, therefore, seem to be the oxide of a complex radicle, analogous to croconic and rhodizonic acids. It is possible that one part of the nickel may be present in the form of nickel monoxide, mixed or combined with a complex oxide of the simpler formula C_2ONi, belonging to the ethylene type or to a more condensed type of the same order, this oxide being formed thus, $C_4O_4Ni + O = C_2ONi + 2CO_2$. C. H. B.

Action of Hydrogen Phosphide on an Ethereal Solution of Bismuth Tribromide. By A. Cavazzi and D. Tivoli (*Gazetta*, **21**, ii, 306—308).—When a solution of bismuth tribromide in dry ether is allowed to fall gradually into a vessel containing dry hydrogen phosphide, a lustrous, black substance is formed which strongly adheres to the sides of the vessel. It becomes dull and hard on drying in a vacuum, and probably has the composition $PBrH(BiBr_2)_3$, being formed according to the equation $3BiBr_3 + PH_3 = 2HBr + PBrH(BiBr_2)_3$. It is very hygroscopic, and is gradually decomposed by cold water and rapidly by boiling water, hydrogen phosphide, hydrobromic and phosphoric acids being formed and bismuth liberated. On heating it with a solution of potash, potassium bromide and phosphate are formed with evolution of hydrogen and hydrogen phosphide.

Concentrated sulphuric acid has no action on it at the ordinary temperature, but, on boiling, bismuth sulphate, phosphoric acid, hydrobromic acid, bromine, and sulphurous anhydride are formed. Concentrated nitric acid also acts very violently on it. When triturated

with fragments of sodium amalgam, it ignites and decomposes with more or less violence, according to the richness of the amalgam in sodium. When heated at 220° in an atmosphere of dry carbonic anhydride, it has the same composition as when dried in a vacuum. When heated in the air, it becomes viscid and decomposes with some violence and with evolution of fumes of bromine, bismuth bromide, and phosphoric anhydride. S. B. A. A.

Auric Sulphide. By U. Antony and A. Lucchesi (*Gazzetta*, **21**, ii, 209—212).—Auric sulphide, prepared by the authors' method (Abstr., 1891, 526), is a graphitic, amorphous powder having a sp. gr. of 8·754 compared with water at 0°; it decomposes into its elements at 197—200°.

Hydrochloric acid has no action on auric sulphide, concentrated nitric acid oxidises it in the cold with separation of gold, whilst aqua regia readily dissolves it. Caustic alkalis (15 per cent.) decompose the sulphide on heating, metallic gold and alkali sulphide and thiosulphate being obtained. Ammonia solution, on prolonged contact, decomposes it, yielding sulphuric acid, free sulphur, and a little hydrogen sulphide. The action of potassium cyanide solution on auric sulphide differs from its action on aurous sulphide and aurosoauric sulphide, both of which dissolve and are reprecipitated by acids. Auric sulphide dissolves in aqueous potassium cyanide (25 per cent.) to a yellow solution, which, on boiling, becomes colourless and deposits aurous potassium cyanide on cooling, $Au_2S_3 + 6KCN = 2AuKC_2N_2 + K_2S + 2KCNS$. This reaction shows the substance to be homogeneous, the auric sulphide prepared by Berzelius having been shown by Krüss and Hoffmann (Abstr., 1887, 1019; 1888, 28) to be a mixture of aurosoauric sulphide with sulphur.

Hydrosulphide and polysulphides of ammonia dissolve auric sulphide readily on warming, gold being deposited. The sulphides and polysulphides of the alkali metals dissolve the substance slowly; whilst the alkali hydrosulphides dissolve it in the cold, yielding a deep reddish-brown solution, which, on boiling, becomes pale yellow and deposits gold. These solutions, on treatment with hydrochloric acid, give a flocculent, yellow precipitate, probably consisting of auric hydrosulphide, which soon turns brown with formation of hydrogen sulphide and auric sulphide.

On precipitation with alcohol at −10°, a concentrated solution of auric sulphide in sodium hydrosulphide gives a yellowish precipitate; this, when filtered through asbestos at the same temperature in an atmosphere of nitrogen and washed with alcohol, yields a white, crystalline product which soon darkens in colour. The freshly prepared substance is very soluble in water and is probably sodium sulphaurate, but it decomposes so rapidly that trustworthy analyses could not be made. W. J. P.

Iodonitro- and Bromonitro-platinum Compounds. By M. Vézes (*Compt. rend.*, **113**, 696—698).—The relative stability of the nitro- and haloïd groups in the iodonitro-platinum compounds is the inverse of that observed in the case of the chloronitro- and bromo-

nitro-compounds (Abstr., 1891, 807). The iodine is displaced by nitrogen oxides, and the stable term of the series is the platonitrite and not the platoiodide. Nitrogen oxides readily decompose potassium platoiodide with liberation of iodine; whilst, on the other hand, iodine in the form of vapour or in solution in hydriodic acid or a solution of potassium iodide does not decompose potassium platonitrite.

The action of an alcoholic solution of iodine on a warm solution of potassium platonitrite, however, yields large, brilliant prisms of the compound $Pt,2NO_2,K_2I_2 + 2H_2O$, described by Nilson, but this, although stable in warm solutions, is decomposed by nitrogen oxides or potassium nitrite, with liberation of iodine and formation of the platonitrite. The author has so far failed to obtain a compound $Pt,4NO_2,K_2I_2$, analogous to the platichloronitrite and the platibromonitrite previously described.

If, however, an excess of an alcoholic solution of iodine is added to a warm concentrated solution of the platonitrite, and the mixture is concentrated as rapidly as possible at a gentle heat, *potassium nitroso-plati-iodide*, PtI_3,NO,K_2I_2, separates on cooling in small, brilliant, black crystals, which remain unaltered at 100°. When heated in a current of hydrogen, this compound yields water, ammonium iodide, iodine, hydrogen iodide, and a residue of potassium iodide and platinum.

If the liquid is slowly concentrated (without ebullition) a different compound is obtained on cooling. It is *potassium platitetraiodonitrite*, $PtI_4,2NO_2,K_2$, and separates in small, well-defined, black crystals with a greenish lustre. Like the preceding compound, it is only slightly soluble in water, yielding a deep brown solution, and it undergoes no change at 100°. When heated in a current of hydrogen, it yields water, ammonium iodide, iodine, and hydrogen iodide, with a residue of potassium iodide and platinum.

When the mixture yielding these two salts is submitted to prolonged ebullition, the excess of iodine is expelled and potassium platoiodonitrite is formed.

When bromine-water is added to a solution of potassium platoiodonitrite until all the iodine is expelled, the brown liquid, when concentrated in a dry vacuum, yields yellow, tabular crystals. The same crystals are obtained by heating a solution of potassium platibromonitrite, $Pt,4NO_2,K_2Br_2$, with alcohol at 80°, aldehyde and other gases being evolved. This new compound is *potassium platobromonitrite*, $Pt,2NO_2,K_2Br_2 + H_2O$, and is very soluble in water. At 100°, it becomes anhydrous and bright yellow; at a higher temperature, it blackens with evolution of nitrogen oxides, a residue containing potassium bromide and platinum in the proportions Pt + 2KBr being left. When heated in hydrogen, it yields the same residue without any formation of ammonium bromide, bromine, or hydrogen bromide.

Two New Seleno-salts. By R. Schneider (*J. pr. Chem.* [2], **44**, 507—512).—*Potassium platinoselenostannate*, $K_2Pt_3SnSe_6$, is prepared by melting together 10 parts of platinum sponge, 6—8 parts of tin selenide, 30—40 parts of potassium carbonate, and 30—40 parts of selenium in a covered porcelain crucible so that the mass shall remain liquid for 8—10 minutes after the frothing has ceased. The melt is extracted

with water, and the undissolved residue digested with concentrated potassium hydroxide solution, whereby the selenostannate is left unattacked. It forms small, well-defined, hexagonal tables which are leaden-grey by reflected light and have a strong metallic lustre; in thin layers they are reddish-brown by transmitted light. In its general habitus it is very similar to the author's potassium platinosulphostannate (*Ann. Phys. Chem.*, **138**, 612). At the ordinary temperature, it is stable in air; when heated in air, it loses all its selenium, the residue consisting of a mixture of platinum with potassium stannate. It is not attacked by water, ammonia, potash, or hydrochloric acid, either hot or cold.

Sodium platinoselenostannate, $Na_2Pt_3SnSe_6$, cannot be obtained by merely substituting sodium carbonate for potassium carbonate in the above prescription. It is readily formed, however, when 10 parts of platinum sponge, 5—6 parts of tin selenide, 40 parts of potassium carbonate, 5—6 parts of sodium carbonate, and 40 parts of selenium are fused together, and the melt treated as described above. It forms leaden-grey, microscopical, hexagonal laminæ with a brilliant, metallic lustre; the remarks concerning the potassium salt apply also to this.

Saline Compounds of the Lower Ruthenium Oxides with the Higher Oxides. By A. Joly (*Compt. rend.*, **113**, 694—695.)—When the products of the sudden decomposition of potassium perruthenate at 440° are kept for a long time at this temperature, interaction takes place with formation of a black, crystalline compound of the composition $K_2O,6Ru_2O_5$. Sodium perruthenate at 440° loses oxygen and water, and after treatment of the residue with water, which removes sodium oxide and the orange sodium ruthenate, a black crystalline powder is left with a composition approximating very closely to that for $Na_2O,3Ru_2O_5$. Barium ruthenate, $BaRuO_4$, at 440° loses oxygen, and yields a ruthenite, $BaRuO_3$, different in properties from a mixture of barium monoxide and ruthenium dioxide. The author directs attention to the analogy between these compounds and the products obtained by Rousseau from the permanganates, and the product K_2O,Os_2O_5, obtained by himself from potassium osmiamate.

C. H. B.

Action of Light on Ruthenium Peroxide. By A. Joly (*Compt. rend.*, **113**, 693—694).—When sealed tubes containing perfectly dry ruthenium peroxide are kept in the dark, no alteration takes place, but on exposure to sunlight, the walls of the tube become coated with a pale brown layer, which gradually increases in thickness and eventually transmits only red light. Beyond this point, the peroxide behind undergoes no further change. The brown deposit dissolves at once in potassium hydroxide solution, forming a yellow liquid without any trace of green, and in hydrochloric acid with evolution of chlorine and formation of a solution of ruthenium sesquichloride. It seems, therefore, that when exposed to sunlight, ruthenium peroxide is reduced to the trioxide, RuO_3.

Mineralogical Chemistry.

Sulphur, Orpiment, and Realgar in the Yellowstone National Park. By W. H. Weed and L. V. Pirsson (*Amer. J. Sci.*, **42**, 401—405).—In the Yellowstone National Park there are, besides the geyser basins, many small hot-spring areas where fumeroles and solfataras are still active. At most of these places, deposits of sulphur occur in and around the vents from which the vapours issue. At Highland Hot Springs and at Crater Hill the vents are very abundant, and large deposits of sulphur are found, frequently forming clusters of delicate crystals. Details of the measurement of the crystals are given by the authors. Although no analysis was made, the material is apparently of great purity.

The presence of arsenic in the hot-spring waters of the Yellowstone Park was noticed by A. Hague (Abstr., 1888, 122), and a careful search for deposits of arsenical sulphides was rewarded by the discovery of realgar and orpiment at the Norris Geyser basin. Siliceous sinter is the only other mineral occurring with these arsenical sulphides. B. H. B.

Occurrence of a Natural Gold Sulphide. By T. W. T. Atherton (*Chem. News*, **64**, 278).—The author observed the occurrence of gold in an exceptionally fine state of sub-division in an arsenical pyrites; further investigation showed that this gold could be extracted by heating the finely pulverised pyrites for some hours with a solution of sodium sulphide. It hence appears that the gold, or at least some of it, is present as sulphide. The following is the percentage composition of the ore in general; it also runs 5 ozs. 3 dwts. 8 grs. of gold, and 16 dwts. of silver, to the ton.

SiO_2.	Al_2O_3.	CaO.	S.	As.	Fe.	Co.	Ni.

It is found in a large irregular lode of arsenical pyrites in a felsite dyke in a mica-schist country. Both in the lode and in its vicinity there are large quantities of pyrophyllite. D. A. L.

New Analyses of Uraninite. By W. F. Hillebrand (*Amer. J. Sci.*, **42**, 390—393).—The author gives the following analyses of uraninite. (See next page.)

I*a* is a re-analysis of nivenite from Llano Co. Texas. It agrees in the main with the original analysis by Hidden and Mackintosh, I*b* (Abstr., 1890, 457). II is from a new locality, Marietta, Grenville Co., South Carolina. III is from the Villeneuve mica mine, Ottawa Co., Quebec. IV represents the composition of a specimen from Johanngeorgenstadt, in Saxony. None of these specimens was fresh, and consequently no light could be thrown on the ultimate composition of the mineral. Valuable data, however, are afforded as to the

presence or absence of nitrogen (compare Abstr., 1890, 456; 1891, 527), and of the rare earths. The species, it will be seen, may be broadly divided into two groups, one of which is characterised by the presence of rare earths, and the other by their absence. With the former group, nitrogen appears to be invariably associated. Probably all the varieties of the first group occur in crystals, whilst the members of the second group are generally free from crystalline form.

B. H. B.

Discovery of Diamonds in Meteoric Iron. By A. E. Foote (*Amer. J. Sci.*, **42**, 413—417).—In 1891, a meteorite was found near Cañon Diablo in Arizona, and was thought to form part of a vein of metallic iron. The largest mass discovered weighs 201 lbs., and has a somewhat flattened rectangular shape showing deep pits, three of which pass entirely through the iron. One other large mass was found weighing 154 lbs. A mass weighing 40 lbs. was broken in pieces with a trip hammer, and it was in cutting one of the fragments of this mass that diamonds were discovered. The diamonds are black and white, their nature being established by their hardness and indifference to chemical agents. Carbon in the form of a pulverulent iron carbide occurs in the same cavity with the diamonds. The proportion of nickel in the general mass is 3 per cent. B. H. B.

The Tonganoxie Meteorite. By E. H. S. Bailey (*Amer. J. Sci.*, **42**, 385—387).—This meteorite was found in 1886 near Tonganoxie, Leavenworth Co., Kansas. The specimen originally weighed 26 lbs. Its shape is that of an irregular triangular pyramid, $9\frac{1}{2}$ inches long, $6\frac{1}{2}$ inches wide, and $4\frac{1}{2}$ inches deep. The sp. gr. is 7·45. As shown by a photograph accompanying the author's paper, the surface of the meteorite is covered with numerous depressions. The entire exterior is covered with a reddish-black coating of iron oxide, with occasional drops of chloride of iron exuding after having been exposed to the air. The analysis of the meteorite gave the following results:—

Fe.	Ni.	Co.	P.	Cu.	Total.
91·18	7·93	0·39	0·10	trace	99·60

On treatment with nitric acid, the surface exhibited the Widman stättian figures very clearly. B. H. B.

Composition of some Subterranean Waters from near Port-Vendres. By J. C. Essner (*Bull. Soc. Chim.* [3], **6**, 148—151).—Eleven samples of water collected from the valley of Cosperons, on the Mediterranean slope of the Albères, in the commune of Port-Vendres, were found to contain calcium, magnesium, aluminium, chlorine, and sulphuric acid. One sample only was neutral, seven contained from 0·024 to 0·065 gram of free sulphuric acid per litre, and three contained respectively 0·175, 0·285, and 0·506 gram of free acid per litre.

The neighbouring rocks contain iron pyrites disseminated throughout; the fissures are filled with a yellow powder consisting of ferric oxide, together with some basic ferric sulphates The natural acidity of these waters is attributed to the formation of this deposit. The waters retain only a trace of iron, as the dissolved salts decompose with formation of free sulphuric acid. This view is confirmed by the behaviour of rain-water collected in a cistern at a height of 250 metres above the level of the sea after several months of dry weather. The cistern and works were constructed of stones and débris of the surrounding rocks. Water taken from the cistern, dirty as collected, gave 9·073 grams of dissolved crystallised substances, and 0·105 gram of suspended matter; it was slightly acid. After six days rest, the filtered water already yielded only 6·179 grams of crystallised residue per litre, and 2·997 grams of basic ferric sulphate had been deposited. After an exposure to free air of one month, the water, after filtration, contained only traces of iron, together with 0·765 gram of sulphuric acid (H_2SO_4), and gave 1·010 grams of residue calcined at a red heat, containing calcium, magnesium, and aluminium, with traces of chlorine, sulphuric acid, iron, potassium, and sodium.

The analysis of the primitive water gave:—

Iron calculated as Fe_2O_3	1·500	grams per litre.
CaO	0·637	,,
MgO	0·354	,,
Al_2O_3	0·012	,,
Chlorine	0·024	,,
Total H_2SO_4	3·672	,,

Organic Chemistry.

A Method for Determining the Constitution of Saturated and Unsaturated Halogen Derivatives and Hydrocarbons. By M. Wildermann (*J. pr. Chem.* [2], **44**, 470—492).—This is a method for the determination of the constitution of the higher

members (above $n = 4$) of the aliphatic series, founded on alternate halogenisation and removal of the elements of halogen hydro-acids, with determination of the heats of combustion of the various hydrocarbons produced. The paper is not suitable for abstraction, as the method could not be made intelligible without a full reproduction of the details both of the argument employed and of the various examples given. A. G. B.

Platinum Thiocyanate and Platinothiocyanates. By I. Guareschi (*Chem. Centr.*, 1891, ii, 620—622; from *Giorn. R. Acad. Med.*, 1891).—The author has prepared potassium platinothiocyanate according to the methods of Buckton, Wyrouboff and Norton. He finds that the salt crystallised from alcohol is anhydrous, whilst that crystallised from water contains 2 mols H_2O. This it loses if dried over calcium chloride, but he does not find that it is so readily lost on exposure to the air at ordinary temperatures as Wyrouboff stated.

Potassium platinothiocyanate, $K_2Pt(CNS)_6$, gives characteristic precipitates with many organic bases, and may be used as a test for certain alkaloïds. The platinothiocyanates of the tertiary amines are less soluble than the corresponding salts of the secondary and primary amines. In many cases, the double salts of the secondary bases melt at a lower temperature than those of the primary.

Monomethylamine platinothiocyanate, $(NH_2Me)_2,H_2Pt(CNS)_6$, is prepared by allowing the mixed solutions of potassium platinothiocyanate and of methylamine hydrochloride to remain for several days, when the double thiocyanate crystallises out in long, red, rhombic prisms. The *dimethylamine* salt, $(NHMe_2)_2,H_2Pt(CNS)_6$, is precipitated as red prisms or needles on mixing the not very concentrated solutions of the respective salts. It melts at 160—170° with decomposition, and is soluble in cold water, more readily in hot water, readily soluble in alcohol, insoluble in ether. The *trimethylamine* salt, $(NMe_3)_2,H_2Pt(CNS)_6$, forms red prisms, sparingly soluble in cold water, soluble in alcohol, but insoluble in ether; it melts at 175° with decomposition.

The *ethylamine* salt is similar to the methylamine salt. The *diethylamine* salt, $(NHEt_2)_2H_2Pt(CNS)_6 + 2H_2O$, is prepared by mixing 1 part of the hydrochloride in 6 parts of water with potassium platinothiocyanate. A liquid precipitate at first separates which rapidly solidifies to a mass of short prisms, or rectangular, lemon-yellow plates, which, after drying in the air, melt at 58—58·5°, and in the anhydrous condition, melt at 79—80°. It is sparingly soluble in cold water, more readily in hot water, very soluble in alcohol, insoluble in ether. The *triethylamine* salt, $(NEt_3)_2,H_2Pt(CNS)_6$, is precipitated, when the solution of the hydrochloride, acidified with hydrochloric acid, is added to potassium platinothiocyanate, as a thick, red liquid, which solidifies gradually when agitated. When recrystallised from water, it separates in the same way. It consists of golden-yellow plates, melts at 165—167°, and decomposes at 180°. It is sparingly soluble in cold water, more readily in hot water and in alcohol, insoluble in ether.

Propylamine, butylamine, and amylamine react in the same manner as methylamine and ethylamine.

The *ethylenediamine* salt, $C_2H_4N_2H_4,H_2Pt(CNS)_6$, is a yellow precipitate, sparingly soluble in water, and blackens at 140—150°. The *pentamethylenediamine* salt, $C_5H_{14}N_2,H_2Pt(CNS)_6$, is obtained by precipitating the solution of the hydrochloride with platinum thiocyanate. The precipitate soon becomes crystalline, and forms reddish needles which commence to turn brown at 160°, and become quite black at 176°, but do not melt. It is soluble in alcohol and water, but insoluble in ether.

The *diacetoneamine* salt, $(COMe{\cdot}CH_2{\cdot}CMe_2{\cdot}NH_2)_2,H_2Pt(CNS)_6$, is obtained by precipitating the solution of diacetoneamine oxalate with the platinothiocyanate. It is thus obtained as a crystalline precipitate, which, when recrystallised from hot water, forms red prisms, soluble in alcohol, insoluble in ether. It melts at 165° with decomposition. The *guanidine* salt, $(C_6H_5N_3)_2,H_2Pt(CNS)_6$, is obtained in beautiful red crystals on mixing solutions of guanidine hydrochloride with the platinothiocyanate. It is also obtained when the solution of guanidine thiocyanate is mixed with platinum chloride. It blackens at 170—175° without melting.

The *aniline* salt, $(NH_2Ph)_2,H_2Pt(CNS)_6$, forms dark-red crystals which melt at 100—105°, soluble in alcohol and water, insoluble in ether. The *α-naphthylamine* salt forms a dark-yellow precipitate, the *β*-salt a light-yellow precipitate, from solutions of the hydrochlorides; they are both somewhat difficult to obtain crystalline; they decompose readily on exposure to moist air, especially the *α*-salt. They both melt to brown liquids, the *α*-salt at 140°, the *β*-salt at 120°

Paratoluidine, allylamine, and furfurine are precipitated in like manner.

Phenylhydrazine reduces the solution of the platinothiocyanate. Tetrahydro-*β*-naphthylamine forms a yellow, crystalline precipitate. The *pyridine* salt, $(C_5H_5N)_2,H_2Pt(CNS)_6$, crystallises in red prisms, and is precipitated from the solution of the hydrochloride. It is not changed by exposure to the air, but commences to decompose at 100—105° and melts at 170—172° to a black liquid; it is soluble in hot water, but only sparingly in cold water. Protracted boiling with water causes decomposition. The *piperidine* salt, $(C_5H_{11}N)_2.H_2Pt(CNS)_6$, is precipitated at first as a liquid, which later solidifies in lemon-yellow prisms, sparingly soluble in cold water, readily so in hot water and in alcohol. *Coniine* as hydrochloride or as hydrobromide is precipitated, if the solution be not too dilute, as a red oil, which could not be obtained crystalline. A solution of coniine hydrobromide 1 : 1000 is not precipitated, but *nicotine* is precipitated as yellow crystals at a dilution of 1 : 3000. This salt is almost insoluble in cold water, and may serve to distinguish coniine from nicotine. The *sparteine* salt forms a sulphur-yellow, powdery precipitate. The *α- and β-quinoline* salts are precipitated as yellow, microscopical crystals; the *α*-salt is the darker; even a solution of 1 : 6000 is precipitated.

Ephedrine, *apomorphine*, *apocodeïne*, *cocaïne*, and *ecgonine* are likewise precipitated. *Glycosamine* is not precipitated.

The reaction was examined in the case of the following alkaloïds with the view of determining the delicacy in each case. *Strychnine* solution, 1 : 40,000, gave a crystalline precipitate after some time; *brucine*, 1 : 18,000; *atropine*, 1 : 20,000; *morphine*, 1 : 1000; *veratrine*, 1 : 10,000; *nicotine*, 1 : 3000; *codeïne*, 1 : 2000, all precipitate immediately. *Quinine*, *cinchonine*, *quinidine*, *cinchonidine*, 1 : 100,000, also give precipitates immediately; *aspidospermine*, 1 : 40,000 is also precipitated immediately. J. W. L.

Decomposition of Hydrocarbons with Steam. By Coquillion and Henrivaux (*Chem. Centr.*, 1891, ii, 577; from *J. Usines à Gaz*, 1890, 355).—The authors have determined the composition of the gaseous mixture obtained by heating methane and steam together. When the gases were subjected to the action of an incandescent platinum wire fixed at the lower end of the eudiometer, the gas produced had the composition: 2·45—2·50 per cent. CO_2, 13·68—16·50 per cent. CO, 17·84—14·60 per cent. CH_4; 66·03—66·40 per cent. H. When the methane and steam were passed through three iron tubes heated to redness, the resulting gas had the composition: 1·00 per cent. CO_2, 19·86 per cent. CO, 8·24 per cent. CH_4, 70·90 per cent. H. After passing through tubes heated to a white heat, the resulting gas has the composition: 12·01 per cent. CO_2, 7·35 per cent. CO, 50·64 per cent. H, no methane remaining. J. W. L.

Hydrocarbons from α- and β-Amyrin. By A. Vesterberg (*Ber.*, **24**, 3834—3836).—As already stated (Abstr., 1887, 733; 1891, 165), α- and β-amyrin are converted by phosphorus pentachloride into dextro-α- and β-amyrilene, $C_{30}H_{48}$, and α-amyrin by phosphorus pentoxide into lævo-α-amyrilene, $C_{30}H_{48}$. Dextro-α-amyrilene is sparingly soluble in acetic acid, readily in light petroleum and benzene, and commences to decompose at its boiling point. Lævo-α-amyrilene is prepared by adding a benzene solution of α-amyrin to phosphorus pentoxide, allowing the cherry-red jelly to remain for some days, and adding water to remove phosphoric acid. The benzene solution, on spontaneous evaporation, deposits prismatic crystals surrounded by a glutinous mass; the latter is removed by ether, and the residue recrystallised from hot benzene. It forms rhombic crystals ($a : b : c = 0·789 : 1 : 0·505$), melts at 193—194°, is sparingly soluble in ether, more readily in light petroleum and benzene, and has the sp. rotatory power $[\alpha]_D = -104·9$.

β-Amyrilene is almost insoluble in alcohol and acetic acid, and less readily soluble in ether, light petroleum, and benzene than dextro-α-amyrilene. H. G. C.

Derivatives of Glycerol. By E. Seelig (*Ber.*, **24**, 3466—3471).—Diacetylglycerol (diacetin) is obtained in quantitative yield by boiling 95 per cent. glycerol (400 grams) with glacial acetic acid (1000 grams) in a reflux apparatus for 8½ hours, distilling up to 116°, replacing the distillate (about 270 grams) by an equal weight of fresh glacial acetic acid, boiling for a further 17 hours, and, after distilling off the acetic acid, rectifying the product under a pressure of

40 mm. It boils at 172—174° (40 mm.), and at 259—261° (760 mm.) has a sp. gr. 1·178, is miscible with water, ether, chloroform, and benzene, but almost insoluble in light petroleum and carbon bisulphide. On one occasion the author treated a sample of ordinary glycerol in the above manner, and obtained a product which was only miscible with water to a limited extent, and did not become acid on boiling with it. Diacetylglycerol can only be converted into the triacetyl derivative (triacetin) as follows:—Coarsely pulverised, anhydrous sodium acetate (60 grams) is well mixed with acetic anhydride (150 grams), diacetylglycerol (200 grams) added, and the mixture boiled in a reflux apparatus for 16 hours; the product is shaken with 1½ times its volume of ether and an equal quantity of water. when the triacetyl derivative is dissolved by the ether, and is isolated by distillation. It boils at 171° (40 mm,), and at 258—259° (760 mm.), has a sp. gr. 1·155, is sparingly soluble in water, and, unlike the diacetyl compound, is not decomposed when boiled with it; it is miscible with alcohol, ether, chloroform, and benzene, but almost insoluble in light petroleum and carbon bisulphide. It would thus appear that the triacetylglycerol described by Schmidt (Abstr., 1880, 312) was in reality the diacetyl derivative, and since a mixture of the two cannot be separated from one another, Böttinger's method (Abstr., 1891, 1183) is invalid.

When diacetylglycerol is dissolved in glacial acetic acid, saturated with hydrogen chloride, and, after heating at 100° for two hours, distilled under a pressure of 40 mm., two fractions, consisting of impure dichloracetyl derivatives, pass over at 101—107° and at 107—113° respectively, whilst chlorodiacetylglycerol, contaminated apparently with chloracetylglycerol, passes over at 137—144° (see below), and, lastly, unaltered diacetylglycerol distils; lower boiling compounds are also formed. The same result is obtained by leading a stream of hydrogen chloride through boiling diacetylglycerol. When cooled acetic anhydride (130 grams) is saturated with dry hydrogen chloride, mixed with diacetylglycerol (190 grams), again saturated with hydrogen chloride, 70 grams of the gas being absorbed in all, and the mixture heated at 110° for 30—40 hours, a chlorodiacetylglycerol boiling at 142—149° (40 mm.). or at 230—240° (760 mm.), a dichloracetylglycerol boiling at 108—112° (40 mm.), or at 189—199° (760 mm.), together with much triacetylglycerol and lower boiling compounds, are obtained; whilst if hydrogen chloride is passed through boiling triacetylglycerol for 70 hours, a chlorodiacetylglycerol boiling at the same temperature as the last-mentioned one, and having a sp. gr. 1·204, is produced. When the fraction boiling at 137—144° (40 mm.) from diacetylglycerol and hydrogen chloride is heated with an excess of acetic anhydride at 180—190°, a chlorodiacetylglycerol boiling at 141—148° (40 mm.) is obtained, whilst a similar compound is produced by heating α-chlorhydrin with an excess of acetic anhydride. When dichlorhydrin (prepared from α-chlorhydrin) is heated with acetic anhydride, it yields two dichloracetylglycerols boiling at 108—112° and at 112—116° (40 mm.) respectively. The dichloracetylglycerol boiling at the lower temperature is probably the symmetrical derivative, and, since only one

monochloro-derivative is formed from the diacetylglycerol, the two acetoxy-groups in this compound probably occupy consecutive positions, and support is afforded to this view by the fact that the diacetylglycerol yields an aldehyde on oxidation with nitric acid; the *hydrazone* from the latter melts at 161°. A. R. L.

Reactions of Xylose and Arabinose. By TOLLENS (*Bull. Soc. Chim.* [3], **6**, 161—162).—This is a note containing extracts from memoirs by Wheeler and Tollens (*Annalen*, **254**, 314), and by Allen and Tollens (*Annalen*, **260**, 304), which show that the coloured reactions of xylose with orcinol and phloroglucinol, given by Bertrand in the *Bull. Soc. Chim.* [3], **5**, 932, were already known. W. T.

Oxidation Products of α- and β-Amyrin. By A. VESTERBERG (*Ber.*, **24**, 3836—3843).—Both α- and β-amyrin, when oxidised with chromic acid in acetic acid solution, yield as chief products the corresponding ketones (or, possibly, aldehydes), α- and β-amyrone.

α-Amyrone, $C_{30}H_{48}O + H_2O$, crystallises from a mixture of alcohol and acetic acid in large tablets, melts at 125—130°, dissolves readily in ether, hot benzene, and acetic acid, sparingly in light petroleum and alcohol. The substance thus obtained is, however, not quite pure, but, on treatment with hydroxylamine, it readily yields pure *α-amyron-oxime*, $C_{30}H_{48}{:}NOH$, which crystallises from benzene in needles, and melts with evolution of gas at 233—234°. *β-Amyrone*, $C_{30}H_{48}O$, forms nodular aggregates of small prisms, melts at 178—180°, is readily soluble in chloroform, ether, and benzene, sparingly in light petroleum and alcohol; its *oxime*, $C_{30}H_{48}{:}NOH$, crystallises from benzene in long, pointed plates which melt with evolution of gas at 262—263°.

When α-amyrin acetate is subjected to the action of chromic acid in acetic acid solution, two atoms of hydrogen are replaced by one of oxygen with formation of *oxy-α-amyrin acetate*, $C_{30}H_{47}O{\cdot}OAc$, which crystallises from benzene in six-sided, rhombic plates ($a : b : c = 0{\cdot}6845 : 1 : 1{\cdot}2538$), melts at 278°, and is insoluble in alcohol and ether, sparingly soluble in acetic acid, readily in benzene. By the action of alcoholic potash, it is converted into *oxy-α-amyrin*, $C_{30}H_{47}O{\cdot}OH + 2H_2O$, which melts at 207—208°, and forms acicular crystals readily soluble in alcohol, ether, and benzene, insoluble in light petroleum; the 2 mols. H_2O are slowly evolved at 100°. Its solutions in alcohol and benzene, like those of bromo-β-amyrin, solidify to jellies on cooling.

β-Amyrin acetate, on oxidation, appears to behave in a manner similar to the α-compound, but the oxy-β-amyrin acetate could not be obtained free from unaltered β-amyrin acetate.

The oxygen atom in these compounds is not present in the form of a hydroxyl or carbonyl group, for oxy-α-amyrin acetate is not acted on by acetic anhydride or hydroxylamine; it is therefore probably present in the same form as in the alkylene oxides. A similar compound was obtained by Schrötter (Abstr., 1882, 66) by the oxidation of borneol acetate.

The alcohols related to amyrin appear to be widely distributed in the vegetable kingdom. Liebermann's cholesterin reagent (acetic

anhydride and concentrated sulphuric acid) gives strongly coloured solutions with almost all amyrin derivatives, the bromine compounds giving a blue, and the others a violet or purple-red, coloration. Lævo-α-amyrilene gives only a yellowish, or, at most, pink, coloration.

H. G. C.

Pectin Substances. By A. Herzfeld (*Chem. Centr.*, 1891, ii, 618—619; from *Zeit. Verein Rübenzück. Ind.*, 1891, 667—678).—*Parapectic acid* was obtained by the author by heating 500 grams of sliced beetroot with 1000 grams of water and 50 c.c. of concentrated hydrochloric acid at 70° for one hour. The liquid was separated from the solid portion, neutralised with sodium carbonate, and precipitated with alcohol. The substance thus obtained was not quite free from mineral matter, and contained 29·6 per cent. of mucic acid and 4 per cent. of furfuraldehyde. Parapectic acid appears to consist of a mixture of substances which yield arabinose and galactose.

Metapectic acid was obtained both from the sliced roots and from parapectin by treatment with calcium carbonate. The specimens thus obtained differed in their optical properties, the one being dextrorotatory, whilst the other was lævo-rotatory, and the amounts of mucic acid and furfuraldehyde obtained from each were not the same.

J. W. L.

First Product of the Reduction of Nitro-compounds with Tin and Hydrochloric Acid, or with Stannous Chloride. By E. Hoffmann and V. Meyer (*Ber.*, **24**, 3528—3535).—It was observed long ago that, in preparing normal butylamine by the reduction of nitrobutane with tin and hydrochloric acid, there is formed a considerable quantity of a substance which reduces Fehling's solution. The authors' recent experiments have shown that other fatty nitro-compounds, such as nitromethane, nitroethane, and secondary nitropropane, show a like behaviour, but that nitrobenzene and nitrophenol do not yield any substances which have a reducing action on Fehling's solution. It was also found that when nitromethane (1 mol.) is treated with pure stannous chloride (1 mol.) in concentrated hydrochloric acid solution, methylamine hydrochloride, ammonium chloride, and β-methylhydroxylamine hydrochloride, NHMe·OH,HCl, are formed; the three compounds are best separated by fractionally precipitating the alcoholic solution of the mixed products with dry ether.

These experiments show that the conversion of nitromethane into methylamine takes place in the following two phases:—$CH_3{\cdot}NO_2 + 2H_2 = H_2O + NHMe{\cdot}OH$ and $NHMe{\cdot}OH + H_2 = H_2O + NH_2Me$, and that the reduction of the Fehling's solution is due to the formation of a hydroxylamine derivative.

F. S. K.

Isomerism of Oximes. By G. Minunni (*Gazzetta*, **21**, ii, 192—205).—The author replies to Hantzsch's criticisms (Abstr., 1891, 823) on his explanation of the isomerism of oximes (Abstr., 1891, 1354). The conversion of the β-oximes into nitriles is readily explained by supposing the formation of a nitroso-derivative as an intermediate product. The intramolecular change noted by Beckmann can

also be explained in a somewhat similar manner. To the argument that three, and not two, isomeric oximes are accounted for by the author's hypothesis, it is replied that the stereochemical hypothesis is, in many cases, open to the same objection. Finally, the author's hypothesis is in no way dependent on the presence of the benzene nucleus, but only requires the compound to contain the group X=C–C=X; as this group is contained in the oximes of succinic acid, the isomerism existing among them is satisfactorily explained. W. J. P.

Action of Oxidising Agents on Aliphatic Thiocarbamides. By D. S. Hector (*J. pr. Chem.* [2], **44**, 492—506; compare Abstr., 1889, 872; 1890, 526).—When thiocarbamide is heated with hydrogen peroxide in hydrochloric acid solution, it is decomposed with the formation of ammonium chloride, sulphur, sulphuric acid, and carbonic anhydride.

Pseudothiocyanogen, $HC_3N_3S_3$, was the ultimate product of the action of hydrogen peroxide on ammonium thiocyanate in hydrochloric acid solution; it did not dissolve in alcohol, but dissolved readily in potassium hydroxide solution, from which it was precipitated by hydrochloric acid; the alkaline solution gave a yellowish-brown precipitate with silver nitrate.

Allylthiocarbamide is decomposed when heated with hydrogen peroxide in neutral solution, and subsequently with barium hydroxide, with formation of sulphuric acid, formic acid, allylamine, and ammonia.

Allylformamidine bisulphide, $S_2[C(NH{\cdot}C_3H_5){:}NH]_2$, is prepared by heating allylthiocarbamide with hydrogen peroxide ($\frac{1}{2}$ mol. proportion) in an acid solution. After filtering off the sulphur, separating sulphuric acid by barium hydroxide, and the excess of the latter by carbonic anhydride, the liquid is evaporated, until a viscid oil separates on cooling. The oil is dried on the water-bath, and cooled in a desiccator, when it sets to a vitreous mass, the analysis of which points to the above formula. The new base is bivalent; it dissolves readily in hot water, but sparingly in cold, and these solutions turn red litmus blue; it also dissolves in alcohol, but not in ether, benzene, or chloroform. It decomposes when heated. Its salts do not crystallise, but are very soluble in water. An aqueous solution of the bisulphide gives a white precipitate with silver nitrate, which rapidly becomes black; it is also precipitated by platinic chloride, mercuric chloride, picric acid, potassium ferrocyanide, and potassium ferricyanide. When it is heated with barium hydroxide, ammonia and allylamine are evolved. The *sulphate*, $C_8H_{14}N_4S_2,H_2SO_4 + H_2O$, forms a viscous, white mass, but does not crystallise; the *picrate*, $C_8H_{14}N_4S_2,2C_6H_3N_3O_7$, forms yellow granules, which melt at 178—180°; the *platinochlorides*, $C_8H_{14}N_4S_2,H_2PtCl_6 + 2H_2O$ and $(C_8H_{14}N_4S_2,2HCl)_3(PtCl_4)_2$, were both obtained; the *mercurochloride*, $C_8H_{14}N_4S_2,4HgCl_2$, is a white, crystalline powder, and melts at 171—172°.

Diallyldithiotetrahydrotriazole, $NH<\begin{matrix}CS{\cdot}N{\cdot}C_3H_5\\ |\\ CS{\cdot}N{\cdot}C_3H_5\end{matrix}$.—This compound is obtained by dropping a solution of potassium nitrite (4 grams) into

a solution of allylthiocarbamide (5 grams) acidified with sulphuric acid; the solution is afterwards shaken with ether, and the ethereal solution washed with dilute sodium hydroxide solution, dried, and evaporated. It is a yellow oil, insoluble in water and dilute acids, but soluble in alcohol and ether; it is a feeble base, giving precipitates with platinic chloride, silver nitrate, mercuric chloride, and copper sulphate. The *platinochloride*, $(C_8H_{11}N_3S_2)_2.H_2PtCl_6$, was obtained.

Dimethyldithiotetrahydrotriazole, $NH<\begin{matrix}CS\cdot NMe\\ |\\ CS\cdot NMe\end{matrix}$ is prepared in like manner, and is a yellow oil, giving similar reactions. A. G. B.

Constitution of Caprylaldehyde. By A. Béhal (*Bull. Soc. Chim.* [3], **6**, 131—137).—Substances having the formula $C_8H_{16}O$ have been prepared by the author in four different ways: (1) by the distillation of castor-oil soap; (2) by oxidation of capryl alcohol obtained by the distillation of castor-oil soap in presence of an alkali; (3) by the action of zinc methyl on œnanthylic chloride; (4) by the addition of the elements of water to true acetylenic caprylidene.

All these substances have the same odour, and boil at 171—172°; their densities at 0° are respectively: (1) 0·8331; (2) 0·8337; (3) 0·8399, 0·8387; (4) 0·8399.

The smaller values obtained in the first two cases are probably due to the presence of a little capryl alcohol. None of these compounds reduce ammoniacal silver nitrate in alcoholic solution. The products are identical, and by the third method of preparation the substance must be a methyl ketone. This is substantiated by the preparation of the oxime, which boils at 218°, and, on treatment with acetic chloride, yields an acetyl-derivative, which gives barium acetate and the original ketone when distilled with baryta.

The products of oxidation of the compound prepared in each of the four ways are caproic and acetic acids. The caproic acid obtained has been prepared in large quantity and purified. The fraction passing over at 204—206° readily crystallises from methyl chloride; it fuses at −10·5°, a point much lower than that indicated by Fittig for the normal acid (*Annalen*, **200**, 49), but this difference is, perhaps, due to a trace of impurity.* Its density at 0° is 0·9456. The calcium salt crystallises in plates containing 1 mol. H_2O. The solubility of this salt is such that at +1° the solution contains 2·084 grams of the anhydrous salt per 100 c.c., and at 23·5° the corresponding amount is 2·852 grams. These numbers correspond with the determinations of the solubility of the calcium salt of normal caproic acid made by Lieben and Rossi.

The so-called caprylaldehyde is therefore normal methyl hexyl ketone. W. T.

Dry Distillation of Organic Silver Salts. By W. Koenigs (*Ber.*, **24**, 3589—3590).—The author points out that the decomposition of organic silver salts when heated frequently takes a course

* The difference between the temperature of fusion found, −10·5°, and that given for the normal acid, −2°, would require as much as 2 per cent. of an impurity of low molecular weight, such as water, for its production, according to Raoult's law.—*Note by Abstractor.*

quite different from that studied by Kachler (this vol., p. 37). He quotes a number of well-known cases in which the silver salt is decomposed, with evolution of carbonic anhydride, yielding considerable quantities of a substance of which the acid in question is a carboxyl-derivative. F. S. K.

Glycocine and its Derivatives. By B. Goldberg, P. Kunz, and K. Kraut (*Annalen*, **266**, 292—310; compare Mauthner and Suida, Abstr., 1891, 38).—Amidoacetic acid (glycocine) is best prepared by gradually adding a concentrated aqueous solution of chloracetic acid to a large excess of concentrated ammonia with constant stirring, and, after keeping for 24 hours, expelling the excess of ammonia, first with a stream of air, and then by warming on the water-bath; the acid is isolated by means of its copper salt. The mother liquors from the copper salt contain di- and tri-glycolamidic acid (compare Heintz, *Annalen*, **122**, 257; **124**, 297), but 20—30 per cent. of the chloracetic acid is converted into products other than those already named, the nature of which could not be determined. The *barium* salt, $(NH_2{\cdot}CH_2{\cdot}COO)_2Ba + 4H_2O$, is obtained in small, lustrous crystals when the acid (1 part) and crystalline barium hydroxide (2 parts) are dissolved in a little water, the filtered solution poured into alcohol, and the precipitated oil left for some days in contact with the supernatant liquid; it melts at about 42°, and cannot be obtained in an anhydrous condition. The *strontium* salt, with $1\frac{1}{2}H_2O$, *calcium* salt, with H_2O, and the *magnesium* salt, with $2H_2O$, were prepared in like manner, and are all crystalline; the calcium salt loses the whole of its water at 105—110°, and its aqueous solution has a strongly alkaline reaction. These experiments prove the inaccuracy of Curtius' statements regarding the non-existence of such salts. A double *salt* of the composition

$$\begin{matrix} HO{\cdot}CH_2COO \\ NH_2{\cdot}CH_2{\cdot}COO \end{matrix}\!\!>Zn + 2H_2O$$

is formed by the union of molecular proportions of zinc amidoacetate and zinc glycollate; it is a crystalline compound, sparingly soluble in cold, and decomposed by hot water with separation of zinc oxide.

When methyl amidoacetate hydrochloride is boiled with excess of copper oxide, it is completely decomposed, yielding methyl alcohol, copper amidoacetate, and cupric chloride; ethyl amidoacetate hydrochloride, under the same conditions, is decomposed in a similar manner. There is, therefore, no reason for supposing that in these compounds copper can be substituted for the hydrogen of the amido-group (compare Curtius and Goebel, Abstr., 1888, 576), and it is probable that all the metallic derivatives of amidoacetic acid are formed by the substitution of the hydrogen of the carboxyl group.

F. S. K.

Diethylamidocaproic Acid. By E. Duvillier (*Bull. Soc. Chim.* [3], **6**, 90—92).—Normal α-bromocaproic acid (1 mol.) is heated in sealed tubes at 100° with excess of diethylamine (3 mols.) in concentrated aqueous solution. The base is recovered by boiling with baryta, the baryta precipitated exactly with sulphuric acid, and the

product treated with silver oxide. A little dissolved silver is removed by hydrogen sulphide, and the solution evaporated to a syrup, from which the pure amido-acid is obtained by conversion into the copper salt, which is deposited on evaporation at a low temperature as a violet salt, accompanied by a small quantity of a green salt, and is purified by crystallisation from aqueous solution over sulphuric acid; the copper diethylamidocaproate is then decomposed by hydrogen sulphide. The acicular crystals of the copper salt are of a dark-violet colour, resembling that of chrome alum; they give fine, violet solutions in water and alcohol, their solubility in the latter being much the greater.

The free acid, $CH_3 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CH(NEt_2) \cdot COOH$, is very soluble in water and alcohol, but insoluble in ether. Its solutions, when strongly concentrated, give a crystalline mass which decomposes on distillation. The *hydrochloride* is a syrupy substance, soluble in all proportions in water and alcohol.

The *platinochloride* is deposited from very concentrated aqueous solutions in orange-red, monoclinic prisms; it is very soluble in water, and soluble in alcohol, but insoluble in pure, dry ether. Ether precipitates it from its alcoholic solution as an orange-coloured oil. It contains 1 mol. H_2O, which it loses at 110°. The corresponding *aurochloride* is almost insoluble in water; it is deposited as a yellow oil from hot solutions, forming small, crystalline plates on cooling. The crystals are anhydrous, very soluble in alcohol, also soluble in pure, dry ether.

The green copper compound accompanying the copper diethylamidocaproate is copper hydroxycaproate; it yields barium hydroxycaproate on treatment with barium sulphide. The barium salt crystallises with $\frac{1}{2}$ mol. H_2O in brilliant needles, forming radiating groups.

W. T.

Derivatives of Isocrotonic Acid. By P. Melikoff and P. Petrenko-Kritschenko (*Annalen*, **266**, 358—378).—When a slight excess of hypochlorous acid is gradually added to an aqueous solution of isocrotonic acid, and the solution then extracted with ether, a thick, acid syrup is obtained, which consists of β-chlor-α-hydroxybutyric acid (m. p. 85—86°), small quantities of α-chloro-β-hydroxybutyric acid (m. p. 62—63°), the formation of which is probably due to the presence of crotonic acid, and α-chloro-β-hydroxybutyric acid (m. p. 80·5°).

The β-chlor-α-hydroxybutyric acid (m. p. 85—86°) is easily isolated by means of its sparingly soluble zinc salt (compare Abstr., 1884, 1301); the other two acids form readily soluble zinc salts and are separated from one another by means of their potassium salts, that of the α-chloro-β-hydroxy-acid (m. p. 62—63°) being much the more readily soluble in alcoholic ether.

α-Chloro-β-hydroxybutyric acid (m. p. 80·5°), prepared from its potassium salt, crystallises from ether in well-defined, rhombic prisms, and is readily soluble in water, alcohol, and ether. The *potassium* salt, $C_4H_6ClO_3K + 1\frac{1}{2}H_2O$, crystallises from hot 96 per cent. alcohol in long, silky, efflorescent prisms, and is readily soluble in water, but only sparingly in cold 96 per cent. alcohol. The *sodium* salt,

$C_4H_6ClO_3Na$, separates from hot alcohol in small, granular crystals, and seems to decompose at 70°. The *calcium* salt, *zinc* salt, and *silver* salt are amorphous. When the acid is distilled with concentrated sulphuric acid, it is converted into α-chlorocrotonic acid (m. p. 99°).

β-Methylisoglycidic acid, isomeric with the β-methylglycidic acid obtained from α-chloro-β-hydroxybutyric acid (m. p. 62—63°), is formed when α-chloro-β-hydroxybutyric acid (m. p. 80·5°) is treated with hot alcoholic potash, and the crystalline potassium salt decomposed with dilute sulphuric acid; it is a thick liquid, having a strong odour of butyric acid. The *potassium* salt, $C_4H_5O_3K + H_2O$, separates from alcoholic ether in prismatic crystals, melts at 82°, and is readily soluble in water and cold alcohol. The *silver* salt, $C_4H_5O_3Ag$, crystallises from hot water in small, colourless needles.

A *β-chlor-α-hydroxybutyric acid*, melting at 125°, and isomeric with the β-chlor-α-hydroxy-acid (m. p. 85—86°) referred to above, is obtained when the potassium salt of β-methylisoglycidic acid is treated with very concentrated hydrochloric acid; it crystallises in prisms and is readily soluble in water, ether, and alcohol. The *calcium* salt, $(C_4H_6ClO_3)_2Ca + 4H_2O$, is crystalline; the *zinc* salt, $(C_4H_6ClO_3)_2Zn$, crystallises in well-defined, transparent plates, and is readily soluble in water. When the acid is treated with alcoholic potash, it is reconverted into β-methylisoglycidic acid; on boiling a solution of its sodium salt, carbonic anhydride, propaldehyde, and sodium chloride are formed.

When α-chloro-β-hydroxybutyric acid (m. p. 80·5°) is heated with concentrated hydrochloric acid at 100°, it yields a dichlorobutyric acid (m. p. 72—73°), identical with the compound obtained from α-chloro-β-hydroxybutyric acid (m. p. 62—63°) in like manner.

β-Methylisoglyceric acid, $C_4H_8O_4$, is formed when β-methylisoglycidic acid is heated with water at 100° for 5—6 hours in sealed tubes; it crystallises in short, seemingly rhombic prisms, melts at 45°, and is readily soluble in alcohol and water, but only sparingly in ether. The *potassium* salt, $C_4H_7O_4K + H_2O$, crystallises from alcohol in prismatic plates, and is readily soluble in water. The *barium* salt, $(C_4H_7O_4)_2Ba + 2H_2O$, is a granular, crystalline compound. The *silver* salt, $C_4H_7O_4Ag$, crystallises from water, in which it is only sparingly soluble, in large prisms. When the acid is repeatedly melted, its melting point rises, possibly because it is partially converted into β-methylglyceric acid (m. p. 80°).

The authors are of the opinion that the chlorhydroxy-acids obtained from isocrotonic acid are the geometrical isomerides of the corresponding crotonic acid derivatives, and that their experiments afford additional proof of the structural identity of crotonic and isocrotonic acids.

F. S. K.

Preparation of Dehydracetic Acid. By H. v. Pechmann (*Ber.*, **24**, 3600).—Dehydracetic acid can be very conveniently prepared by treating acetonedicarboxylic acid with acetic anhydride, dissolving the crystalline substance (m. p. 154°) obtained in this way in dilute soda (1 mol.), evaporating to dryness, and then precipitating the aqueous solution of the residue with acetic acid; the yield is about 300 grams from 1 kilo. of citric acid. F. S. K.

Resolution of Inactive Lactic Acid by Penicillium Glaucum. By G. Linossier (*Bull. Soc. Chim.* [3], **6**, 10—12).—After three months, solutions of ammonium lactate (corresponding with 5 per cent. lactic acid) in which pure cultivations of *Penicillium glaucum* have been growing become alkaline and lævogyrate. From the products the author has isolated a dextrogyrate lactic acid, which yields a lævogyrate zinc salt. Mixtures of hot solutions of this salt and of dextrogyrate zinc paralactate deposit, on cooling, crystals of inactive zinc lactate.

During the first two months, when the mould is vigorously growing, no active acid appears; it is only in its later stages of development, when fat appears in its hyphæ, that the nutrient solution manifests optical activity. Hence it appears that the healthy fungus attacks both varieties of lactic acid equally, but, when weakened, the lævorotatory variety is more easily assimilated. T. G. N.

Decomposition of Glutaric Acid at a High Temperature. By W. Lossen (*Annalen*, **266**, 264—266).—A reply to Claus (this vol., p. 40).—The author does not deny that carbonic anhydride is evolved when glutaric acid is heated under certain conditions; his and Wisbar's experiments (Abstr., 1891, 1011) were undertaken simply in order to ascertain whether, and if so which, butyric acid is formed on heating glutaric acid; they found that butyric acid is not produced, and, consequently, Claus' original statement is untrue.

F. S. K.

Conversion of Unsaturated Acids into their Stereochemical Isomerides by Soda. By A. Delisle (*Ber.*, **24**, 3620—3622).—Maleïc acid undergoes no change when it is heated with aqueous or alcoholic potash for a short time at 100°, as has lately been shown by Skraup (Abstr., 1891, 1338). The author finds that 30 per cent. soda is also without action at 100°, but that when the temperature is raised to 106°, the maleïc acid is slowly transformed into fumaric acid; malic acid is converted into fumaric acid under the same conditions.

When a solution of citraconic acid (6·5 grams) in 28 per cent. soda (100 c.c.) is heated for six hours on the water-bath, it yields mesaconic acid (3·7 grams) and itaconic acid (1·2 grams), but a considerable quantity of citraconic acid remains unchanged; when mesaconic acid (6·5 grams) is treated in like manner, it gives citraconic acid (1·8 grams) and itaconic acid (1 gram), a large quantity (3·7 grams) remaining unchanged.

Pyrocinchonic acid is not acted on by concentrated soda at 100°, but diphenylmaleïc acid is converted into a substance which melts considerably above 250°, and which seems to have the same percentage composition as diphenylmaleïc anhydride. F. S. K.

$\alpha\beta$-Dimethylglyceric Acid from Angelic Acid. By P. Melikoff and P. Petrenko-Kritschenko (*Annalen*, **226**, 378—380).—When the liquid dimethylglyceric acid obtained from angelic acid (Abstr., 1890, 862) is kept for a long time, it gradually solidifies to a mass of

crystals; this crystalline acid is identical with the $\alpha\beta$-dimethylglyceric acid obtained from tiglic acid. F. S. K.

Derivatives of Glutamic Acid. By A. Menozzi and G. Appiani (*Rend. Acad. Linc.*, **7**, i, 33—40).—Glutamic acid, prepared by the method of Hlasiwetz and Habermann, melts at 200°, and in aqueous solution (2—4 per cent.) has a specific rotatory power $[\alpha]_D = +12{\cdot}5°$ at 22°. For the hydrochloride in aqueous solutions (4 per cent.) $[\alpha]_D = +27{\cdot}5°$ at 15°, and for the calcium salt $[\alpha]_D = -3{\cdot}6°$ at 16°. These results agree fairly with those of Scheibler (Abstr., 1884, 1308). The authors were unable to prepare the diammonium salt described by Habermann (*Annalen*, **179**, 248).

Glutimide is best prepared by passing dry hydrogen chloride into a solution of glutamic acid (20 grams) in absolute alcohol (100 grams); the ethyl glutamate hydrochloride thus obtained is decomposed by moist silver oxide, and the dissolved silver precipitated by hydrogen sulphide; on concentration, ethyl glutamate separates, and, after being recrystallised from dilute alcohol, is converted into glutimide by heating in a closed tube with alcoholic ammonia for 7—8 hours at 140°. Or an alcoholic solution of glutamic acid may be saturated with hydrogen chloride, alcoholic ammonia added, the solution filtered from ammonium chloride, saturated with ammonia, and then heated in a closed tube for conversion into glutimide. The glutimide thus obtained is optically inactive, and crystallises without water of crystallisation in the oblique system, $a : b : c = 1{\cdot}403 : 1 : 1{\cdot}421$; $\beta = 86° 58'$.

Active *glutimide*, $C_5H_8N_2O_2$, is prepared by saturating the solution of ethyl glutamate obtained as above with ammonia in the cold; after some time glutimide separates, and, on recrystallisation from water, is obtained in large, orthorhombic prisms or tables ($a : b : c = 0{\cdot}661 : 1 : 1{\cdot}016$) containing 1 mol. H_2O, which is lost on drying over sulphuric acid or on heating at 100°. It melts at about 165°, and its specific rotatory power $[\alpha]_D = -140°$ in aqueous solution (8·5 per cent.) at 15°. The aqueous solution is not changed by boiling with magnesia, but readily yields ammonia when boiled with hydroxides of the alkalis or alkaline earths. The anhydrous compound dissolves in 13 parts of water at 9°, and in 125 parts of absolute alcohol at 13°. When heated with alcoholic ammonia in a closed tube for 8—9 hours at 140—150°, it is completely converted into inactive glutimide.

On treating inactive glutimide with concentrated hydrochloric acid, ammonium chloride and inactive *glutamic acid hydrochloride* are obtained. The latter substance forms orthorhombic crystals ($a : b : c = 0{\cdot}8852 : 1 : 0{\cdot}3866$), part of which show right-handed and part left-handed hemihedrism; it is therefore a mixture of the hydrochlorides of dextro- and lævo-glutamic acid.

On boiling the aqueous solution of inactive glutimide with barium hydroxide, precipitating with sulphuric acid, and concentrating the filtrate, inactive glutamic acid is obtained in orthorhombic crystals. These crystals are completely holohedral, but, on repeated crystallisation from water, crystals showing right- and left-handed hemihedrism are obtained. W. J. P.

A New Isomeride of Galactonic Acid and of Mucic Acid. By E. FISCHER (*Ber.*, **24**, 3622—3629).—When galactonic acid is heated with quinoline or, better, with pyridine, it is partially converted into a stereochemical isomeride, which bears the same relationship to galactonic acid as gluconic does to mannonic acid; this new compound, which the author names talonic acid, yields, on reduction, a syrupy sugar (talose), which is converted into talomucic acid, the stereochemical isomeride of mucic acid, on oxidation with nitric acid.

Talonic acid is prepared by heating a 50 per cent. aqueous solution of pure galactonic acid (125 grams) with pyridine (125 grams) and water (1 litre) for two hours at 150° in a closed vessel; the filtered solution is boiled with crystalline barium hydroxide (125 grams) until free from pyridine, mixed with a quantity of sulphuric acid exactly sufficient to precipitate the barium, treated with animal charcoal, neutralised with cadmium carbonate and cadmium hydroxide, and filtered. On cooling, the sparingly soluble cadmium salt of galactonic acid is deposited in crystals; after separating this compound as completely as possible, the diluted mother liquors are treated with hydrogen sulphide, and the talonic acid in the hot, filtered solution precipitated with basic lead acetate. The colourless basic salt obtained in this way is decomposed with hydrogen sulphide, the filtered solution, which still contains galactonic acid, boiled with brucine and evaporated to a syrup; the brucine salt of talonic acid, which is deposited in crystals on cooling, is washed with a little alcohol and then dissolved in hot methyl alcohol, from which it separates in slender crystals melting at 130—133°, and readily soluble in water. The yield of the pure salt is 23 per cent. of the galactonic acid employed, which is equivalent to 7 per cent. of talonic acid. The free acid is obtained by boiling an aqueous solution of the brucine salt with barium hydroxide, evaporating the cold filtered solution to dryness, and extracting the residual barium salt with boiling alcohol to free it from brucine; if now the barium salt is decomposed with sulphuric acid in the usual way, and the filtrate evaporated, there remains a syrup which consists of a mixture of talonic acid and its lactone; this syrup is strongly dextrorotatory, and is readily soluble in hot alcohol. The *calcium*, *strontium*, *barium*, and *zinc* salts of the acid are very readily soluble in water, and do not crystallise. The *cadmium* salt, $(C_6H_{11}O_7)_2Cd + H_2O$, is a colourless, crystalline compound, very readily soluble in cold water. The *hydrazide*, $C_6H_{11}O_6{\cdot}N_2H_2Ph$, crystallises from hot alcohol in small, colourless prisms, melts at about 155° with slight decomposition, and is much more readily soluble in water than the corresponding derivative of galactonic-acid.

Talose, prepared from the mixture of the acid and its lactone in the usual manner, is a colourless syrup; its *hydrazone* differs from that of galactose in being very readily soluble in water, but its *osazone* cannot be distinguished from the corresponding galactose derivative.

When talonic acid is heated with pyridine under the conditions described above, it is partially converted into galactonic acid.

Talomucic acid, $C_6H_{10}O_8$, is obtained when talonic acid is evaporated with dilute nitric acid, and is purified by means of its calcium salt. It crystallises from acetone in colourless, microscopic, quadratic plates,

melts at about 158° with decomposition, and is very readily soluble in cold water and warm alcohol, but only sparingly in warm acetone, and almost insoluble in ether, chloroform, and benzene; its specific rotatory power is $[\alpha]_D^{20} = +29{\cdot}4°$ (approximately), but this value rapidly decreases on boiling the solution, owing to the formation of the lactone; it does not reduce Fehling's solution even on boiling. Aqueous solutions of the acid give colourless precipitates with lead acetate and with barium hydroxide, and in neutral solutions, cadmium sulphate produces a colourless precipitate. The *silver* salt is insoluble, and is decomposed by boiling water. The *potassium hydrogen* salt is a colourless syrup, very readily soluble in water. The *calcium* salt, $C_6H_8O_8Ca$, separates from hot water in the form of a colourless, crystalline powder; when boiled with water, it changes to a pasty mass, and only dissolves to a slight extent, but it is more readily soluble in hot, very dilute acetic acid. The *phenylhydrazide* crystallises in almost colourless plates, melts at 185—190° with decomposition, and is much more readily soluble in water than the dihydrazide of mucic acid. When talomucic acid is heated with concentrated hydrochloric and hydrobromic acids at 150°, it is converted into dehydromucic acid; on treatment with pyridine and water at 140°, it gives mucic acid. F. S. K.

Constitution of the Hydroxamic Acids. By F. Tiemann (*Ber.*, **24**, 3447—3453).—The reactions by which the hydroxamic acids are formed suggest at once that they are hydroxamido-derivatives of the general formula R·CO·NH(OH); the hydrogen of the hydroxyl group being displaceable by alkyl and alkoyl radicles. Lossen at first put forward this view, but he has since expressed the belief that they are oximido-derivatives of the general formula R·C(NOH)·OH on the ground that they are convertible into compounds containing either an oximido-group or an alkylated or alkoylated oximido-group. Thus, when treated with silver nitrate in alkaline solution, silver derivatives are formed which, on subsequent treatment with alkyl iodides, yield the compounds R·C(NOR′)·OR′, but Tafel and Enoch have shown (Abstr., 1890, 491) that certain aromatic amides, under similar conditions, yield compounds analogous to the last mentioned, thus, R·C(NH)·OR′, from which it might with equal force be urged that these amides had the constitution R·C(NH)·OH. The author is inclined to ascribe these phenomena to tautomerism, and he holds the opinion that the hydroxamic acids have the constitution R·CO·NH·OH. A. R. L.

Alkyl and Acidyl Sulphides. By S. H. Davies (*Ber.*, **24**, 3548—3552).—A compound of the composition Me_3IS is obtained when methyl bisulphide or methyl tersulphide is heated at 100° for 3—4 hours with methyl iodide; it crystallises in colourless needles, and, after having been converted into the corresponding chloride, gives a *platinochloride* of the composition $(Me_3SCl)_2,PtCl_4$.

Acetic sulphide (thiacetic anhydride), SAc_2, prepared by heating acetic acid with phosphorus pentasulphide, boils at 66—67° under a pressure of 20 mm., and at 156—158° under a pressure of 747·5 mm.,

with partial decomposition; when heated with water, it is decomposed into acetic acid and thiacetic acid. F. S. K

Thio-derivatives of Furfuraldehyde. By E. Baumann and E. Fromm (*Ber.*, **24**, 3591—3599; compare Abstr., 1891, 1008).—*α-Trithiofurfuraldehyde*, $(C_5H_4SO)_3$, and the *β*-compound described below, are produced when an alcoholic solution of furfuraldehyde is carefully mixed with alcoholic hydrochloric acid at −5°, and then saturated with hydrogen sulphide in the cold; after keeping for 24 hours, excess of sodium carbonate is added, the precipitate separated by filtration, dried in a desiccator, and dissolved in benzene or chloroform; on adding alcohol to the solution, the *β*-compound is for the most part precipitated, the *α*-compound remaining in solution. *α*-Trithiofurfuraldehyde is obtained in colourless crystals when the brown alcoholic benzene mother liquors are shaken with animal charcoal, the solution evaporated, and the residue repeatedly recrystallised from dilute alcohol; it melts at 128°, turns yellowish-brown on exposure to the air, and is very readily soluble in benzene and chloroform, but rather more sparingly in alcohol, and insoluble in water. Molecular weight determinations by Raoult's method in naphthalene solution gave results agreeing with those required by a compound of the molecular formula given above.

β-Trithiofurfuraldehyde, $(C_5H_4SO)_3$, is obtained in colourless needles when the precipitate referred to above is repeatedly recrystallised from benzene, using animal charcoal; it is formed when the *α*-compound, in benzene solution, is treated with ethyl iodide containing a trace of free iodine. It melts at 229° with decomposition, turns yellow on exposure to the air, and is readily soluble in chloroform, but more sparingly in benzene, and almost insoluble in alcohol; molecular weight determinations showed that the compound has the molecular formula assigned to it above.

The polymeride of thiofurfuraldehyde described by Cahours (*Annalen*, **69**, 85) is deposited in colourless crystals when an alcoholic solution of furfuraldehyde is treated with alcoholic ammonium sulphide at the ordinary temperature; it softens at 80°, melts completely at 90—91°, and has the empirical formula C_5H_4SO. Its molecular weight was determined by Raoult's method in naphthalene solution, and found to be about 2200, a result which corresponds approximately with the molecular formula $(C_5H_4SO)_{20}$; as, however, the depression of the freezing point of the naphthalene increases continuously with the time during which the solution is heated, it seems likely that the molecule is even greater than that given above, probably $(C_4H_5SO)_{24}$. It is readily soluble in benzene, and if ethyl iodide containing free iodine is added to the solution, *β*-trithiofurfuraldehyde is deposited in crystals after some time. When heated at a temperature just below 160° for 10—12 hours, it yields large quantities of the furfurostilbene described by Cahours and Schwanert; this compound is also obtained when either of the trithiofurfuraldehydes is heated at about 230°; it melts at 101°, and has the molecular formula $C_{10}H_8O_2$, as was proved by molecular-weight determinations in glacial acetic acid solution. F. S. K.

Constitution of Tetrole Nuclei. By G. Ciamician and A. Angeli (*Gazzetta*, **21**, ii, 109—133).—The authors' views of the constitution of tetrole nuclei have been lately expounded by Ciamician (Abstr., 1891, 1195), and in the case of thiophen are greatly supported by the following experiments, showing that derivatives of that substance on oxidation yield open chain compounds containing the group —CO·C:C·CO—.

Synthetical tetrabromothiophen (1 part), on treatment with nitric acid (sp. gr. 1·52, 10 parts), cooled in a mixture of snow and salt, is converted into a brown, semi-solid substance; on withdrawing the cooling mixture, this dissolves with development of heat, bromine being liberated, and on pouring the product into cold water, a white, crystalline compound separates which, however, soon redissolves. After being nearly neutralised with caustic alkali, extracted with ether, and the latter evaporated, dibromomaleïc anhydride is left, the yield being almost theoretical. It melts at 117—118°, and not at 114—115° as previously stated.

Tetrabromothiophen (3 grams), on oxidation in boiling acetic acid solution (50 c.c.) with chromic anhydride (5 grams), gives off bromine and yields a yellowish product which is insoluble in most of the ordinary solvents. On boiling with alcohol, and crystallising from boiling xylene, yellow scales are obtained which darken at 240°, and do not melt at 310°; this compound probably has the composition $C_9Br_4S_2O_2$. It dissolves in boiling caustic potash, yielding a brown solution, and with alcoholic potash gives a solution which is yellow while hot, and brown when cold. On heating the compound with phenylhydrazine, either directly or in solution in xylene or acetic acid, amorphous, highly-coloured products are obtained. On concentrating the xylene mother liquors from the crystallisation of the substance, a yellow, amorphous substance is obtained which is soluble in benzene, and melts at 220°; it is possibly a decomposition product of the less soluble substance.

Synthetical α-methyltribromothiophen (1 part) is gradually introduced into nitric acid (sp. gr. 1·52, 10 parts) cooled in snow and salt; it immediately dissolves to a reddish-brown liquid, but bromine is not evolved. If the solution is now poured into water (60 parts), the excess of acid partly neutralised by an alkali hydroxide, and the solution extracted with ether, the ether on evaporation leaves an oily residue; when this is suspended in water, and again extracted with ether, a yellow oil is obtained which solidifies after a time; by dissolving the product in warm benzene, precipitating by light petroleum, and crystallising it from benzene, colourless, orthorhombic prisms, $a : b : c = 0{\cdot}6381 : 1 : 0{\cdot}4670$, of *dibromoacetylacrylic acid* are obtained melting at 78—79°. This acid dissolves in solutions of the alkali carbonates with effervescence, is very soluble in hot water, ether, and alcohol, sparingly in cold water and benzene, and insoluble in light petroleum; on reduction with 2·5 per cent. sodium amalgam in dilute sulphuric acid solution, it yields dibromolevulinic acid. With phenylhydrazine in acetic acid solution, a deposit of yellow needles is obtained; this, after crystallisation from dilute alcohol, melts at 84—100°, and is probably a mixture.

β-Methyltribromothiophen (1 part), when dissolved in nitric acid (sp. gr. 1·52, 10 parts), and treated in a manner similar to the above, yields a yellow oil which soon solidifies. If this is dissolved in benzene, decolorised by animal charcoal, and precipitated several times by light petroleum, bromocitraconic anhydride is obtained melting at 100—101°, a slightly higher temperature than has previously been given.

Experiments on the oxidation of 2 : 5-dimethyldibromothiophen and 2 : 5-methylphenyltribromothiophen led to no positive result, the oxidation products being badly characterised.

The above experiments show the great analogy existing between the thiophen, pyrroline, and furfuran nuclei, and also afford a method of determining the position of the alcohol radicles in substituted thiophen derivatives.

The speed at which the oxidation proceeds was determined by allowing nitric acid of known strength to act on the thiophen derivative for a fixed time, interrupting the reaction, and estimating the sulphuric acid produced. Nitric acid of sp. gr. 1·47, acting for 18 minutes, decomposed 2·92 per cent. of tetrabromothiophen, 84·62 per cent. of α-methyltribromothiophen, and 72·00 per cent. of β-methyltribromothiophen; acid of sp. gr. 1·45, acting for 51 minutes, converted 24·14 per cent. of α-methyltribromothiophen and 31·12 per cent. of β-methyltribromothiophen. W. J. P.

Derivatives of Ethyl Acetothienoneoxalate. By S. Salvatori (*Gazzetta*, **21**, ii, 268—294).—Acetothienoneoxalic (thenoïlpyruvic) acid, obtained by Angeli (Abstr., 1891, 550) by the action of sulphuric acid on the ethyl derivative, may conveniently be prepared by treating a mixture of acetothienone and ethyl oxalate with sodium ethoxide, proceeding according to Brömme and Claisen's method of preparing benzoylpyruvic acid (Abstr., 1888, 691). The *ethyl* derivative, $C_4SH_3{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}COOEt$, described by Angeli, gives rise to a series of metallic salts; the *copper* salt, $(C_{10}H_9SO_4)_2Cu$, forms a very insoluble, pale-green mass; the *ammonium* salt, $C_{10}H_{10}SO_4{,}2NH_3$, is obtained as a pale salmon-coloured, crystalline powder soluble in alcohol, benzene, and ethyl acetate. It melts at 125° with decomposition, and its solutions evolve ammonia on heating to 60—70°. No nitroso-derivative could be obtained either from the acid or from the ethyl derivative by V. Meyer's method, the product consisting of α-thiophenic acid.

Thienylphenylpyrazolic Acid, $\begin{matrix}CH{\cdot}C(COOH)\\ \|\\ C(C_4SH_3){\cdot}NPh\end{matrix}\!\!>\!N$.—The ethyl derivative of this acid is formed by the condensation of a molecule of ethyl acetothienoneoxalate with a molecule of phenylhydrazine with elimination of 2 mols. H_2O. It crystallises from alcohol in colourless, monoclinic prisms, $a : b : c = 1{\cdot}177 : 1 : 0{\cdot}716$; $\beta = 64°\,10'$, melts at 81°, dissolves in most solvents, but not in water. The acid is obtained from the ethereal salt by hydrolysis. It separates from alcohol in triclinic crystals, melts at 195°, and decomposes at a slightly higher temperature; the *silver* salt, $C_{14}H_9AgSN_2O_2$, forms a white, curdy

mass; salts of copper, mercury, zinc, lead, barium, and iron have also been prepared. On heating it above its melting point, it loses carbonic anhydride, and yields the corresponding *thienylphenylpyrazole*, $C_{13}H_{10}SN_2$. The latter crystallises from alcohol in white needles, melts at 54°, and distils unaltered above 300°. It is freely soluble in alcohol, ether, and benzene, and sparingly in water; it is dissolved by concentrated mineral acids, and reprecipitated on dilution; it gives Knorr's reaction for pyrazoles.

The *ethiodide*, $C_{13}H_{10}SN_2,EtI$, crystallises from water in colourless prisms melting at 173—174°; the *platinochloride*, $(C_{13}H_{10}SN_2)_2,H_2PtCl_6$, separates in dark orange-yellow flakes.

Thienylisoxazolic Acid, $\begin{matrix}CH\cdot C(COOH)\\ \|\\ C(C_4SH_3)-O\end{matrix}\!\!>\!N$.—The ethyl derivative of this acid was prepared by Angeli by the condensation of ethyl acetothienoneoxalate with hydroxylamine. The free acid may be obtained in colourless crystals melting at 177° with decomposition, and readily soluble in alcohol, ether, and water. The silver salt, $C_8H_4AgSNO_3$, separates in white flakes; salts of copper, lead, mercury, barium, and iron were also prepared.

A hydrated *oxime* of acetothienoneoxalic acid, $C_8H_7SNO_4 + H_2O$ may be prepared by dissolving the acid in a slight excess of sodium carbonate, and adding the theoretical quantity of hydroxylamine, also dissolved in sodium carbonate, the solutions being kept so dilute that 30—40 c.c. of the liquid only contain 1 gram of acid; the mixture is then allowed to remain for some time. On acidifying with hydrochloric acid, the oxime gradually separates in minute crystals. It may be obtained pure by allowing a cold ethereal solution to evaporate spontaneously, and collecting the first crop of prismatic crystals deposited. It melts with decomposition at 110—112°, and dissolves in most solvents, but is partially converted into thienylisoxazolic acid. The conversion is more speedily effected by the action of acetic anhydride, no acetyl derivative being formed. This compound is of interest as being the first of the monoximes of the β-diketonic acids which has been isolated.

Cyanacetothienone, $C_4H_3S\cdot CO\cdot CH_2\cdot CN$, is prepared by heating small quantities of thienylisoxazolic acid in a narrow tube until the evolution of carbonic anhydride ceases, and treating the residue with sodium carbonate. When pure, it crystallises from alcohol in colourless, lustrous plates, and from water in large needles, melts at 137°, and does not decompose at 200°. It resembles cyanacetophenone generally in its properties.

An *oxime* of benzoylpyruvic acid, $C_{10}H_9NO_4 + H_2O$, may be obtained by the method adopted for the preparation of acetothienoneoxalic oxime; but if the digestion with hydroxylamine is prolonged for more than three hours, the oxime formed at first is gradually converted into phenylisoxazolic acid. It bears a general resemblance to the preceding oxime, but is even more unstable; it melts at 98—100° with decomposition, and crystallises from its cold ethereal solution in prisms.

When phenylisoxazolic acid is heated above its melting point in

the manner described for the preparation of cyanacetothienone, the product is identical with the cyanacetophenone described by Haller (Abstr., 1886, 440). The formation of these nitriles shows that the constitution of the oximes may be respectively represented by the formulæ $C_4SH_3{\cdot}CO{\cdot}CH_2{\cdot}C(NOH){\cdot}COOH$ and $CH_2Bz{\cdot}C(NOH){\cdot}COOH$. The author believes that the behaviour of these oximes, and especially the high temperatures necessary for the formation of the nitriles, indicates that they are α-monoximes, and hence form an exception to Hantzsch's hypothesis. S. B. A. A.

Use of Sodium Hypophosphite in Sandmeyer's Reaction. By A. Angeli (*Gazzetta*, **21**, ii, 258—261).—Sandmeyer's original reaction has the disadvantage of involving the use of cuprous salts which are not very stable and must be freshly prepared. Gattermann's modification (Abstr., 1890, 970) involves the preparation of finely-divided copper perfectly free from zinc, and necessitates the constant agitation of the liquid, especially at the commencement of the reaction. The following process obviates these difficulties; it depends on the circumstance that when a solution of copper sulphate and sodium hypophosphite is acidified with hydrochloric acid and gently warmed, cuprous chloride speedily separates according to the equation $2CuCl_2 + H_3PO_2 + H_2O = H_3PO_3 + 2HCl + Cu_2Cl_2$ (Abstr., 1886, 771). A mixture of copper sulphate and sodium hypophosphite may therefore be added to acid solutions instead of cuprous salts or metallic copper. Aniline is, for example, converted into chloro-, bromo-, iodo-, and nitro-benzene as follows:—

Chlorobenzene.—A solution of aniline (9·3 grams) in hydrochloric acid (40 grams) and water (60 grams) is slowly mixed with a solution of sodium nitrite (7 grams), and then with a solution of copper sulphate (12·5 grams) and sodium hypophosphite (7 grams), when a brisk effervescence ensues, owing to the evolution of nitrogen; as soon as this is over, the product is steam-distilled, and the chlorobenzene separated and rectified. It passes over almost entirely at 132°, and is converted by concentrated nitric acid into parachloronitrobenzene melting at 183°.

Bromobenzene can be prepared in like manner by treating a solution of aniline (9·3 grams) in sulphuric acid (40 grams) and water (90 grams) with a solution of sodium nitrite (7 grams), allowing the mixture to remain for a while, then adding sulphuric acid (20 grams) diluted with water, and solutions of potassium bromide (36 grams), copper sulphate (12·5 grams), and sodium hypophosphite (7 grams).

Iodobenzene may be prepared in like manner.

Nitrobenzene is obtained by mixing a solution of diazobenzene nitrate acidified with nitric acid with solutions of copper sulphate and sodium hypophosphite, and gently warming.

The yields are very good, and the operations speedily performed. The reaction is also available for the preparation of cuprous bromide and iodide in a state of purity. S. B. A. A.

Displacement of the Nitro-group by Chlorine or Bromine. By C. A. Lobry de Bruyn (*Ber.*, **24**, 3749—3750).—When the

dinitrobenzenes are treated with chlorine or bromine in the absence of any substance that can act as a carrier of the halogen, the reaction does not begin until the temperature of 200° is reached.

With chlorine, orthodinitrobenzene yields dichlorobenzene; exceedingly little, if any, orthochloronitrobenzene is formed. Metadinitrobenzene yields metachloronitrobenzene and dichlorobenzene. Paradinitrobenzene yields parachloronitrobenzene only.

With bromine, the three dinitrobenzenes yield the corresponding bromonitrobenzenes; the further action of bromine leads to the substitution of bromine for hydrogen. An oxychloride or oxybromide of nitrogen is always formed in the reactions described. C. F. B.

Dithiocarbonic Acids. By G. Daccomo (*Chem. Centr.*, 1891, ii, 532—533; from *Ann. Chim. Farm.*, **13**, 273—280).—Bearing in mind the fact that potassium ethoxide and carbon bisulphide react with formation of potassium xanthate, the author studied the reaction between potassium hydroxide and carbon bisulphide. Solid potassium hydroxide, left in contact with carbon bisulphide, reacts gradually; the bisulphide becomes coloured at first yellow, which deepens into red, and, finally, a reddish-brown mass is produced. After washing with alcohol and drying over sulphuric acid, a crystalline, reddish-brown powder is obtained, which is readily soluble in water. With dilute acids, it is decomposed with formation of hydrogen sulphide, carbonic anhydride, carbon oxysulphide, and sulphur. With salts of the metals, precipitates are formed; and with diazo-derivatives, compounds are produced similar to those obtained by Leuckart with potassium xanthate. With diazobenzene nitrate, two new compounds, the one crystalline and the other liquid, are formed. Both have the empirical formula COS_2Ph_2, and are phenyl dithiocarbonates. In order to determine which has the formula OPh·CS·SPh, and which the formula $CO(SPh)_2$, the author treated both with alcoholic potash. The following reactions would take place:—

$$OPh{\cdot}CS{\cdot}SPh + 2KOH = PhSH + PhOH + K_2CO_2S.$$
$$CO(SPh)_2 + 2KOH = 2PhSH + K_2CO_3.$$

In neither case, however, was the formation of phenol observed, nor was there any carbon oxysulphide liberated from the product by treatment with acid; only thiophenol and potassium carbonate could be detected. It is suggested, therefore, that a molecular change takes place in the one or the other during hydrolysis, as Solomon has already noticed in the case of the hydrolysis of ethyl xanthate.

By treating the crystalline product of the action of potassium hydroxide on carbon bisulphide with metachlorodiazobenzene, a reddish-brown oil, *chlorophenyl dithiocarbonate*, is obtained which also gradually separated into a crystalline and a liquid portion, and these both react with alcoholic potash, forming potassium carbonate and metachlorothiophenol. Paradiazotoluene behaves in an exactly similar manner. J. W. L.

Metachlorothiophenol. By G. Daccomo (*Chem. Centr.*, 1891, ii, 533—534; from *Ann. Chim. Farm.*, **13**, 343—352).—The author has

carefully examined the metachlorothiophenol mentioned in the preceding abstract, since it differs from the one obtained by Otto from chlorobenzenesulphonic chloride. The method of preparation was as follows:—Nitrobenzene was treated with chlorine in presence of iodine, according to Laubenheimer's method (*Ber.*, **8**, 1621). It was reduced with fuming hydrochloric acid and tin, and a very pure metachloraniline boiling at 230—232° was obtained. From this, the corresponding diazochlorobenzene was formed by the action of potassium nitrite. Lastly, the metachlorodiazobenzene was treated with potassium dithiocarbonate, yielding chlorophenyl dithiocarbonate, from which metachlorothiophenol was obtained by hydrolysis.

Chlorophenyl dithiocarbonate is a dark-coloured oil, readily soluble in ether, benzene, chloroform, and carbon bisulphide, sparingly soluble in alcohol, and insoluble in water. It may be distilled in a current of steam, but it is readily decomposed by heating. Potassium xanthate reacts with metachlorodiazobenzene in a similar manner to the dithiocarbonate.

Metachlorothiophenol is a colourless, limpid liquid which refracts light strongly, and has an especially penetrating odour. It is insoluble in water, but readily soluble in alcohol, ether, chloroform, and carbon bisulphide. It is readily soluble in alkalis, and is precipitated from the solutions by acids. Its sp. gr. is 1·2637 at 12·5°. The ethereal solution reacts with mercuric oxide, and a thick, crystalline mass of the mercury salt is formed. The neutral solutions of the potassium or sodium salts precipitate solutions of lead salts, light yellow; copper salts, dirty yellow; mercury salts, white; silver nitrate, yellow. With concentrated sulphuric acid, no reaction takes place in the cold, but, on warming, a beautiful, light violet coloration suddenly appears.

With chloral, a chemical change is indicated by the development of heat, but no definite product could be separated. The potassium salt, C_6H_4ClSK, consists of small, prismatic, colourless needles, readily soluble in water, sparingly so in alcohol; the barium salt, $(C_6H_4ClS)_2Ba$, consists of shining scales, little soluble in water; the mercury salt, $(C_6H_4ClS)_2Hg$, pearly scales, almost insoluble in water and alcohol. All the salts have the characteristic odour of metachlorothiophenol.

With acid chlorides, metachlorothiophenol reacts readily, hydrogen chloride being liberated, and the corresponding salt produced. The *acetyl* derivative, C_6H_4ClSAc, is a colourless, strongly refractive liquid which distils between 255° and 268°. The *benzoyl* derivative, C_6H_4ClSBz, forms triclinic prisms melting at 72·5°. J. W. L.

Ortho- and Para-chlorothiophenol. By G. Daccomo (*Chem. Centr.*, 1891, ii, 656—657; from *Ann. Chim. Farm.*, **14**, 1—13).—The author has obtained ortho- and para-chlorothiophenols by the same method as that employed for the preparation of the meta-derivative.

Parachlorophenyl dithiocarbonate, obtained from diazochlorobenzene chloride, prepared from parachloraniline, forms white, pearly scales, which are readily soluble in most organic solvents, but the compound

does not melt at a definite temperature. The author considers it possible that it is a mixture of the isomerides $CO(S\cdot C_6H_4Cl)_2$ and $C_6H_4Cl\cdot S\cdot CS\cdot OC_6H_4Cl$. If diazobenzene chloride is added to potassium xanthate instead of to the dithiocarbonate, the *chlorophenylxanthate*, $OEt\cdot CS\cdot S\cdot C_6H_4Cl$, is obtained; this forms white crystals which melt at 124—126° to a colourless liquid. By hydrolysing each of these compounds with alcoholic potash, *parachlorothiophenol*, $C_6H_4Cl\cdot SH$, is obtained, which possesses all the characteristics of Otto's compound (*Annalen*, **143**, 109). With sulphuric acid, it produces the same violet coloration as the meta-compound does.

Acetylparachlorothiophenol, obtained by the action of acetic chloride, is crystalline, readily soluble, and boils at 255° under ordinary atmospheric pressure. Its sp. gr. is 1·2629 at 19·5°. The benzoyl derivative forms large crystals, and melts at 75·5°.

Orthochlorothiophenol is prepared in an exactly similar manner from orthodiazochlorobenzene. It forms a colourless, strongly refractive liquid, of penetrating, but not disagreeable, odour; boils at 204—206°, and has sp. gr. 1·2752 at 19·5°. It resembles the meta-derivative in its reactions, but is less stable, and gradually evolves hydrogen sulphide with formation of chlorophenyl sulphide. The *acetyl* compound boils at 254—258°; sp. gr. 1·2659 at 19·5°. The *benzoyl* compound boils at 335—340°, sp. gr. 1·2785.

For the sake of comparison, the author prepared the three corresponding chlorophenols; the ortho- and para-compounds, by the action of dry chlorine on phenol at the ordinary temperature; the meta-compound according to the methods of Beilstein and Kurbatoff, and of Uhlemann. The following derivatives are described: *acetylorthochlorophenol*, liquid, boiling point 204—208°; sp. gr. 1·1709 at 19·5°. *Benzoylorthochlorophenol*, liquid, boiling point 308—312°; sp. gr. 1·1974 at 19·5°. *Acetylmetachlorophenol*, liquid, boiling point 226—228°; sp. gr. 1·2165. *Benzoylmetachlorophenol*, solid, melting point 71°. *Acetylparachlorophenol*, liquid, boiling point 230—232; sp. gr. 1·2404 at 19·5. *Benzoylparachlorophenol*, solid, melting point 87°.

J. W. L.

Action of Methylchloroform and Ethylchloroform on Alkaline Solutions of Phenols. By F. Heiber (*Ber.*, **24**, 3677—3687).—*Phenyl orthacetate*, $CMe(OPh)_3$, is obtained when methylchloroform (16·8 parts) is gradually added in the course of several days to a hot solution of phenol (38·4 parts) and sodium hydroxide (22·6 parts) in water (22·6 parts). It crystallises from hot alcohol in transparent plates, melts at 98—98·5°, and is readily soluble in ether, chloroform, and benzene, but almost insoluble in water; it dissolves in concentrated sulphuric acid with a red coloration, and on prolonged boiling with alcoholic potash, it is decomposed into phenol and acetic acid. The *tribromo*-derivative, $C_{20}H_{15}O_3Br_3$, is formed when phenyl orthacetate is treated with bromine in cold glacial acetic acid solution; it crystallises from hot alcohol in transparent plates, melts at 132—133°, is very stable towards acids and alkalis, and is moderately easily soluble in ether, chloroform, and benzene, but insoluble in water.

Orthonitrophenyl orthacetate, $CMe(O\cdot C_6H_4\cdot NO_2)_3$, prepared from methylchloroform and orthonitrophenol in like manner, melts at

167—168°, and is only sparingly soluble in most ordinary solvents with the exception of boiling benzene; it is very stable towards dilute acids and alkalis.

Paracresyl orthacetate, $CMe(O\cdot C_6H_4Me)_3$, crystallises from alcoholic ether in rhombic plates, melts at 135·5° (?), and is soluble in all the ordinary organic solvents, but insoluble in water; it is only slowly acted on by boiling acids and alkalis. The *tribromo*-derivative, $C_{23}H_{21}O_3Br_3$, separates from boiling acetic acid in crystals, melts at 160—161°, and is insoluble in water, but more or less readily soluble in all the ordinary organic solvents.

Metacresyl orthacetate, $C_{23}H_{24}O_3$, crystallises in needles, melts at 99—100°, and is insoluble in water, but readily soluble in ether, chloroform, and boiling alcohol; the *tribromo*-derivative, $C_{23}H_{21}O_3Br_3$, melts at 151·5—153°.

Orthocresyl orthacetate, $C_{23}H_{24}O_3$, forms transparent crystals, melts at 87·5—89°, and is readily soluble in all ordinary organic solvents, but only sparingly in water.

Resorcinyl orthacetate, $CMe(O\cdot C_6H_4\cdot OH)_3$, is a yellow powder, melts at about 155—159° with decomposition, and is readily soluble in cold alcohol, ether, and glacial acetic acid, but only sparingly in hot water, and insoluble in benzene.

Hydroxybenzophenone, $COPh\cdot C_6H_4\cdot OH$, is obtained, together with phenyl benzoate (m. p. 70·5—71·5°) and a yellowish-red, resinous substance, when an alkaline solution of phenol is warmed with benzotrichloride (phenylchloroform); it crystallises from dilute alcohol in colourless plates, melts at 41°, and is readily soluble in alcohol, ether, glacial acetic acid, and alkalis, but insoluble in water.

F. S. K.

Derivatives of Carvacrol. By G. Mazzara and G. Plancher (*Gazzetta*, **21**, ii, 155—157).—Paternò and Canzoneri obtained nitrosocarvacrol by the action of potassium nitrite on carvacrol, but the yield was very small; 70 per cent. of the theoretical may be obtained, however, by slowly dropping amyl nitrite (35 grams) into an ice-cold solution of carvacrol (50 grams), and soda (15 grams) in the smallest possible quantity of alcohol. The ethyl alcohol is eliminated by spontaneous evaporation, the solution diluted with much water, separated from the precipitated amyl alcohol and resin, and acidified with sulphuric acid. The nitrosocarvacrol, which separates, is dissolved in ammonia, reprecipitated with sulphuric acid, and finally crystallised from benzene.

Diacetylamidoethenylamidocarvacrol, $NAc_2\cdot C_6HMePr<\begin{matrix}O\\N\end{matrix}>CMe$, is obtained by heating acetic anhydride with monacetylamidoethenylamidocarvacrol in molecular proportion at 180—190°; the excess of acetic anhydride is evaporated off, the product cooled to 60°, and washed with water. After recrystallisation from boiling alcohol, it is obtained in transparent tables which melt at 123—125°, and lose their transparency on exposure to light.

Acetyldinitrocarvacrol, $C_6H(NO_3)_2PrMe\cdot OAc$, is prepared by heating a mixture of dinitrocarvacrol with acetic chloride for some hours in a reflux apparatus. The product is washed with dilute sodium

carbonate solution, and dissolved in boiling alcohol; on cooling, it separates as an oil which soon solidifies. By crystallisation from light petroleum, it is obtained in yellowish rhombohedra, which turn red on exposure to light; it melts at 72—73°.

The acetyl and benzoyl derivatives of dinitrothymol melt at higher temperatures than those of dinitrocarvacrol, whilst the ethenyl and benzenyl derivatives of carvacrol melt at higher temperatures than the isomeric thymol derivatives. W. J. P.

Action of Dinitrochlorobenzene on Polyhydric Phenols. By R. Nietzki and B. Schündelen (*Ber.*, **24**, 3585—3589).—*Tetranitrodiphenylresorcinol*, $C_6H_4[O\cdot C_6H_3(NO_2)_2]_2$, is formed when molecular proportions of resorcinol, sodium ethoxide, and chlorodinitrobenzene $[Cl : (NO_2)_2 = 1 : 2 : 4]$ interact in alcoholic solution at the ordinary temperature. It crystallises from glacial acetic acid in almost colourless plates, melts at 184°, and is insoluble in alkalis, and only very sparingly soluble in most ordinary organic solvents; it seems to be completely decomposed by reducing agents, and when boiled with aniline, it yields dinitrodiphenylamine. On treatment with cold fuming nitric acid, it is converted into *pentanitrodiphenylresorcinol*, $C_{18}H_9N_5O_{12}$, but with a warm mixture of nitric and sulphuric acid, it yields the *hexanitro*-derivative, $C_{18}H_8N_6O_{14}$; the former melts at 68°, the latter at 220°, and both compounds are decomposed by boiling aniline with formation of dinitrodiphenylamine.

Tetranitrodiphenylquinol, $C_{18}H_{10}N_4O_{10}$, prepared from quinol in like manner, crystallises from glacial acetic acid in lustrous plates, melts at 240°, and is very sparingly soluble in most ordinary organic solvents; it is not decomposed by boiling aniline. Its *dinitro*-derivative, $C_{18}H_8N_6O_{14}$, crystallises from glacial acetic acid in almost colourless plates, and melts at 190°; its *trinitro*-derivative melts at 220°; both these compounds are decomposed by boiling aniline with formation of dinitrodiphenylamine.

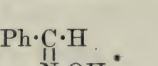
Hydroxydinitrodiphenylamine, $C_{12}H_9N_3O_5$, is obtained by treating orthamidophenol with chlorodinitrobenzene in presence of sodium acetate; it crystallises in brownish-yellow needles, and melts at 190°.

Dihydroxydinitrodiphenylamine, $C_{12}H_9N_3O_6$, prepared from amidoresorcinol in like manner, crystallises in brown needles, and melts at 183°. F. S. K.

Oxidation of Aromatic Compounds containing the Side Chain C_3H_5. By G. Wagner (*Ber.*, **24**, 3488—3491).—When safrole is oxidised in the cold with a 1 per cent. solution of potassium permanganate, it yields the corresponding glycol, $C_{10}H_{12}O_4$, which crystallises from ether in prismatic needles, melts at 78·5°, and gives a diacetyl derivative boiling at 262° under a pressure of 90 mm. (compare Tiemann, this vol., p. 47). Besides the glycol, which, contrary to Tiemann's statement, is more soluble in cold alcohol than in boiling ether, piperonal, piperonylic, α-homopiperonylic, formic, and other acids are produced, but not acetic. When isosafrole is oxidised, it yields a glycol crystallising in thick prisms and melting at 101—102°. The glycol obtained from methyleugenol crystallises

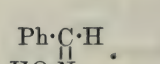
in prismatic needles, melts at 68—69°, and gives a diacetyl derivative boiling at 248° (35 mm.); whilst the glycol from methylisoeugenol crystallises in rhombic plates and melts at 88°. A. R. L.

Myristicin and its Derivatives. By F. W. Semmler (*Ber.*, **24**, 3818—3823).—In a previous communication, the author has shown that myristicin has the composition $C_{12}H_{14}O_2$, and is a derivative of benzene containing an unsaturated side chain (Abstr., 1890, 1150). To obtain further information as to its constitution, it was subjected to the action of oxidising agents; nitric acid and chromic acid act in too violent a manner, but the oxidation may be readily carried out by means of dilute potassium permanganate. The liquid is filtered hot from the manganese precipitate, allowed to cool, and the white, crystalline compound which separates collected and recrystallised several times from water. It has the composition $C_9H_8O_4$, melts at 130° (uncorr.), boils at 290—295°, reduces silver solution, and combines with hydroxylamine and phenylhydrazine. It is, therefore, an aldehyde $C_8H_7O_3{\cdot}CHO$, and may be termed *myristicinaldehyde;* it is also found to contain one methoxyl group, and, as already stated, is a derivative of benzene; the formula may therefore be further resolved into $CH_2O_2{\cdot}C_6H_2(OMe){\cdot}CHO$. The oxygen must be present in the form of an oxymethylene group, for neither myristicin nor myristicinaldehyde behaves as a phenol; hence myristicinaldehyde has the constitutional formula $CH_2{<}\overset{O}{\underset{O}{>}}C_6H_2(OMe){\cdot}CHO$, and occupies an intermediate position between piperonaldehyde, $CH_2{<}\overset{O}{\underset{O}{>}}C_6H_3{\cdot}CHO$, and apionaldehyde, $CH_2{<}\overset{O}{\underset{O}{>}}C_6H(OMe)_2{\cdot}CHO$. The constitution of myristicin itself is, therefore, $CH_2{<}\overset{O}{\underset{O}{>}}C_6H_2(OMe){\cdot}C_4H_7$, and it may be termed *oxymethylenemethoxybutenylbenzene.*



The filtrate from myristicinaldehyde contains the corresponding *myristic acid*, $CH_2{<}\overset{O}{\underset{O}{>}}C_6H_2(OMe){\cdot}COOH$, which separates in white, crystalline flakes on the addition of phosphoric acid, and, after recrystallisation from hot water, forms long, yellowish-white needles. It melts at 208—210° (uncorr.), does not boil without decomposition, even in a vacuum, and is only sparingly soluble in water.

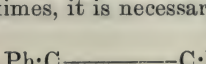
In order to ascertain the positions occupied by the side chains in these compounds, myristic acid was heated with phosphorus and hydriodic acid in a sealed tube; the product of the reaction was found to be gallic acid, showing that the methoxyl and oxymethylene groups must occupy the positions 3 : 4 : 5, the carboxyl, aldehyde, or butenyl groups occupying the position 1.



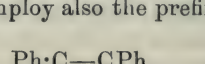
When myristicin is treated with bromine in acetic acid solution, carbonic anhydride is evolved, and a voluminous precipitate separates; this, after recrystallisation from alcohol, forms slender, snow-white needles, and melts at 159—160° (uncorr.). It has the composition $C_8H_5O_3Br_3$, and appears to be *methyloxymethylenetribromopyrogallol.* H. G. C.

Action of Carbonyl Chloride on Benzylamine. By B. Kühn and J. Riesenfeld (*Ber.*, **24**, 3815—3818).—Hitherto, benzyl isocyanate has not been prepared in the pure condition, the product obtained by acting on silver cyanate with benzyl bromide or chloride (this Journal, 1872, 446; *Ber.*, **10**, 46) always containing chlorine or bromine. The authors have endeavoured to prepare it by the action of carbonyl chloride on benzylamine hydrochloride; the product is, however, a mixture of varying quantities of benzyl isocyanate and benzylchloroformamide, $CH_2Ph{\cdot}NH{\cdot}COCl$, which cannot be separated by fractional distillation, nor can the latter derivative, like methylchloroformamide (Abstr., 1887, 569), be converted into the former by distilling with potash, benzyl cyanurate being thus obtained. The same compound is precipitated when a large quantity of light petroleum is added to the mixture of benzyl isocyanate and chloroformamide. When the mixture is treated with aniline, the sole product is phenylbenzylcarbamide; methylaniline converts it into *benzylphenylmethylcarbamide* melting at 84°, metanitraniline into *benzylmetanitrophenylcarbamide* melting at 188°, α-naphthylamine into *benzyl-α-naphthylcarbamide* melting at 203°, isobutylamine into *benzylisobutylcarbamide* melting at 78—79°, and piperidine into *benzylpiperidylcarbamide* melting at 101—102°. H. G. C.

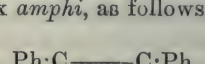
Nomenclature of Stereoisomeric Nitrogen Compounds and of Rings containing Nitrogen. By A. Hantzsch (*Ber.*, **24**, 3479—3488).—The author proposes to distinguish the stereoisomeric nitrogen compounds by the Greek prefixes *syn*, *anti*, and *amphi*, these being equivalent to *cis*, *trans*, and *cistrans*, which are employed by v. Baeyer for certain other stereoisomeric compounds. The prefix *syn* is used with those compounds containing certain groups which are capable of intramolecular change, whilst *anti* is employed with the isomeride containing the same groups which are incapable of it; for example, *syn* is prefixed to that benzaldoxime from which benzonitrile is obtainable, thus:—



Synbenzaldoxime.



Antibenzaldoxime.



For distinguishing such compounds as the three isomeric benziledioximes, it is necessary to employ also the prefix *amphi*, as follows:—

Synbenzilediоxime.

Antibenzilediоxime.

Amphibenzilediоxime.

The author is of opinion that the term "*azo*," in its application to closed-ring compounds, should be restricted to those containing triad nitrogen, whilst, for such as contain the group NH, the term "*imid*" should be employed. He proposes the following alterations in nomenclature:—*Imidole* for pyrroline, *thiole* for thiophen, and

oxole for furfuran; derivatives obtained by displacing a CH group in these by N are designated *imidazole* = $C_3H_3(NH)N$, *oxazole* = $C_3H_3(O)N$, and *thiazole* = $C_3H_3(S)N$ respectively. The isomerism of these compounds may then be indicated by the above-mentioned prefixes; thus, the two imidazoles [NH : N = 1 : 2 and 1 : 3] are call d *synimidazole* and *amphimidazole* respectively, whilst Widman's triazoles, $C_2H_2(NH)N_2$, are named *imidodiazoles* or *azimidazoles*, and the three isomerides [$NH_2 : N_2$ = 1 : 2 : 5, 1 : 2 : 3, and 1 : 3 : 5] are distinguished as *synazimidazole*, *synimidodiazole*, and *amphimidodiazole*. The three six-membered ring compounds $C_4H_4N_2$ are designated *syndiazine*, *amphidiazine*, and *antidiazine*, according as they have the constitutions [N : N = 1 : 2, 1 : 3, and 1 : 4]. A. R. L.

Action of Benzyl Chloride on Ortho- and Para-toluidines. By C. Rabaut (*Bull. Soc. Chim.* [3], **6**, 137—140).—*Methylbenzylorthotoluidine*, $C_6H_4Me{\cdot}NMe{\cdot}CH_2Ph$, is obtained by heating a mixture, in molecular proportion, of benzylorthotoluidine and methyl iodide for 40 hours. The product is heated with dilute sodium carbonate and extracted with benzene. At 210—215°, under 15·2 mm. pressure, a yellowish oil passes over; this is insoluble in water, soluble in alcohol, benzene, &c., and has no basic character.

The sulphonic derivative of benzylorthotoluidine is obtained by heating benzylorthotoluidine for two hours at 125—130° with sulphuric acid containing 15 per cent. of anhydride; its lead and barium salts are soluble in water and crystallise well. The acid is a crystalline powder, soluble in water. Its aqueous solution, when treated with lead dioxide, becomes first green and then blue.

Benzylparatoluidine.—A mixture of paratoluidine (2 mols.) and benzyl chloride (1 mol.) is maintained at 155—165° for 40 hours. A yellowish oil is separated, as above; this distils at 205—215° under 10—15 mm. pressure, and darkens in colour on cooling. It remains liquid, even in melting ice, whereas the dibenzyl derivative melts at 54·5—55°, and benzoylorthotoluidine melts at 56—57°. The yield in the case of benzylorthotoluidine is 40 per cent., whilst in the case of benzylparatoluidine it is only 30 per cent. At a temperature higher than 170°, large quantities of a black, resinous product are formed; this does not distil up to 270° under 20 mm. pressure.

The salts of benzylparatoluidine are white and well crystallised, but little soluble in cold water, more soluble in, and readily decomposed by hot water. The methyl and ethyl derivatives of this base are obtained by heating it with the corresponding alcoholic iodides. *Benzylethylparatoluidine* is a yellow liquid boiling at 200—210° under 10 mm. pressure. *Benzylmethylparatoluidine* is a slightly yellow liquid boiling at 210—220° under 30 mm. pressure. These derivatives have no basic characters.

Benzoylbenzylparatoluidine.—This compound is formed by the action of benzoic chloride on benzylparatoluidine. The product, if distilled when hydrochloric acid ceases to be disengaged, yields a thick liquid, which passes over at 275—285° under a pressure of 20 mm., and rapidly solidifies. No salts have been obtained with acids. When dissolved in glacial acetic acid and added drop by drop to fuming nitric acid, a

nitro-derivative is obtained, which is precipitated by the addition of water. It dissolves in alcohol and crystallises in yellow needles, 1 cm. long, which melt at about 135—137°. It appears to consist of two substances, into which it separates on fusion; that in greater quantity melts at 135—137°. W. T.

Action of Benzyl Chloride on Metaxylidine. By Jablin-Gonnet (*Bull. Soc. Chim.* [3], **6**, 21).—A mixture of benzyl chloride (1 mol.) and metaxylidine (2 mols.) is heated in a reflux apparatus at 160—165° for 50 hours. The resulting crystalline mass is boiled with saturated sodium carbonate solution, and the oily, brown layer which separates is, after extraction with benzene, distilled under reduced pressure. *Benzylmetaxylidine*, $C_6H_3Me_2{\cdot}NHBz$, passes over at 200—210° under a pressure of 15 mm. as a pale yellow liquid, which is soluble in alcohol and benzene; with acids, it forms white, unstable salts, which are decomposed by water. Methyl, ethyl, and acetyl derivatives have been made and will be described later.

T. G. N.

Action of Hydroxylamine Hydrochloride on Acetomesitylene. By E. Feith and S. H. Davies (*Ber.*, **24**, 3546—3548).—Acetylmesidine (m. p. 216—217°) is formed, when an alcoholic solution of acetomesitylene is heated at 160° for six hours with hydroxylamine hydrochloride and sodium acetate, the oxime which is first produced immediately undergoing intramolecular change.

Acetophenone and acetopseudocymene are not acted on by hydroxylamine under the conditions just stated, but propiomesitylene, at a rather higher temperature (180°), yields, on prolonged heating, a very small quantity of a crystalline compound which melts at 154·5°, and is insoluble in potash. F. S. K.

Derivatives of Trinitroquinol. By R. Nietzki and H. Kaufmann (*Ber.*, **24**, 3824—3830).—Twelve years ago Nietzki showed that one of the nitro-groups in trinitrodiethylquinol may be readily replaced by an amido- or substituted amido-group; thus aniline yields a diethoxydinitrodiphenylamine. The latter, on boiling with alkali, was found to yield a substance having acid properties, which was regarded as diethyldinitrotrihydroxybenzene (Abstr., 1878, 866).

Further investigation has shown that this supposition is incorrect, the substance having the composition $C_{14}H_{13}N_2O_6$, instead of $C_{10}H_{12}O_7N_2$; it must, therefore, be formed by the hydrolysis of one of the ethoxy-groups, and is an *ethoxyhydroxydinitrodiphenylamine*,

$$OEt{\cdot}C_6H(OH)(NO_2)_2{\cdot}NHPh$$

[OEt : NHPh : NO_2 : OH : NO_2 = 1 : 2 : 3 : 4 : 5]. It crystallises from alcohol in yellow needles, and melts at 152°.

When diethoxydinitrodiphenylamine is reduced with tin and hydrochloric acid, it yields the corresponding *diethoxydiamidodiphenylamine*, $C_6H(OEt)_2(NH_2)_2{\cdot}NHPh$, which crystallises in almost colourless needles, and melts at 77°; its *hydrochloride*, $C_{16}H_{21}N_3O_3,2HCl$, forms colourless needles, which become blue on drying, and are less stable than the free base. On boiling with acetic anhydride, it yields a deriva-

tive which is simultaneously an acetyl compound and an anhydro-base, and has the constitution $NHAc{\cdot}C_6H(OC_2H_5)_2{<}^{NPh}_{\ \ N}{>}CMe$; it forms colourless needles, melts at 162°, and is readily soluble in hot water, alcohol, ether, and dilute acids.

Trinitrodiethylquinol also readily reacts with an excess of dimethyl-paradiamidobenzene, the reaction proceeding in the same manner as with aniline; the nitro-group is evolved as nitrous acid, and converts a portion of the diamine into dimethylaniline. The chief product of the action, which has the constitution

$$C_6H(NO_2)_2(OEt)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NMe_2,$$

has distinctly basic properties, and crystallises from alcohol in beautiful, red needles melting at 148°. Its *hydrochloride* forms needles which have a green surface lustre, and are decomposed by water. It is readily reduced by tin and hydrochloric acid, but the resulting triamido-compound cannot be isolated, as it rapidly undergoes oxidation; if manganese dioxide be added, and the mixture boiled till the original blue colour has changed to brown, the residue, on extraction with boiling alcohol, yields the product of oxidation in beautiful needles having a green lustre. The analysis showed that it has the composition $C_{18}H_{22}N_4O_2$, and it is, therefore, as would be expected from its mode of formation, a *diethoxydimethyldiamidophenazine*, $NH_2{\cdot}C_6H(OEt)_2{<}^{N}_{N}{>}C_6H_3{\cdot}NMe_2$, and has all the properties of a eurhodine. It dissolves in concentrated sulphuric acid with a green colour, which, on dilution, passes through blue into red, and colours silk with a slightly violet-red nuance. The *picrate*,

$$C_{18}H_{22}N_4O_2,C_6H_3N_3O_7,$$

crystallises in needles having a green lustre; the *acetyl* derivative, $C_{18}H_{21}N_4O_2Ac$, crystallises in pale red needles melting at 179°, and yields red salts with acids.

Paradiamidobenzene does not undergo condensation with trinitrodiethylquinol so readily, but its acetyl derivative gives more satisfactory results; the product of the reaction forms yellow, silky needles, melts at 199°, and has the constitution $C_6H(OEt)_2(NO_2)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NHAc$. On boiling with dilute alkali, the acetyl group is not eliminated, but instead one of the ethyl groups is removed, with formation of a substance having the constitution $OH{\cdot}C_6H(OEt)(NO_2)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NHAc$, which forms yellowish-brown crystals, readily soluble in alcohol, and melts at 206°. More concentrated alkali converts it into a *dinitroethyltrihydroxybenzene*, $OEt{\cdot}C_6H(OH)_2(NO_2)_2$, which forms yellow needles, and melts at 210°; it is not identical with the dinitroethyltrihydroxybenzene obtained by Nietzki from diamidodinitrophenetoïl (Abstr., 1883, 466).

Trinitrodiethylquinol also undergoes condensation with dimethyl-metadiamidobenzene and α-naphthylamine; the first yields a compound of slightly basic properties, having the constitution

$$C_6H(OEt)_2(NO_2)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NMe_2,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad 1 \qquad\qquad 3$$

which crystallises in orange-yellow needles and melts at 106°. The compound obtained from α-naphthylamine,

$$C_6H(OEt)_2(NO_2)_2\cdot NH\cdot C_{10}H_7{}^{\alpha},$$

forms yellow needles melting at 128°, and may be separated from the α-amidoazonaphthalene simultaneously formed by taking advantage of its lesser solubility in alcohol. H. G. C.

Diazobenzene Perbromide. By C. E. Saunders (*Amer. Chem. J.*, **13**, 486—490).—On treating an aqueous solution of diazobenzene sulphate, best prepared by Knoevenagel's method (Abstr., 1891, 54), with an excess of cold solution of bromine in moderately strong hydrobromic acid, diazobenzene perbromide separates as a dark, pasty mass, which, when repeatedly washed with ether and dried between filter paper, loses most of its colour, and almost ceases to smell of bromine. The liquid product originally obtained by Griess (*Phil. Trans.*, 1864, 673), which was probably a mixture or compound of the perbromide with free bromine, may be formed by exposing the dry solid to bromine vapour, of which it absorbs a very large quantity; the perbromide may be recovered by treatment with ether. In the preparation of the perbromide, symmetrical tribromobenzene occurs as a bye-product; it is dissolved, however, by the ether.

When diazobenzene perbromide is treated with bromine-water, it yields tribromophenol, and when boiled with water alone, it yields in addition phenol, hydrogen bromide, and bromine. When boiled with alcohol, it gives, not bromobenzene alone, as stated by Griess (*loc. cit.*), but a mixture of this substance with parabromophenetoïl, melting at 4° (compare Remsen and Orndorff, Abstr., 1888, 268). With boiling ether and with glacial acetic acid, it yields bromobenzene, mixed, in the latter case, with another compound of much higher boiling point. Jn. W.

Intramolecular Formation of an Azo-group. By E. Lellmann and B. Arnold (*Ber.*, **24**, 3557—3560; compare Täuber, this vol., p. 183).—*Orthazodibenzylamine*, $NH<\begin{matrix}CH_2\cdot C_6H_4\cdot N\\ \|\\ CH_2\cdot C_6H_4\cdot N\end{matrix}$, is obtained when an alkaline solution of the theoretical quantity of stannous chloride is gradually added to a hot alcoholic solution of orthodinitrodibenzylamine; it crystallises in small, orange needles, melts at 230°, and is only very sparingly soluble in alcohol, but more readily in benzene. The *hydrochloride*, $C_{14}H_{13}N_3,HCl + H_2O$, crystallises in slender, orange needles, and is converted into the base when heated at 80°.

Paratolylorthazodibenzylamine, $C_6H_4Me\cdot N<\begin{matrix}CH_2\cdot C_6H_4\cdot N\\ \|\\ CH_2\cdot C_6H_4\cdot N\end{matrix}$, can be obtained from orthodinitrodibenzylparatoluidine in like manner. F. S. K.

Alkyl Derivatives of Hydroxylamine. By R. Kothe (*Annalen*, **266**, 310—323; compare Behrend and König, Abstr., 1891, 1032).—When α-benzylhydroxylamine is oxidised with potassium dichromate and glacial acetic acid, it yields benzyl alcohol and traces of benzyl nitrite and benzyl acetate, nitric oxide being evolved.

When α-dibenzylhydroxylamine is treated with potassium dichromate and sulphuric acid, it yields benzylbenzaldoxime and small quantities of benzaldehyde and benzoic acid; if the potassium dichromate is added very gradually to a very dilute sulphuric acid solution of the α-dibenzylhydroxylamine, the yield of benzylbenzaldoxime is much smaller, but benzyl alcohol and other compounds are formed in its place.

Tribenzylhydroxylamine is not acted on by potassium dichromate and sulphuric acid under the conditions employed by the author.

When tribenzylhydroxylamine is distilled under reduced pressure, it is decomposed into β-dibenzylhydroxylamine, stilbene, benzylamine, β-benzylhydroxylamine, and ammonia. F. S. K.

Amidoximes and Azoximes. By F. Tiemann (*Ber.*, **24**, 3648—3650).—General remarks on the papers of Marcus, Goldbeck, Paschen, and Richter. (Compare following abstracts.) F. S. K.

Nitrogenous Derivatives of some Aromatic Dihydroxyaldehydes. By E. Marcus (*Ber.*, **24**, 3650—3657).—*β-Resorcylaldoxime*, $C_6H_3(OH)_2{\cdot}CH{:}NOH$ [CH : (OH)$_2$ = 1 : 2 : 4], prepared from β-resorcylaldehyde, crystallises in colourless needles, melts at 191°, and is readily soluble in alcohol and ether; it gives with ferric chloride a brownish-red coloration, and with Fehling's solution a green precipitate. The corresponding hydrazone (m. p. 158—159°) was also prepared. (Compare Rudolph, Abstr., 1889, 251.)

Diacetyl-β-resorcylonitrile, $CN{\cdot}C_6H_3(OAc)_2$, is formed when the aldoxime is boiled with acetic anhydride; it crystallises from alcohol in colourless prisms, melts at 72°, and is readily soluble in alcohol, ether, chloroform, and benzene.

β-Resorcylonitrile, $C_7H_5NO_2$, is produced when the diacetyl derivative is hydrolysed with dilute potash. It separates from a mixture of ether and light petroleum in crystals, melts at 175°, and is readily soluble in water, alcohol, and ether; its aqueous solution gives a red coloration with ferric chloride.

β-Resorcenylamidoxime, $C_6H_3(OH)_2{\cdot}C(NH_2){:}NOH$, prepared by treating the nitrile with hydroxylamine at the ordinary temperature, turns brown at 160°, melts at 166°, and is readily soluble in water, alcohol, and ether; it reduces Fehling's solution, and gives a brown coloration with ferric chloride.

The *dioxime*, $(OH)_2C_6H_2(CH{:}NOH)_2$ [(CH)$_2$: (OH)$_2$ = 1 : 6 : 2 : 4], is obtained when resorcyldialdehyde is treated with hydroxylamine; it melts at 209°, and is readily soluble in alcohol, ether, and potash, but only sparingly in water; in its aqueous solutions, ferric chloride produces a black, and copper sulphate a blue, precipitate.

Orthomethoxyparahydroxybenzophenylhydrazone, $C_{14}H_{14}N_2O_2$, prepared from the corresponding aldehyde, is a yellow, crystalline substance melting at 151—152°; it is readily soluble in alcohol, ether, benzene, and chloroform, but insoluble in water. The corresponding *aldoxime*, $C_8H_9NO_3$, melts at 171°, and is soluble in water, alcohol, ether, and soda, its solutions giving a brownish-red coloration with ferric chloride.

Acetylvanillonitrile, $CN\cdot C_6H_3(OMe)\cdot OAc$ [CN : OMe : OAc = 1 : 3 : 4], prepared by heating vanillinaldoxime (m. p. 117°) with acetic anhydride, crystallises from hot water in colourless needles, melts at 110°, and is soluble in alcohol, ether, and benzene.

Vanillonitrile, $C_8H_7NO_2$, is formed when the acetyl derivative is dissolved in cold, dilute potash; it crystallises from hot water in colourless needles, melts at 87°, and is soluble in alcohol, ether, and benzene. In its aqueous solution, ferric chloride produces a blue coloration, and, on warming, a crystalline substance is precipitated.

Vanillenylamidoxime, $C_8H_{10}N_2O_3$, prepared from the nitrile just described, crystallises from water in prisms, melts below 100°, and dissolves freely in alcohol, hydrochloric acid, and soda, but is only sparingly soluble in ether, and insoluble in benzene; in its aqueous solutions, ferric chloride produces a reddish-violet, and Fehling's solution a green, coloration.

Piperonalaldoxime, $CH_2<^{O}_{O}>C_6H_3\cdot CH{:}NOH$, crystallises from hot water in lustrous needles, melts at 110°, and dissolves freely in alcohol, ether, benzene, chloroform, and carbon bisulphide. The corresponding *nitrile*, $C_8H_5NO_2$, is readily soluble in alcohol, ether, and benzene, and crystallises from water in lustrous needles melting at 95°. The *amidoxime*, $C_8H_8N_2O_3$, melts at 151°, and is soluble in hot water, alcohol, ether, acids, and alkalis; its *hydrochloride*, $C_8H_8N_2O_3,HCl$, is a colourless, crystalline compound melting at 193°.

Ethenylpiperonenylazoxime, $CH_2<^{O}_{O}>C_6H_3\cdot C<^{NO}_{N}>CMe$, is formed when piperonenylamidoxime is heated with acetic anhydride; it melts at 110° and is readily soluble in alcohol, ether, and benzene, but insoluble in water. F. S. K.

Nitrogenous Derivatives of Parahomosalicylic Acid. By O. Goldbeck (*Ber.*, **24**, 3658—3667).—*Parahomosalicylaldoxime*, $OH\cdot C_6H_3Me\cdot CH{:}NOH$ [Me : CH_2 : OH = 1 : 3 : 4], crystallises in long, colourless needles, melts at 105°, and dissolves freely in hot water, alcohol, ether, chloroform, and benzene, but is only sparingly soluble in light petroleum and cold water; its aqueous solution gives a dirty violet coloration with ferric chloride.

Acetylparahomosalicylonitrile, $C_{10}H_9NO_2$, prepared by boiling the aldoxime with acetic anhydride, melts at 56—57°, and is readily soluble in alcohol, ether, benzene, acetone, chloroform, and hot light petroleum, but only sparingly in water.

Parahomosalicylamide, $C_8H_9NO_2$, obtained by heating ethyl parahomosalicylate with concentrated ammonia, crystallises from dilute alcohol in colourless needles, melts at 177—178°, and is readily soluble in alcohol and ether, but more sparingly in benzene and chloroform; its aqueous solution gives with ferric chloride a dark-violet coloration. The corresponding *thiamide*, C_8H_9NOS, was obtained in an impure condition by melting the amide with phosphorus pentasulphide; it dissolves freely in alcohol, ether, chloroform, benzene, alkalis, and hot water, melts at 126—127°, and gives with ferric chloride a dark-violet coloration, with copper sulphate a green,

and with silver nitrate a reddish-brown, precipitate. The *nitrile*, C_8H_7NO, is formed, with evolution of hydrogen sulphide, when the thiamide is submitted to dry distillation. It melts at 100—101°, dissolves freely in alcohol, ether, benzene, and chloroform, and is decomposed by boiling alkalis; in its aqueous solution, ferric chloride produces a violet coloration.

Parahomosalicenylamidoxime, $C_8H_{10}N_2O_2$, prepared by heating the thiamide with hydroxylamine in dilute alcoholic solution, crystallises from hot benzene in plates, and from hot water in needles, melting at 123—124°; it is readily soluble in ether, alcohol, hot water, and chloroform, and in its aqueous solution ferric chloride produces a reddish-violet coloration, and copper sulphate a light-green precipitate. The *hydrochloride* melts at 215° with decomposition. The *benzoyl* derivative, $C_{15}H_{14}N_2O_3$, obtained by triturating the amidoxime with benzoic chloride, melts at 181—182°, and is readily soluble in acetone, but only sparingly in alcohol, ether, and benzene, and insoluble in water and light petroleum; its alcoholic solution gives a green coloration with ferric chloride.

Benzenylparahomosalicenylazoxime, $OH\cdot C_6H_3Me\cdot C\begin{matrix}NO\\ \diagup\!\diagdown\\ N\end{matrix}CPh$, is formed when the benzoyl derivative (m. p. 181—182°) is heated with water at 100°; it melts at 151°, dissolves freely in ether, alcohol, chloroform, benzene, light petroleum, and alkalis, and gives with ferric chloride in alcoholic solution a green coloration.

Dibenzoylparahomosalicenylamidoxime, $C_{22}H_{18}N_2O_4$, prepared by shaking the amidoxime with potash and benzoic chloride, melts at 143°, and is readily soluble in hot alcohol, ether, chloroform, and benzene, but insoluble in water, acids, and alkalis.

Acetylparahomosalicenylamidoxime, $C_{10}H_{12}N_2O_3$, is obtained when the amidoxime is treated with acetic anhydride at the ordinary temperature; it crystallises from hot benzene in plates, melts at 148—149°, and dissolves freely in alcohol, ether, chloroform, benzene, dilute acids, and alkalis; its dilute alcoholic solution gives a violet coloration with ferric chloride.

Ethenylparahomosalicenylazoxime, $C_{10}H_{10}N_2O_2$, separates from ether in prismatic crystals, melts at 45°, and is readily soluble in ether, alcohol, benzene, chloroform, and alkalis, but insoluble in water and dilute acids; in its alcoholic solution, copper sulphate produces a reddish-brown precipitate, and ferric chloride a blue coloration.

Propenylparahomosalicenylazoxime-ω-carboxylic acid,

$$OH\cdot C_6H_3Me\cdot C\begin{matrix}NO\\ \diagup\!\diagdown\\ N\end{matrix}C\cdot CH_2\cdot CH_2\cdot COOH,$$

can be obtained by heating the amidoxime with succinic anhydride at about 115°. It crystallises from dilute alcohol in slender, colourless needles, melts at 103°, and is readily soluble in ether, benzene, and hot water, but more sparingly in chloroform, and insoluble in light petroleum; its aqueous solution gives a violet coloration with ferric chloride, and in its neutral solutions silver nitrate produces a colourless, crystalline precipitate. F. S. K.

Derivatives of Orthohomosalicylaldehyde and of Orthohomoparahydroxybenzaldehyde. By E. PASCHEN (*Ber.*, **24**, 3667—3675).—*Orthohomosalicylphenylhydrazone*,

$$OH{\cdot}C_6H_3Me{\cdot}CH{:}N_2HPh\ [Me : OH : CH = 1 : 2 : 3],$$

crystallises from alcohol in colourless, rhombic plates, melts at 95°, and turns greenish on exposure to the air; it is readily soluble in alcohol, ether, and chloroform, but more sparingly in hot water, and insoluble in light petroleum. The *aldoxime*, $C_8H_9NO_2$, crystallises in long, colourless needles, melts at 99°, and dissolves freely in hot water, alcohol, ether, benzene, and chloroform, but is insoluble in light petroleum and cold water; in its aqueous solutions, ferric chloride produces a violet coloration, and Fehling's solution a brownish-red precipitate.

Orthohomosalicylonitrile, C_8H_7NO, is obtained when the aldoxime is boiled with acetic anhydride, and the oily product decomposed with cold, dilute soda; it crystallises from hot alcohol in colourless plates, melts at 88·5°, and is readily soluble in alcohol, ether, benzene, chloroform, and hot water, but insoluble in light petroleum.

Orthohomosalicenylamidoxime, $C_8H_{10}N_2O_2$, crystallises from alcohol in large, colourless plates, melts at 126·5°, and is insoluble in light petroleum; it dissolves freely in alcohol, benzene, chloroform, and hot water, and gives a dirty-green precipitate with Fehling's solution. The *dibenzoyl* derivative, $C_{23}H_{16}N_2O_4$, separates from alcohol in small, colourless needles, melts at 164°, and is readily soluble in ether, benzene, and chloroform, but insoluble in light petroleum and cold water.

Benzenylorthohomosalicenylazoxime, $C_{15}H_{12}N_2O_2$, prepared by boiling the dibenzoyl derivative (m. p. 164°) with soda, forms colourless needles, and melts at 150°; it is insoluble in light petroleum, but dissolves freely in most of the other ordinary organic solvents.

Orthohomoparahydroxybenzophenylhydrazone, $C_{14}H_{14}N_2O$, melts at 151°, and is readily soluble in alcohol, ether, benzene, and chloroform, but only sparingly in hot water, and insoluble in light petroleum. The *aldoxime*, $C_8H_9NO_2$, crystallises in colourless needles, and melts at 143·5°; it gives with ferric chloride a dark-green, and with Fehling's solution a light-green, coloration.

Acetylorthohomoparahydroxybenzonitrile, $C_{10}H_9NO_2$, is formed when the aldoxime (m. p. 143·5°) is boiled with acetic anhydride; it crystallises in colourless plates, melts at 75—76°, and is insoluble in light petroleum, but readily soluble in ether, alcohol, benzene, and chloroform. The *nitrile*, C_8H_7NO, prepared by hydrolysing the acetyl derivative with dilute soda, crystallises in colourless needles, melts at 93°, and resembles the preceding compound in its behaviour with solvents.

Orthohomoparahydroxybenzenylamidoxime, $C_8H_{10}N_2O_2$, forms colourless scales, melts at 152° with decomposition, and turns bluish-grey on exposure to the air; it is readily soluble in alcohol, but more sparingly in ether and hot water, and insoluble in benzene and light petroleum; it gives a bluish-green coloration with Fehling's solution. The *hydrochloride*, $C_8H_{10}N_2O_2,HCl$, crystallises in needles.

Ethenylorthohomoparahydroxybenzenylazoxime, $C_{10}H_{10}N_2O_2$, prepared by heating the amidoxime with acetic anhydride, crystallises from hot, dilute alcohol in small, colourless needles, melts at 89°, and is insoluble in water and light petroleum, but readily soluble in alcohol, ether, benzene, and chloroform. F. S. K.

β-Trichloro-α-hydroxypropenylamidoxime. By E. Richter (*Ber.*, **24**, 3676—3677).—*β-Trichloro-α-hydroxypropenylamidoxime*, $CCl_3{\cdot}CH(OH){\cdot}C(NH_2){:}NOH$, can be obtained by treating the nitrile of trichlorolactic acid with an aqueous solution of hydroxylamine at the ordinary temperature; it crystallises from hot water in plates, melts at 145° with decomposition, and is almost insoluble in benzene and ether, but more readily in alcohol. The *hydrochloride*,

$$C_3H_5N_2Cl_3O_2,HCl,$$

crystallises in plates.

Ethenyl-β-trichloro-α-hydroxypropenylazoxime,

$$CCl_3{\cdot}CH(OH){\cdot}C\begin{matrix}NO\\ \diagdown\!\!\diagup\\ N\end{matrix}CMe,$$

prepared by warming the amidoxime with acetic anhydride, crystallises from hot water in needles, melts at 160—161°, and is readily soluble in alcohol and ether, but only sparingly in benzene.

F. S. K.

Phenylglyoximes. By A. Russanow (*Ber.*, **24**, 3497—3511).—*Antiphenylamphiglyoxime*, $\begin{matrix}Ph{\cdot}C & ---- & C{\cdot}H\\ \| & & \|\\ N{\cdot}OH & & N{\cdot}OH\end{matrix}$, is best prepared by treating sodioisonitrosoacetophenone (1 mol.) with hydroxylamine hydrochloride (1 mol.) and sodium hydroxide (1 mol.) in aqueous solution at the ordinary temperature (compare Scholl, Abstr., 1891, 287); the product is precipitated with acetic acid, washed with chloroform, and recrystallised from ether. It melts at 168°, is almost insoluble in chloroform, and is identical with the phenylglyoxime previously described by Schramm (*Ber.*, **16**, 2186) and by Strassmann (Abstr., 1889, 610).

Phenylantiglyoxime, $\begin{matrix}Ph{\cdot}C & - & C{\cdot}H\\ \| & & \|\\ OH{\cdot}N & & N{\cdot}OH\end{matrix}$, is precipitated, as hydrochloride, when hydrogen chloride is passed into an ethereal solution of the preceding compound; this salt is stable in dry air, but in a moist atmosphere it is quickly converted into the glyoxime with elimination of hydrogen chloride. This glyoxime is also formed when isonitrosoacetophenone is treated with hydroxylamine hydrochloride in dilute alcoholic solution; it crystallises in well-defined prisms melting at 180°. It is stable in acid solution, but it is very readily converted into its isomeride (m. p. 168°) by most ordinary neutral solvents, except ether, from which it crystallises unchanged; it resembles its isomeride very closely in appearance and in properties, but differs from it as regards melting point.

The *diaceiyl* derivative, $C_{12}H_{12}N_2O_4$, is formed when either of the glyoximes described above is treated with acetic anhydride at 0°, but a slight difference in the behaviour of the two compounds, as regards

the rapidity of solution, is observed. It crystallises in well-defined, highly refractive prisms, melts at 92°, and is readily soluble in most ordinary organic solvents, except ether.

Phenylazoxazole (*phenylfurazan*), $\begin{matrix}CH:N\\ |\\ CPh:N\end{matrix}>O$, is formed when the diacetyl derivative is kept in contact with sodium carbonate until it is completely converted into an oil, and also, but only slowly and to a limited extent, when either of the glyoximes or the diacetyl derivative is distilled with steam; it is best prepared by precipitating an alkaline solution of the glyoxime with carbonic anhydride, and extracting the precipitate with chloroform (see below). It crystallises from dilute alcohol in needles, melts at 30° (36°?), is volatile with steam, and volatilises very readily at the ordinary temperature; it is insoluble in water and cold alkalis, but very readily soluble in ether, chloroform, and benzene, and it dissolves unchanged in concentrated sulphuric acid.

Phenyloximidoacetonitrile, NOH:CPh·CN, is formed when phenylazoxazole or the diacetyl derivative (m. p. 92°) is warmed with soda or sodium carbonate, and also when phenylglyoxime is boiled with sodium carbonate; when the glyoxime is boiled with soda, it is only very slowly converted into the nitrile. Phenyloximidoacetonitrile is also the principal product (50 per cent. of the theoretical) of the action of hydroxylamine on dibromacetophenone in alkaline solution, a fact which was overlooked by Strassmann and by Schramm. It crystallises in plates, melts at 128°, dissolves freely in hot water and in the ordinary organic solvents, and is not volatile with steam; it is not hydrolysed by boiling, concentrated hydrochloric acid, and when heated with concentrated soda, it is only very slowly converted into phenyloximidoacetic acid, with evolution of ammonia. The *acetyl* derivative, NOAc:CPh·CN, prepared by boiling the nitrile, or either of the glyoximes, with acetic anhydride, separates from dilute alcohol in well-defined, rhombic crystals, melts at 68°, dissolves freely in all ordinary solvents, and is decomposed by soda, yielding the nitrile.

The following observations point to the existence of a third glyoxime, which is probably *phenylsynglyoxime*, $\begin{matrix}Ph\cdot C\text{———}C\cdot H\\ \|\qquad\qquad\|\\ N\cdot OH\quad OH\cdot N\end{matrix}$. When either of the glyoximes described above is dissolved in soda, and carbonic anhydride passed through the solution cooled to −10°, a precipitate, containing about 33—36 per cent. of the theoretical quantity of phenylazoxazole, is produced; after extracting this compound by shaking with chloroform, there remains undissolved a substance which melts at 148—154°; this, on being dissolved in a very small quantity of acetic anhydride, yields an oily product. When this oil is distilled with water, it yields in the first few minutes a far larger quantity (above 51 per cent. of the theoretical) of phenylazoxazole than is obtained in the same time from either of the glyoximes, or from the acetyl derivative (m. p. 92°) described above, and then the rate of formation of this compound quickly diminishes; this oil is also very quickly converted into phenylazoxazole on treatment with cold soda, whereas the diacetyl derivative yields phenyloximidoaceto-

nitrile under the same conditions. These facts seem to show that the precipitate produced with carbonic anhydride consists principally of phenylazoxazole, and contains, in addition, a phenylglyoxime which differs from the other two compounds in properties, and probably has the configuration given above.

No evidence of the existence of the fourth theoretically possible isomeride was obtained. F. S. K.

Action of Nitrous Acid on Benzenylamidethoxime. By F. Tiemann (*Ber.*, **24**, 3453—3458; compare Tiemann and Krüger, Abstr., 1884, 1325; 1885, 790).—The author finds that when sodium nitrite is added in molecular proportion to a solution of benzenylamidethoxime acidified with a mineral acid or a strong organic acid, the character of the product depends on the acid employed. Benzenylethoxime chloride (*loc. cit.*) is formed in the presence of hydrochloric acid.

Benzenylethoxime bromide, CPhBr:NOEt, is obtained by dissolving the amidethoxime (1 mol.) in hydrobromic acid (2 mols.), cooling, cautiously adding a solution of sodium nitrite (1 mol.), gently heating at 40° until the evolution of nitrogen ceases, extracting with ether, and, after evaporating the solvent, distilling in a partial vacuum; it is an oil, insoluble in water, but readily soluble in alcohol and ether, and boils at 150° (45 mm.).

Benzenylethoxime nitrite, NO_2·CPh:NOEt, is formed when a solution of the amidethoxime (1 mol.) in dilute sulphuric acid is treated with sodium nitrite (2 mols.) in the cold. It is an oil of little stability, which dissolves in hot alkalis with decomposition, and is quickly converted into benzoic acid and ethoxylamine by hydrochloric acid; when it is shaken with cold potassium hydroxide solution and carbonic anhydride passed through the solution, ethyl benzhydroxamate is formed.

Benzenylethoxime acetate, OAc·CPh:NOEt, is prepared by dissolving benzenylamidethoxime in concentrated acetic acid, adding sodium nitrite solution at the temperature of the room, carefully neutralising, and extracting with ether; it is an oil which does not solidify decomposes into phenyl isocyanate on distillation, undergoes partial decomposition on boiling with water, and is readily soluble in alcohol and ether; when carefully warmed with a solution of potassium hydroxide in dilute alcohol, the potassium derivative of ethyl benzhydroxamate is obtained. A. R. L.

Dyeing with Aniline-black in the Dry Way. By S. Grawitz (*Compt. rend.*, **113**, 746—747).—It is well known that dyeing with aniline-black in the dry way seriously weakens the fibre, and that this result cannot be avoided by using a neutral salt of aniline.

According to Nietzki, aniline-black is a monobasic tetramine, and, if this be so, its formation will be represented by the equation $4C_6H_7N,HCl + 4O = C_{24}H_{20}N_4,HCl + 3HCl + 4H_2O$. The hydrogen chloride liberated in contact with the dry cellulose converts it into hydrocellulose and weakens the fibre. The remedy lies in adding acetates, or other organic salts of the alkalis or alkaline earths, to

the mixture for producing the black. Koechlin has stated that the presence of acetates prevents the formation of the black, but the author finds that this is not the case when the quantity of acetate added contains less than one equivalent of base for each equivalent of acid present in the form of aniline salt. Half an equivalent gives comparatively little protection, but the maximum benefit is obtained with a quantity of acetate equivalent to three-fourths of the aniline salt present, a result which supports Nietzki's view, according to which three-fourths of the acid in the aniline salt is liberated in the process of oxidation. C. H. B.

Thiophenylcarbamides. By S. Paschkowezky (*Ber.*, **24**, 3492).—The author has received a private communication from Bernthsen, in which he points out that the differences in the melting points recorded for thiodiphenylcarbamide chloride and dithiotetraphenylcarbamide by Paschkowezky (this vol., p. 164), and by Fränkel (Abstr., 1885, 1130), are due to the latter having neglected to correct the values he obtained. A. R. L.

Action of Potassium Cyanide on Halogen Derivatives of Ketones. By A. Obrégia (*Annalen*, **266**, 324—358).—The potassium derivative of cyanacetophenone is formed, with evolution of hydrogen cyanide, when bromacetophenone (1 mol.) is treated with potassium cyanide (2 mols.) in dilute alcoholic solution; after evaporating the alcohol and taking up the residue with water, the filtered solution is acidified, and the precipitated cyanacetophenone recrystallised from boiling water. The yield of pure cyanacetophenone (m. p. 80—81°) is 64 per cent. of the theoretical; its aqueous solution has an acid reaction. The *sodium* derivative crystallises in small, nacreous plates, is readily soluble in alcohol, and is only slowly decomposed by carbonic anhydride; the ammonium derivative is unstable; on treating a solution of the sodium derivative with metallic salts, the corresponding metallic derivatives are precipitated. The *hydrazone* separates from alcohol in almost colourless crystals, melts at 134—135° with previous softening, and is very readily soluble in ether and chloroform, but only moderately easily in cold alcohol, and insoluble in cold water.

A compound of the composition $C_9H_8N_2O$ is formed when an alkaline solution of cyanacetophenone is treated with hydroxylamine at the ordinary temperature; it crystallises in colourless, lustrous, rectangular plates or short needles, melts at 110—112°, and is readily soluble in chloroform, alcohol, benzene, ether, and acetone, but almost insoluble in light petroleum, cold alkalis, and concentrated ammonia; it has a neutral reaction, and crystallises unchanged from hot soda. The *hydrochloride* melts at 98—100°; the *sulphate* decomposes at 169—173°, and is resolved into its components by cold water. When boiled with dilute acids, it yields cyanacetophenone and phenylisoxazolone; the last-named compound is also formed when an alcoholic solution of cyanacetophenone and hydroxylamine hydrochloride is kept for a long time. It will be seen that the compound just described does not show all the properties of a true oxime; its constitution is probably represented by the formula $\begin{matrix}CH_2\cdot CO\\ |\\ CPh:N\end{matrix}>NH$.

Benzoylacetamide, $CH_2Bz{\cdot}CO{\cdot}NH_2$, is obtained when cyanacetophenone is treated with concentrated sulphuric acid at the ordinary temperature, and, after keeping for about 48 hours, the product precipitated with ice; it crystallises from hot water in lustrous needles or prisms, melts at 111—113°, and is almost insoluble in light petroleum, and only moderately easily soluble in benzene and ether, but readily in alcohol, chloroform, acetone, alkalis, and ammonia; it has a neutral reaction, and its solutions give an intense violet coloration with ferric chloride. It is decomposed by boiling alkalis with formation of ammonia, acetic acid, and benzoic acid, and when heated alone or with water, it yields carbonic anhydride and acetophenone. The *hydrazone* crystallises from dilute alcohol in yellowish needles, melts at 128—130°, and is soluble in ether. When benzoylacetamide is treated with hydroxylamine hydrochloride in alcoholic or ammoniacal solution, it is converted in phenylisoxazolone.

The crystalline compound (m. p. 179—180°) obtained by treating chloracetone with potassium cyanide in aqueous solution (compare Hantzsch, Abstr., 1890, 1094) has the molecular formula $C_8H_{10}N_2O_2$, as was proved by molecular weight determinations, by Raoult's method, in glacial acetic acid solution, and its constitution is probably that of a *β-methylhydroxy-γ-cyanacetobutyronitrile*,

$$CN{\cdot}CHAc{\cdot}CMe(OH){\cdot}CH_2{\cdot}CN.$$

Hydroxyhydrocyanomesitenelactone, $CN{\cdot}C\lessdot^{CMe(OH){\cdot}CH_2}_{CMe—O—CO}$, the *nitrile* of *hydroxyhydroisodehydracetic acid*, is obtained when the crystalline compound (m. p. 179—180) just mentioned is dissolved in very dilute sulphuric acid; it crystallises from hot water in colourless, lustrous needles, melts at 65°, and is very readily soluble in alcohol, chloroform, benzene, acetone, and boiling water, but only moderately easily in ether, and almost insoluble in light petroleum. Its aqueous solution gives, with ferric chloride, first a brownish, and then a violet, coloration; the freshly prepared solution in dilute alcohol has only a very feebly acid reaction, but after keeping for some time the acidity increases very considerably. It dissolves unchanged in cold, concentrated acids, and also in alkalis, ammonia, and alkali carbonates. The *bromo*-derivative, $C_8H_5BrNO_3$, can be prepared by treating the lactone or the crystalline compound (m. p. 179—180°) with bromine in alcoholic solution; it crystallises from dilute alcohol in slender, lustrous needles, melts at 98—100°, and is readily soluble in benzene, chloroform, ether, alcohol, and boiling water; its aqueous solution has an acid reaction, and only gives a slight violet coloration with ferric chloride after having been boiled.

β-Hydroxy-γ-acetoisovaleric acid, $CH_2Ac{\cdot}CMe(OH){\cdot}CH_2{\cdot}COOH$, is formed, with liberation of carbonic anhydride, when the lactone is boiled with barium hydroxide until the evolution of ammonia is at an end; it is a thick, yellow, odourless liquid, readily soluble in water, alcohol, and ether. The *phenylhydrazone* is an oil; the *paratolylhydrazone* is a yellowish, very unstable substance, and decomposes at 81—85°. The *barium* salt is a yellowish, amorphous powder, readily soluble in water and alcohol; it seems to have the composition

$(C_7H_{11}O_4)_2Ba + C_7H_{10}O_4Ba$. The *silver* salt, $2C_7H_{11}O_4Ag + C_7H_{10}O_4Ag_2 + H_2O$, is very unstable, and very readily soluble in cold water. The *copper* salt is a green, vitreous, hygroscopic substance.

A compound of the composition $C_8H_{13}N_3O_4 + 3H_2O$ is obtained when hydroxyhydrocyanomesitenelactone is treated with hydroxylamine in very dilute alkaline solution, and the precipitate recrystallised from boiling water, from which it separates in colourless, lustrous needles; it slowly loses the whole of its water over sulphuric acid, the anhydrous crystals decomposing at 184—185°. It is very sparingly soluble in ether, acetone, light petroleum, and cold water, but more readily in alcohol, chloroform, benzene, and boiling water; its aqueous solution has a pronounced acid reaction, and gives, with ferric chloride, a brownish-violet coloration. This compound is probably the lactam of β-methylhydroxy-γ-acetoxime-δ-isonitrosoamidovaleric acid, and its constitution may be represented by the formula $NOH{:}CMe{\cdot}CH{<}\begin{matrix}C(NOH)—NH\\CMe(OH){\cdot}CH_2\end{matrix}{>}CO$. F. S. K.

Action of Ammonia and Aniline on Halogen-substituted Nitrobenzoic Acids. By A. Grohmann (*Ber.*, **24**, 3808—3815).—In a previous communication (Abstr., 1891, 305), the author has shown that the halogen in the ethyl salt, amide, and anilide of 4 : 3-bromonitrobenzoic acid may be readily replaced by the amido- and anilido-groups; in the present paper he describes similar experiments made with 2 : 5-bromonitrobenzoic acid.

2 : 5-*Bromonitrobenzoic chloride*, $NO_2{\cdot}C_6H_3Br{\cdot}COCl$, is readily obtained by the action of phosphorus pentachloride on the acid, and crystallises from alcohol in greyish crystals melting at 63°. The *amide*, $NO_2{\cdot}C_6H_3Br{\cdot}CONH_2$, is prepared from the chloride by warming with ammonium carbonate on the water-bath, and crystallises from alcohol in white, lustrous needles which melt at 197—198°; the *anilide*, $NO_2{\cdot}C_6H_3Br{\cdot}CO{\cdot}NHPh$, obtained by gently warming the chloride with aniline, forms yellowish-white, acicular crystals, and melts at 166°; both compounds are soluble in alcohol and acetone, and insoluble in water and benzene.

When ethyl 2 : 5-bromonitrobenzoate is heated in a sealed tube with alcoholic ammonia, it is converted into *ethyl* 2 : 5-*amidonitrobenzoate*, $NO_2{\cdot}C_6H_3(NH_2){\cdot}COOEt$, which crystallises from alcohol in pale-yellow needles melting at 148°. If aniline be substituted for ammonia, the corresponding *ethyl* 2 : 5-*anilidonitrobenzoate* is obtained; it separates from alcohol in small, yellow plates, and melts at 118°. The amide and anilide above described also readily react with ammonia and aniline respectively, forming the corresponding amido- and anilido-compounds. 2 : 5-*Amidonitrobenzamide*,

$$NO_2{\cdot}C_6H_3(NH_2){\cdot}CONH_2,$$

crystallises in orange-yellow needles, and melts at 230°; 2 : 5-*anilidonitrobenzanilide*, $NO_2{\cdot}C_6H_3(NHPh){\cdot}CO{\cdot}NHPh$, separates from alcohol in tufts of very slender, yellow needles, resembling silk fibres, and melts at 159°.

2 : 4-*Chloronitrobenzoic chloride* is prepared from the acid in the

usual manner, and is a yellowish-brown substance melting at 115°. It is converted by ammonium carbonate and aniline respectively into the *amide* and *anilide;* the former crystallises from alcohol in grey scales, and melts at 172°, whilst the latter is a white, amorphous substance melting at 168°. In these compounds, unlike the 4 : 3- and 2 : 5-compounds, the halogen cannot be displaced by further heating with ammonia or aniline. The same is also true of 4 : 2-*chloronitrobenzoic acid*, which was prepared by displacing the amido-group in 4 : 2-amidonitrotoluene by chlorine and oxidising the chloronitrotoluene thus obtained.

From these results, it appears that when the nitro- and carboxyl-groups are simultaneously in the ortho- and para-position relatively to the halogen, the latter may be readily displaced, but that this is no longer possible when one of these groups takes up the meta-position.

To his previous communication on 4 : 3-bromonitrobenzoic acid (*loc. cit.*), the author adds that this acid is converted by alcoholic ammonia at 170° into the 4 : 3-amidonitrobenzoic acid described by Griess (*Ber.*, **5**, 855) and Salkowski (*Annalen*, **173**, 53).

H. G. C.

Oximes of some Ketonic Acids. By F. Garelli (*Gazzetta*, **21**, ii, 173—188).—In a previous memoir (Abstr., 1891, 711), the author reported his inability to prepare the oximido-compounds of dioxymethylenephenylglyoxylic acid, apionylglyoxylic acid, and paramethoxyglyoxylic acid; he has, however, since succeeded in preparing them, and finds them to be very unstable, readily losing the elements of water and carbonic anhydride, and yielding the corresponding nitriles.

Methyl dioxymethylenephenylglyoxylate, $CH_2<^{O}_{O}>C_6H_3\cdot CO\cdot COOMe$, is prepared by saturating a solution of dioxymethylenephenylglyoxylic acid in methyl alcohol with dry hydrogen chloride. The alcohol is distilled off and water added; the salt separates as an oil which soon solidifies, and is crystallised from dilute alcohol. Small colourless needles, melting at 66°, soluble in alcohol and ether, and almost insoluble in water, are thus obtained. The alcoholic solution of this ethereal salt is treated with a slight excess of hydroxylamine hydrochloride and heated in a reflux apparatus on the water-bath for two hours. The alcohol is distilled off, the residual oil dissolved in dilute potash, filtered from a small quantity of piperonylnitrile, and the solution saturated with carbonic anhydride; *methyl dioxymethylenephenyloximidoacetate* is then thrown down, and on reprecipitation from its solution in benzene, by the addition of light petroleum, is obtained in tufts of small crystals melting without decomposition at 102°. This substance is soluble in water and alcohol, and on hydrolysis with dilute potash at a temperature below 60°, yields *dioxymethylenephenyloximidoacetic acid*

$$CH_2<^{O}_{O}>C_6H_3\cdot C(NOH)^{\beta}\cdot COOH,$$

as a whiteish mass; on precipitation from its acetic solution by light

petroleum, it may be obtained in minute crystals, soluble in sodium carbonate solution, alcohol, ether, benzene, and water. It melts with decomposition at 150—151°, and its aqueous solution gives white precipitates with lead and mercury salts and a green precipitate with copper acetate in concentrated solutions. This acid may also be prepared by heating a dilute solution of dioxymethylenephenylglyoxylic acid at 60—70° with the calculated quantity of hydroxylamine hydrochloride. It is readily converted into piperonylonitrile by passing a current of dry hydrogen chloride into its ethereal solution; the conversion also proceeds spontaneously in dilute aqueous solutions, and is hastened by the presence of acids or of hydroxylamine hydrochloride. The *acetyl* derivative is obtained on heating it with a slight excess of acetic chloride; on cooling, colourless, rectangular prisms separate, melting with decomposition at 139—140°. When hydrolysed at 0° with dilute potash and extracted with ether, the oxime is regenerated; at higher temperatures, the nitrile is the principal product of the action.

Compounds analogous to those of dioxymethylenephenylglyoxylic acid may be prepared from apionylglyoxylic acid by the same methods. *Methyl apionylglyoxylate*, $CH_2<^{O}_{O}>C_6H(OMe)_2\cdot CO\cdot COOMe$, crystallises from dilute alcohol in needles melting at 62°; it is very soluble in alcohol and ether, sparingly in benzene, and insoluble in water. Its *oxime*, $CH_2<^{O}_{O}>C_6H(OMe)_2\cdot C(NOH)^{\beta}\cdot COOMe$, is obtained in minute, colourless crystals melting at 129° without decomposition; on hydrolysis, it yields *apionyloximidoacetic acid* in splendid, white scales, very soluble in alcohol, sparingly in boiling water, less so in benzene, and insoluble in ether. Its aqueous solution gives no precipitate with salts of lead, copper, or mercury. No acetyl derivative could be prepared.

Paramethoxyphenyloximidoacetic acid, $OMe\cdot C_6H_4\cdot C(NOH)^{\beta}\cdot COOH$, is prepared from paramethoxyphenylglyoxylic acid in the manner indicated above, and separates from ethyl acetate in large, colourless crystals, very soluble in water, alcohol, and ether; it melts at 145—146° with complete decomposition. The α-oximido-acid cannot be prepared by carrying out the reaction at 0°. On heating with acetic anhydride or acetic chloride, a small quantity of an *acetyl* derivative is obtained. It melts with complete decomposition at 118°, is decomposed with formation of anisonitrile by cold solutions of the alkali carbonates, and on hydrolysis at 0°, yields only the original β-oximido-acid.

Ciamician and Silber (Abstr., 1890, 965) found that isosafrole yielded piperonylic acid and dioxymethylenephenylglyoxylic acid on oxidation with permanganate, the author finds that a small quantity of dioxymethylenephenylglycollic acid is also produced (30 grams of isosafrole yield 0·5 gram of the acid). This acid is separated by means of its solubility in water, and melts at 156°, not at 152—153°, as found by Lorenz (Abstr., 1881, 727).

The ketonic acids obtained from safrole, anethoïl, methyleugenol, and apiole, when dissolved in benzene and treated with thiophen in

concentrated sulphuric acid solution, impart an intense red coloration to the thiophen, the benzene solution remaining colourless; on dilution, the solution becomes successively violet and dirty green. The solutions of these acids in phenol, when heated with concentrated sulphuric acid on the water-bath, soon turn blue; gas is then abundantly evolved and the solution becomes red; on pouring the product into water, the colouring matter separates as a flocculent precipitate insoluble in water, but readily soluble in soda, and in solutions of the alkali carbonates. A green colouring matter is produced on heating the acids with dimethylaniline and zinc chloride.

W. J. P.

Derivatives of Mesitylene. By E. Feith (*Ber.*, **24**, 3542—3545; compare Claus, Abstr., 1890, 979, and Dittrich and Meyer, Abstr., 1891, 1224).—The air-dried barium salt of mesitylglyoxylic acid contains 3 mols. H_2O, of which it loses two over sulphuric acid. The *zinc* salt, with $4H_2O$, crystallises in lustrous plates and loses 3 mols. H_2O over sulphuric acid. The *methyl* salt, $C_{12}H_{14}O_3$, boils at about 170° under a pressure of 100 mm. When mesitylglyoxylic acid is heated, it is decomposed into trimethylbenzaldehyde and trimethylbenzoic acid, the *methyl* salt of which crystallises in colourless plates melting at 139—140°.

Trimethylbenzaldehyde, $C_6H_2Me_3{\cdot}CHO$, is an oil, boils at 235—240°, and gradually oxidises on exposure to the air; its *oxime*,

$$C_6H_2Me_3{\cdot}CH{:}NOH,$$

crystallises in small needles, melts at 127°, and dissolves freely in alcohol, ether, and alkalis; its *hydrazone*, $C_6H_2Me_3{\cdot}CH{:}N_2HPh$, separates from dilute alcohol in colourless crystals, and is very unstable.

Mesitylglycollic acid, $C_6H_2Me_3{\cdot}CH(OH){\cdot}COOH$, prepared by reducing mesitylglyoxylic acid with sodium amalgam in alkaline solution, crystallises from water in large, well-defined, transparent plates, melts at 147°, and is readily soluble in alcohol and ether, but only sparingly in cold water. The *silver* salt, $C_{11}H_{13}O_3Ag$, is amorphous. The *methyl* salt, $C_{12}H_{16}O_3$, prepared from the silver salt, separates from light petroleum in colourless, nodular crystals, and melts at 92°. The *chloralide*, $C_6H_2Me_3{\cdot}CH{<}\overset{O\text{——}}{CO{\cdot}O}{>}CH{\cdot}CCl_3$, is formed when the acid is heated at 120—130° for two days with anhydrous chloral; it crystallises from light petroleum in well-defined plates, melts at 125°, and is readily soluble in benzene, chloroform, and ether, but more sparingly in alcohol.

F. S. K.

Thiocoumarin and its Analogues. By F. Aldringen (*Ber.*, **24**, 3459—3466).—Tiemann has shown (Abstr., 1886, 880) that thiocoumarin is formed when coumarin is fused with phosphorus pentasulphide. The object of the present work was to examine the behaviour of certain homologues of coumarin and of some other δ-lactones.

α-Methylthiocoumarin, $C_6H_4{<}\overset{CH{:}\dot{C}Me}{O\text{—}CS}$, is prepared by heating

α-methyl-coumarin (m. p. 90°) with phosphorus pentasulphide, boiling the melt with benzene, crystallising from absolute alcohol, and washing the crystals with carbon bisulphide; it forms yellow needles, melts at 122°, sublimes without decomposition, and is insoluble in water and light petroleum, but readily soluble in alcohol, ether, and benzene; it yields α-methylcoumarin on boiling with alcoholic potash.

α-Methylcoumaroxime, $C_6H_4<\begin{matrix}CH:CMe\\ |\\ O—C:NOH\end{matrix}$, is formed when the α-methylthiocoumarin is boiled with hydroxylamine in alcoholic solution; it crystallises from water or dilute alcohol in colourless needles, and melts at 166°. Ferric chloride does not give a coloration as with coumaroxime (see Tiemann, *loc. cit.*), and the same is true of the homologous compounds to be described; they are also without action on Fehling's solution. It dissolves in alkalis and acids, is stable towards the former, but yields α-methylcoumarin when boiled with concentrated hydrochloric acid; the *acetyl derivative*,

$$C_6H_4<\begin{matrix}CH:CMe\\ |\\ O—N\cdot OAc,\end{matrix}$$

obtained by dissolving the oxime in an excess of warm acetic chloride, melts at 56°. The *hydrazone*, $C_6H_4<\begin{matrix}CH:CMe\\ |\\ O—C:N_2HPh,\end{matrix}$ is produced by boiling α-methylthiocoumarin with phenylhydrazine in alcoholic solution for about a week; it crystallises from alcohol in yellow needles, melts at 116°, is insoluble in water, and dissolves in concentrated sulphuric acid with an intense green colour.

The following derivatives of α-ethylcoumarin (m. p. 71°) were prepared in a similar manner to the methyl compounds:—*α-Ethylthiocoumarin* forms small, yellowish-red plates, and melts at 93—94°; *α-ethylcoumaroxime* crystallises in long, white needles, melts at 157°, and yields an *acetyl derivative* melting at 61°; whilst *α-ethylcoumarophenylhydrazone* melts at 115°.

Derivatives of α-Isopropylcoumarin (m. p. 54°).—*α-Isopropylthiocoumarin* forms reddish-yellow needles, and melts at 81°; *α-isopropylthiocoumaroxime* crystallises in white prisms, melts at 171°, and yields an *acetyl derivative* melting at 85°; whilst *α-isopropylcoumarophenylhydrazone* melts at 112°.

Derivatives of Methylumbelliferone (m. p. 114°).—Umbelliferone is not readily converted into the thio-derivative by fusion with phosphorus pentasulphide, whereas the methyl derivative exhibits the same behaviour as coumarin.

Methylthioumbelliferone, $OMe\cdot C_6H_2<\begin{matrix}CH:CH\\ |\\ O—CS\end{matrix}$ (OMe at 4, CH:CH at 1, O—CS at 2), forms yellow needles, melts at 114°, and dissolves in boiling alkalis with decomposition. *Methylumbelliferonoxime* crystallises from water in long, felted needles, melts at 138°, and gives a brownish-red colour with ferric chloride. *Methylumbelliferonephenylhydrazone* is obtained by boiling for a fortnight a mixture of methylthioumbelliferone with phenylhydrazine in molecular proportion, dissolved in alcohol; it crystallises

from alcohol in thick, yellow needles, melts at 115°, and dissolves in concentrated sulphuric with a bluish-green colour. A. R. L.

Action of Ammonia and Aniline on Negatively-substituted Halogen-benzenesulphonic Acids. By P. Fischer (*Ber.*, **24**, 3785—3808).—It was found that in the case of the two chloronitrobenzenesulphonic acids $NO_2{\cdot}C_6H_3Cl{\cdot}SO_3H$ [$Cl : NO_2 : SO_3H = 1 : 2 : 4$ and $1 : 4 : 2$ respectively], the two bromosulphobenzoic acids $COOH{\cdot}C_6H_3Br{\cdot}SO_3H$ [$Br : COOH : SO_3H = 1 : 2 : 4$ and $1 : 4 : 2$ respectively], and bromobenzenedisulphonic acid, $C_6H_3Br(SO_3H)_2$ [$Br : (SO_3H)_2 = 1 : 2 : 4$], the action of ammonia or aniline is to displace the halogen by the amido- or anilido-group. In all of these acids a para- and an ortho-position, relatively to the halogen atom, are occupied by negative groups.

Metanitroparamidobenzenesulphonic acid, $NH_2{\cdot}C_6H_3(NO_2){\cdot}SO_3H$ [$1 : 2 : 4$], is obtained as the ammonium salt by heating metanitroparachlorobenzenesulphonic acid with alcoholic ammonia at 120—140°. The *barium salt*, $(C_6H_5N_2SO_5)_2Ba + 2\frac{1}{2}H_2O$, forms yellow crystals; the acid itself forms an amorphous, yellow precipitate. When heated with concentrated hydrochloric acid at 150°, the sulphonic group is removed, and orthonitraniline is formed; this proves that the NO_2 group and the chlorine atom in the original nitrochlorosulphonic acid occupy the ortho-positions relatively to each other. *Paramidometanitrobenzenesulphonamide*, $NH_2{\cdot}C_6H_3(NO_2){\cdot}SO_2{\cdot}NH_2$ [$1 : 2 : 4$], is obtained by heating parachlorometanitrobenzenesulphonamide with alcoholic ammonia at 120°. It crystallises from alcohol or water in deep yellow needles or lustrous, golden plates, melts at 206—207°, and is such a feeble base that it forms no salts with acids.

Metanitro-orthamidobenzenesulphonic acid [$NH_2 : NO_2 : SO_3H = 1 : 4 : 2$] was obtained in the same way as the isomeric acid. The barium salt, $(C_6H_5N_2SO_5)_2Ba + H_2O$, forms yellow crystals. The acid itself crystallises from water in small, yellow crystals, and yields paraphenylenediaminesulphonic acid, $C_6H_3(NH_2)_2{\cdot}SO_3H$, on reduction by Claisen's method. Its *sulphonamide* forms yellow needles or plates melting at 210°.

With parachlorometanitrobenzenesulphonic acid, aniline yields an *aniline salt*, $NO_2{\cdot}C_6H_3Cl{\cdot}SO_3{\cdot}NH_3Ph$ [$= 2 : 1 : 4$], in lustrous, white crystals. This, when heated with excess of aniline, yields the *aniline salt* of *metanitroparanilidobenzenesulphonic acid*,

$$NO_2{\cdot}C_6H_3(NHPh){\cdot}SO_3{\cdot}NH_3Ph\ [= 2 : 1 : 4],$$

which forms large groups of yellowish-brown needles, and dissolves in alcohol, acetic acid, acetone, and hot water, but not in ether or benzene. The *barium salt*, $(C_{12}H_9N_2SO_5)_2Ba + H_2O$, forms lustrous, dark golden plates. The acid forms orange-coloured crystals, decomposing at 200° without melting, and dissolves readily in water, alcohol, acetic acid, and acetone, but not in benzene and ether. The *alkali salts*, $C_{12}H_9N_2SO_5Na + H_2O$, &c., are orange-yellow, but at 110° lose water and become brick-red; the anhydrous salts, however, take up water from the air, becoming again orange-yellow. The *ammonium salt*,

$$C_{12}H_9N_2SO_5{\cdot}NH_4 + \tfrac{1}{2}H_2O,$$

forms lustrous, yellow plates. By the action of phosphorus pentachloride on the acid, the *sulphochloride* is obtained; it crystallises from ether in yellowish-brown needles, and with ammonium carbonate yields the *sulphonamide*, as lustrous, red crystals melting at 162°. The *sulphanilide* is best obtained by the action of aniline on the chloronitrobenzenesulphonic chloride; it forms long, orange-yellow needles, melts at 157°, and dissolves readily in alcohol, acetone, and acetic acid.

Paranilidometamidobenzenesulphonic acid, $NHPh\cdot C_6H_3(NH_2)\cdot SO_3H$ [=1 : 2 : 4], is prepared by reducing the barium salt of the corresponding anilidonitro-acid by Claisen's method; it forms a crystalline precipitate, which darkens in the air and gives a violet-red colour with ferric chloride. The *barium salt*, $(C_{12}H_{11}N_2SO_6)_2Ba + 2H_2O$, forms tiny, brownish needles. The *sulphanilide*, prepared by reducing the corresponding nitrosulphanilide with alcoholic ammonium sulphide, forms colourless, lustrous needles melting at 157°, and giving a deep violet colour with concentrated sulphuric acid. The *hydrochloride* forms white needles melting at 181—182° with decomposition. Metanitroparanilidobenzenesulphonic acid yields orthodinitrodiphenylamine when heated at 130—140° with concentrated hydrochloric acid. By adding potassium nitrite to an acetic acid solution of this base, *orthonitrodiphenylnitrosamine*, $NO_2\cdot C_6H_4\cdot NPh\cdot NO$, is obtained. It forms nearly colourless plates melting at 99—100°; it does not give Liebermann's nitrosamine reaction with phenol and sulphuric acid, but yields a deep violet, and not a deep blue, colour.

Orthochlorometanitrobenzenesulphonic acid yields, with aniline, the *aniline salt*, which forms long, lustrous, white needles, decomposing above 200° without melting. When heated with aniline, this yields *metanitro-orthanilidobenzenesulphonic acid*, as the *aniline salt*, in large, brown needles with a violet lustre; it dissolves in water, alcohol, and acetone, but not in ether or benzene. The *barium salt*,

$$(C_{12}H_9N_2SO_5)_2Ba + 5H_2O,$$

forms lustrous, orange needles. The *acid* itself crystallises in small, lustrous, olive-green plates. The *potassium salt* forms anhydrous, orange needles, and with phosphorus pentachloride yields the *sulphonic chloride*, as greenish-yellow needles melting at 102—104° and readily soluble in ether, benzene, and chloroform. With ammonium carbonate, it yields the *sulphonamide*, which separates from alcohol in reddish-yellow crystals melting at 173°, and insoluble in water. The *sulphanilide* was obtained from aniline and the chloronitrosulphonic chloride; it crystallises from alcohol in lustrous, greenish-yellow needles melting at 164°. *Orthanilidometamidobenzenesulphonic acid*, $NHPh\cdot C_6H_3(NH_2)\cdot SO_3H$ [= 1 : 4 : 2], is obtained as the *barium salt*, $(C_{12}H_{11}N_2SO_3)_2Ba + H_2O$ (lustrous, silver-grey plates), by reducing the barium salt of the corresponding nitro-acid by Claisen's method. It yields highly-coloured oxidation products; for example, with ferric chloride, it gives a red colour passing into violet. The acid forms dark-coloured plates. The *sulphanilide*, obtained by reducing the corresponding nitrosulphanilide with alcoholic ammonium sulphide at 120—130°, forms lustrous plates melting at 171°, and gives a violet colour with strong sulphuric acid. Its *hydrochloride* blackens at 200°,

and melts with decomposition at 215°, and gives an olive-green colour with ferric chloride.

Paramidometasulphobenzoic acid,

$$NH_2{\cdot}C_6H_3(SO_3H){\cdot}COOH\ [1:2:4],$$

is obtained as the diammonium salt by heating the corresponding bromosulphobenzoic acid with alcoholic ammonia at 160°–180°. The *barium salt*, $C_7H_5NSO_5Ba + 2H_2O$, forms large, colourless crystals, the *potassium salt* anhydrous, transparent needles. The acid itself crystallises from water in slender needles. Parabromometasulphobenzoic acid yields with aniline the *aniline salt*, which crystallises from water in long, lustrous, white needles, decomposing above 200° without melting, and when heated with aniline yields the *aniline salt* of *paranilidometasulphobenzoic acid*, $NHPh{\cdot}C_6H_3(SO_3H){\cdot}COO{\cdot}NH_3Ph$. The *barium salt*, $C_{13}H_9NSO_5Ba + 3\frac{1}{2}H_2O$, with sulphuric acid, yields the free acid as small, lustrous, nearly colourless plates.

Orthobromometasulphobenzoic acid, $SO_3H{\cdot}C_6H_3Br{\cdot}COOH\ [4:1:2]$, was prepared by treating orthobromobenzoic acid (obtained by oxidising orthobromotoluene) with fuming sulphuric acid. When heated with alcoholic ammonia at 160—180°, it yields the ammonium salt of the *amido-acid*. The *barium salt*, $C_7H_5NSO_5Ba + 2\frac{1}{2}H_2O$, forms colourless crystals. With aniline, the bromo-acid yields an *aniline salt*, and this, when heated with aniline in glycerol solution, yields the *aniline salt* of *orthanilidometasulphobenzoic acid*,

$$NHPh{\cdot}C_6H_3(SO_3H){\cdot}COO{\cdot}NH_3Ph\ [1:4:2],$$

in brownish plates. The *barium salt*, $C_{13}H_9NSO_5Ba + 5H_2O$, forms lustrous, yellowish plates. The acid crystallises from water in fine needles which decompose without melting.

Amidobenzenemetadisulphonic acid (*disulphanilic acid*),

$$NH_2{\cdot}C_6H_3(SO_3H)_2\ [1:2:4],$$

was obtained as the neutral ammonium salt by heating the corresponding bromodisulphonic acid with alcoholic ammonia at 160—180°. The *amidodisulphonamide*, $NH_2{\cdot}C_6H_3(SO_2{\cdot}NH_2)_2\ [1:2:4]$, was obtained from ammonia and the bromodisulphonamide. It crystallises from water in lustrous, white plates melting at 235°. The bromodisulphonic acid yields with aniline the *dianiline salt*, which forms transparent, colourless plates soluble in water and glycerol, but not in alcohol. When heated with aniline in glycerol solution, it yields *anilidobenzenemetadisulphonic acid* (*diphenylamineorthoparadisulphonic acid*), which is very soluble in water, and could not be obtained crystalline. The *barium salt*, $C_{12}H_9NS_2O_6Ba + 3H_2O$, is a yellowish, amorphous substance. The *disulphanilide* is best obtained by heating the corresponding bromobenzenedisulphonic chloride with aniline. It forms large, yellowish crystals melting at 221—222°, and dissolves readily in alcohol, less readily in acetic acid, sparingly in glycerol, and not at all in water. C. F. B.

Acetoximes. By H. Wege (*Ber.*, **24**, 3537—3540).—The acetyl and the isobutyl derivatives of acetoxime were prepared from the oxime by Hinsberg's method (Abstr., 1891, 49); they are both oils.

Acetoximephenylsulphone, $CMe_2{:}N{\cdot}O{\cdot}SO_2Ph$, is easily obtained by shaking a concentrated aqueous solution of acetoxime with soda and phenylsulphonic chloride; it crystallises from a mixture of ether and light petroleum in long, colourless needles, melts at 52·5°, and explodes at 128°, with formation of phenylsulphonic acid, ammonia, and small quantities of nitrogen.

Acetoximeparatolylsulphone, $CMe_2{:}N{\cdot}O{\cdot}SO_2{\cdot}C_6H_4Me$, prepared in like manner, crystallises from dilute alcohol in colourless scales, melts at 89°, and decomposes at 135° with a slight explosion. The corresponding *β-naphthyl* derivative, $C_{13}H_{13}NO_3S$, crystallises from alcohol in colourless or reddish plates melting at 87°.

When camphoroxime is shaken with soda and phenylsulphonic chloride, it seems to be converted into campholenonitrile. Benzophenoneoxime, under the same conditions, is converted into benzanilide; a similar intramolecular change also takes place when the chlorides of paratoluenesulphonic acid and naphthalenesulphonic acid are employed in the place of phenylsulphonic chloride.

F. S. K.

Action of Sulphonic Chlorides on Orthamidobenzamide. By E. Franke (*J. pr. Chem.* [2], **44**, 417—432; compare Abstr., 1887, 1043, 1044; 1890, 1289).—Benzenesulphoneorthamidobenzamide (Abstr., 1890, 1289) is insoluble in cold water and light petroleum, but dissolves in alcohol; it does not yield an anhydride when heated with water.

Ethyl benzenesulphoneorthamidobenzoate, $COOEt{\cdot}C_6H_4{\cdot}NH{\cdot}SO_2Ph$, obtained by the action of ethyl orthamidobenzoate (Abstr., 1885, 665) on benzenesulphonic chloride, crystallises from aqueous alcohol in white, quadratic prisms, melts at 92·5°, and dissolves easily in absolute alcohol, but not in water. When heated with aqueous ammonia at 140° for seven hours, or with alcoholic ammonia at 160° for 12 hours, it is converted into benzenesulphoneorthamidobenzamide; with alcoholic methylamine at 140°, it yields benzenesulphoneorthamidobenzomethylamide (see below).

The *potassium* and *silver* compounds of benzenesulphoneorthamidobenzamide are described, and the precipitates which the base gives with several of the salts of the heavy metals are detailed; the metals displace 1 atom of hydrogen from a molecule of the amide. The author retracts his former statements as to the obtaining of a hydrochloride and methyl derivative melting at 116° from benzenesulphoneorthamidobenzamide (Abstr., 1890, 1289).

The author did not succeed a second time in obtaining an anhydride by acting on benzenesulphoneorthamidobenzamide with phosphoric anhydride, or by dissolving it in dilute sodium hydroxide solution and precipitating by hydrochloric acid, or by heating it in alcohol at 210° (Abstr., 1890, 1289). *Anhydrobenzenesulphoneorthamidobenzamide*, $C_6H_4{<}\begin{matrix}CO{\cdot}NH\\ |\\ N:SOPh\end{matrix}$, is, however, readily obtained by heating a mixture of benzenesulphoneorthamidobenzamide and phosphoric chloride in molecular proportion, first at 60—70°, and finally at 175°; the mass is afterwards extracted with benzene, the solution precipitated

with water, and the compound recrystallised from dilute alcohol. It crystallises in pale yellow needles, melts at 145°, is very soluble in alcohol and hot benzene, less so in chloroform, ether, and water; it also dissolves in alkalis, and is precipitated unchanged by acids. When heated with concentrated hydrochloric acid, it is decomposed. Its *sodium*, *silver*, and *potassium* compounds were prepared.

Benzenesulphoneorthamidobenzomethylamide,

$$NHMe\cdot CO\cdot C_6H_4\cdot NH\cdot SO_2Ph,$$

is obtained as described above, or by heating anhydrobenzenesulphoneorthamidobenzamide with potassium hydroxide and methyl iodide in alcohol in a sealed tube at 120°, or by bringing together orthamidobenzomethylamide and benzenesulphonic chloride in molecular proportion. It crystallises from aqueous alcohol in white needles, melts at 114°, and is insoluble in cold water and light petroleum, but easily soluble in hot benzene, ether, and alcohol.

Benzenesulphoneorthomethamidobenzamide,

$$NH_2\cdot CO\cdot C_6H_4\cdot NMe\cdot SO_2Ph,$$

is prepared by heating molecular proportions of orthomethamidobenzamide (Abstr., 1887, 1044) and benzenesulphonic chloride together on the water-bath; the new compound is extracted from the product by very dilute alcohol, and recrystallised from hot benzene. It forms beautiful, rhombic laminæ, melts at 154° (uncorr.), and dissolves readily in warm alcohol and in warm, dilute alkalis; it is precipitated unchanged from the alkaline solutions on the addition of an acid.

Benzenesulphoneorthamidobenzophenylamide,

$$NHPh\cdot CO\cdot C_6H_4\cdot NH\cdot SO_2Ph,$$

prepared from benzenesulphonic chloride and orthamidobenzophenylamide, crystallises in needles which melt at 144—144·5°. *Benzenesulphoneorthamidobenzoylphenylhydrazine*, $N_2H_2Ph\cdot CO\cdot C_6H_4\cdot NH\cdot SO_2Ph$, was obtained by heating benzenesulphonic chloride and orthamidobenzoylphenylhydrazine together at 130—140°; the dirty-white needles which crystallised from water melted at 140—142°, but the yield was very small, and further investigation is needed.

Methylsulphoneorthamidobenzamide, $NH_2\cdot CO\cdot C_6H_4\cdot NH\cdot SO_2Me$, is obtained by the action of methylsulphonic chloride (b. p. 160—161°) on orthamidobenzamide; it crystallises from hot, dilute alcohol in almost white, very slender prisms, which melt at 156—157°; an anhydro-derivative could not be prepared.

When sulphuryl chloride and orthamidobenzamide react, dichloranthranilamide, $NH_2\cdot CO\cdot C_6H_2Cl_2\cdot NH_2$, is produced; this crystallises in dirty-yellow needles, and melts at 175—176°; on hydrolysis, it yields Dorsch's dichloranthranilic acid melting at 223—225° (Abstr., 1886, 360). Dorsch, however, gives the melting point of the amide corresponding with his acid as 284°. A. G. B.

Displacement of Halogen Atoms in the Benzene Ring. By M. Schöpff (*Ber.*, **24**, 3771—3784; compare Abstr., 1891, 304).—The general result of this research may be expressed thus:—If in

the benzene ring in which the halogen atom is contained there are also two negative groups, like or unlike, in the ortho- and para-positions relatively to this atom, then other groups, such as ·NH, ·NHR, and ·OH, can easily be substituted for the halogen; but if only one negative group is present, no such replacement occurs, except when this one group is ·NO_2. The negative groups may be ·NO_2, ·SO_3H, ·COOH, ·CO·R, or ·COH.

Parabromometanitrobenzophenone, $NO_2 \cdot C_6H_3Br \cdot COPh$ [Br : NO_2 : CO = 4 : 3 : 1], is obtained by heating benzene with parabromometanitrobenzoic chloride in the presence of aluminium chloride. It forms white plates melting at 112—113°, and dissolves easily in benzene, acetone, chloroform, ether, and acetic acid, less easily in light petroleum. When heated with alcoholic ammonia at 130°, it yields *paramidometanitrobenzophenone*, $NH_2 \cdot C_6H_3(NO_2) \cdot COPh$, as small, yellow needles melting at 135°, and dissolving very readily in water. With alcoholic ethylamine, it yields *parethylamidometanitrobenzophenone*, $NHEt \cdot C_6H_3(NO_2) \cdot COPh$, as yellow needles melting at 99—100°, and with aniline, *paranilidometanitrobenzophenone*,

$$NPHh \cdot C_6H_3(NO_2) \cdot COPh,$$

as orange-coloured needles melting at 157°.

Diparabromometanitrobenzophenone,

$$NO_2 \cdot C_6H_3Br \cdot CO \cdot C_6H_4Br \text{ [Br : } NO_2 \text{ : CO = 4 : 3 : 1 and CO : Br = 1 : 4]},$$

is obtained by warming parabromometanitrobenzoic chloride and bromobenzene with aluminium chloride in carbon bisulphide. It forms needles melting at 118°, and has the same solubility as the monobromo-compound. With alcoholic ammonia at 130°, it yields *paramidometanitroparabromobenzophenone*, $NH_2 \cdot C_6H_3(NO_2) \cdot CO \cdot C_6H_4Br$, as a yellow substance melting at 171°. The corresponding *anilido-derivative*, $NHPh \cdot C_6H_3(NO_2) \cdot CO \cdot C_6H_4Br$, forms yellow needles melting at 180°.

Diparabromodimetanitrobenzophenone,

$$CO(C_6H_3Br \cdot NO_2)_2 \text{ [Br : } (NO_2) \text{ : CO = 4 : 3 : 1]},$$

is obtained by treating either diparabromobenzophenone or diparabromometanitrobenzophenone with fuming nitric acid. It forms needles melting at 152—153°. With aniline, it yields *diparanilidodimetanitrobenzophenone*, $CO[C_6H_3(NO_2) \cdot NHPh]_2$, melting at 219°.

Orthobromometanitrobenzophenone, $NO_2 \cdot C_6H_3Br \cdot COPh$, melting at 115°, was prepared in a similar manner to the isomeric parabromo-compound, and resembles the latter in its chemical behaviour; with aniline, it yields *orthanilidometanitrobenzophenone* in lemon-coloured needles melting at 135°.

Parabromometanitrobenzaldehyde, $NO_2 \cdot C_6H_3Br \cdot CHO$ [Br : NO_2 : CO = 4 : 3 : 1] (the *aldoxime* of which, $NO_2 \cdot C_6H_3Br \cdot CH{:}NOH$, forms yellow needles melting at 145—146°, and dissolves readily in alcohol, less readily in water), when boiled with aqueous soda, yields *parahydroxymetanitrobenzaldehyde*, $OH \cdot C_6H_3(NO_2) \cdot CHO$, which crystallises from water in yellowish-brown needles melting at 139—140·5°. The *hydrazone*, $OH \cdot C_6H_3(NO_2) \cdot CH{:}N_2HPh$, crystallises from alcohol in small,

dark-red needles melting at 175—176°. The aldehyde is identical with the substance obtained by nitrating parahydroxybenzaldehyde.

When asymmetrical bromoxylene, $C_6H_3Me_2Br$ [Br : Me_2 = 1 : 2 : 4], is boiled with aqueous potassium permanganate, it is oxidised to *asymmetrical bromisophthalic acid*, $C_6H_3Br(COOH)_2$, but a little asymmetrical hydroxyisophthalic acid, $OH{\cdot}C_6H_3(COOH)_2$, is also formed. To separate these, they are converted into their ethereal salts, of which that of the hydroxy-acid may be removed by dissolving it in dilute aqueous soda, which does not dissolve the other salt. *Asymmetrical ethyl bromisophthalate*, $C_6H_3Br(COOEt)_2$, is thus obtained pure; it is a colourless oil with an odour like that of rum; it boils at 320—325° under 365 mm. pressure, and, when treated with concentrated hydrochloric acid, yields *asymmetrical bromisophthalic acid*, $C_6H_3Br(COOH)_2$ [Br : $(COOH)_2$ = 1 : 2 : 4]. This forms white needles melting at 283°, and subliming without decomposition; it dissolves readily in alcohol, sparingly in water. It is identical with the acid obtained by oxidising α- and β-bromocymene with nitric acid. The *ammonium salt* forms fine, colourless, asymmetric crystals ($a : b : c$ = 1·5030 : 1 : 0·9753; β = 70°) which decompose at 100°. The *barium salt* is white; the *copper* and *silver salts* form respectively light-blue and white precipitates. The acid may also, although less conveniently, be obtained by saponifying *parabromometacyanobenzoic acid*, $CN{\cdot}C_6H_3Br{\cdot}COOH$, with concentrated hydrochloric acid. This acid is obtained from parabromometamidobenzoic acid by the action of sodium nitrite on an aqueous solution in the presence of copper cyanide. It forms white needles melting at 186°, and subliming without decomposition. It dissolves readily in hot water and alcohol; the copper and lead salts form respectively light-green and yellowish-brown precipitates. Asymmetrical bromisophthalic acid yields the corresponding hydroxy-acid with alkalis or alkaline carbonates, and with ammonia the corresponding amido-acid.

Parabromometasulphobenzaldehyde,

$$SO_3H{\cdot}C_6H_3Br{\cdot}CHO\ [Br : SO_3H : COH = 4 : 3 : 1],$$

is obtained as the *barium salt*, $(C_7H_4BrSO_4)_2Ba + 5H_2O$, by heating parabromobenzaldehyde with fuming sulphuric acid at 150°, and saturating with barium carbonate. It does not lose all its water until heated to 220°. When boiled with aqueous sodium carbonate, it yields the sodium salt of parahydroxymetasulphobenzaldehyde, $SO_3Na{\cdot}C_6H_3(ONa){\cdot}CHO$. C. F. B.

Friedel-Crafts' Synthesis. By M. Schöpff (*Ber.*, **24**, 3766—3770).—When haloïd derivatives of benzene are treated with acetic or benzoic chloride in the presence of aluminium chloride, the acetyl or benzoyl group takes the para-position relatively to the halogen, forming respectively parabromacetophenone, $C_6H_4Br{\cdot}COMe$ (the *hydrazone* of which, $C_6H_4Br{\cdot}CMe{:}N_2HPh$, forms yellowish plates melting at 126°), and parachlorobenzophenone, $C_6H_4Cl{\cdot}COPh$. If the para-position is already occupied, no reaction occurs, as in the case of paradibromo- and paradiiodo-benzene, and of 1 : 4-dibromonaphthalene.

With parabromobenzoic chloride and bromobenzene, the reaction takes place much less easily, and besides diparabromobenzophenone (the hydrazone of which, $C(C_6H_4Br)_2{:}N_2HPh$, forms yellow plates melting at 138°), some monobromobenzophenone is also formed.

The homologues of the halogen benzenes react, although less easily than these, if the para-position to the halogen is still unsubstituted; in the opposite case, no reaction takes place, as, for example, with parabromotoluene and unsymmetrical bromometaxylene, $C_6H_3BrMe_2$ [Br : Me_2 = 1 : 2 : 4]. Orthobromotoluene and acetic chloride yield *parabromometatoluyl methyl ketone*,

$$C_6H_3BrMe{\cdot}COMe \text{ [Br : Me : COMe} = 4 : 3 : 1],$$

as a yellowish oil with a feeble-greenish fluorescence boiling at 269—272°; when oxidised with permanganate, it yields parabromometatoluic acid. Bromoparaxylene and acetic chloride yield a small quantity of *bromoparaxylyl methyl ketone*, $C_6H_2BrMe_2{\cdot}COMe$ [Br : Me_2 : COMe = 4 : 3 : 6 : 1], which melts at 39°. C. F. B.

Deoxybenzoïns. By H. Wege (*Ber.*, **24**, 3540—3542).—*Benzyl orthoxylyl ketone*, $CH_2Ph{\cdot}CO{\cdot}C_6H_3Me_2$, prepared by Friedel and Crafts' method from orthoxylene and phenylacetic chloride, crystallises in yellow plates, melts at 95°, and boils at 210—220° under a pressure of 25 mm.; it is soluble in alcohol, ether, and light petroleum, and its *oxime* crystallises from light petroleum in lustrous, colourless needles. The *benzyl* derivative, $CH_2Ph{\cdot}CHPh{\cdot}CO{\cdot}C_6H_3Me_2$, obtained by boiling the ketone with an alcoholic solution of benzyl chloride and sodium ethoxide, crystallises from light petroleum in lustrous needles melting at 75°. The *isobutyl* derivative, $C_4H_9{\cdot}CHPh{\cdot}CO{\cdot}C_6H_3Me_2$, forms colourless or yellowish crystals, and melts at 91·5°.

Benzyl metaxylyl ketone is a thick, yellow oil, boils at 206—208° under a pressure of 22 mm., and is readily soluble in ether, but more sparingly in alcohol; its *benzyl* derivative boils at 365—375°.

Benzyl paraxylyl ketone boils at 220—230° under a pressure of 26 mm.; its *oxime*, $C_{16}H_{17}NO$, melts at 99°, its *hydrazone* at 96°, and its *benzyl* derivative at 60·5°. F. S. K.

Stereochemical Isomerism of Nitrogen Compounds. By A. Hantzsch and F. Kraft (*Ber.*, **24**, 3511—3528).—The authors have prepared a number of compounds, other than oximes, having the general formula $\frac{X}{Y}{>}C{:}NZ$, with the object of ascertaining whether such substances are capable of existing in stereochemically isomeric forms; if such were the case, there would be strong grounds for thinking that Auwers and Meyer's explanation of the isomerism of oximes is incorrect, because their hypothesis is based on the supposition that this isomerism is due to the peculiar constitution of hydroxylamine.

Paramethoxybenzhydrylamine, $NH_2{\cdot}CHPh{\cdot}C_6H_4{\cdot}OMe$, is obtained when either of the stereochemically isomeric paramethoxybenzophenoneoximes is reduced with sodium amalgam in the cold; it is a thick, optically-inactive oil, yields a sparingly soluble crystalline

hydrochloride melting at 191°, and a crystalline *acetyl* derivative which melts at 159°. The formation of a base isomeric with the above was not observed.

Imidobenzophenone hydrochloride, $CPh_2{:}NH,HCl$, is formed when benzophenone chloride (1 mol.) is heated with ethyl amidoformate (3 mols.) at about 130° until the evolution of hydrogen chloride ceases; it is a colourless, crystalline powder, sublimes when heated, and is insoluble in ether and benzene, and only moderately easily soluble in chloroform; it is quickly decomposed by cold water, yielding benzophenone and ammonium chloride. *Imidobenzophenone*, prepared by passing anhydrous ammonia into a chloroform solution of the hydrochloride, is a colourless oil, and is decomposed by water.

Paramethoxybenzophenone chloride, $CPhCl_2{\cdot}C_6H_4{\cdot}OMe$, can be obtained by warming paramethoxybenzophenone with slightly more than the theoretical quantity of phosphorus pentachloride. It crystallises in colourless plates, melts at 54°, and is readily soluble in benzene, chloroform, and ether; it is decomposed by warm water and by alcohol into hydrochloric acid and paramethoxybenzophenone.

Paramethoxybenzophenoneparachloraniline,

$$OMe{\cdot}C_6H_4{\cdot}CPh{:}N{\cdot}C_6H_4Cl,$$

is formed when the preceding compound (1 mol.) is warmed with parachloraniline (3 mols.) in chloroform solution. It crystallises in yellow plates, melts at 104°, and is readily soluble in benzene, ether, and chloroform, but more sparingly in alcohol; it is quickly decomposed into its components by hot dilute acids, but is not acted on by boiling water. All attempts to obtain an isomeride of this compound were unsuccessful.

Paramethoxybenzophenoneparatoluidine, $OMe{\cdot}C_6H_4{\cdot}CPh{:}N{\cdot}C_6H_4Me$, prepared in like manner, separates from chloroform in yellow crystals, melts at 96°, and resembles the preceding compound in its behaviour with acids. The chloroform mother liquors obtained in the preparation of this compound yield, on evaporation, not inconsiderable quantities of an oily product which does not crystallise when kept at 0°; it is possible that this oil contains an isomeride of the crystalline product (m. p. 96°).

Paramethoxybenzophenone-β-naphthylamine, $OMe{\cdot}C_6H_4{\cdot}CPh{:}N{\cdot}C_{10}H_7$, prepared from paramethoxybenzophenone chloride and β-naphthylamine, is a crystalline compound melting at 132°, but the products obtained in like manner from benzylamine and from paramidophenol are oils, as is also the condensation product of paratolyl phenyl ketone chloride with paratoluidine.

An additive product of the composition $OH{\cdot}CHPh{\cdot}NH{\cdot}C_6H_4{\cdot}COOH$ is obtained, together with the condensation product immediately described below, when metamidobenzoic acid is shaken with water and benzaldehyde; it separates from ether in crystals, is readily soluble in chloroform, and is decomposed by warm dilute hydrochloric acid. The condensation product $CHPh{:}N{\cdot}C_6H_4{\cdot}COOH$ is gradually deposited from the mother liquors of the preceding compound; it is a yellowish, microcrystalline powder melting at 119°; the formation of an isomeride of this condensation product was not observed.

Benzophenoneparamidobenzoic acid, $CPh_2{:}N{\cdot}C_6H_4{\cdot}COOH$, prepared by heating benzophenone chloride with paramidobenzoic acid in chloroform solution, crystallises from chloroform in yellow prisms, melts at 240°, and is only sparingly soluble in ether, benzene, and cold alcohol, but moderately easily in hot alcohol, and very readily in chloroform; it is slowly decomposed by cold alcohol, and quickly by boiling dilute acids, yielding benzophenone and the amido-acid.

Paramethoxybenzophenoneparamidobenzoic acid, $C_{21}H_{17}NO_3$, is formed when paramethoxybenzophenone chloride is treated with paramidobenzoic acid in chloroform or toluene solution; it crystallises in yellow plates or microscopic needles, melts at 216°, and resembles the preceding compound in its behaviour with solvents and with dilute acids. The chloroform mother liquors from this compound contain a substance melting at about 164°; this, and the fact that the crude condensation product has no well-defined melting point, whilst that obtained from benzophenone chloride under like conditions melts quite sharply at 240°, lead the authors to conclude that possibly an isomeric paramethoxybenzophenoneparamidobenzoic acid is produced in the above reaction.

Two isomeric *hydrazones* of the composition $C_{20}H_{18}N_2O$, are produced when paramethoxybenzophenone chloride (1 mol.) is gradually added to a chloroform solution of phenylhydrazine (3 mols.); after keeping for some hours, the filtered solution is evaporated at the ordinary temperature, and the two products separated by fractional crystallisation. The one melts at 132°, crystallises from alcohol in small prisms, and is only sparingly soluble in cold alcohol, but moderately easily in ether, and very readily in chloroform and benzene; it is decomposed into its components by concentrated hydrochloric acid. The other hydrazone, which forms at the most only about 10 per cent. of the crude product, is a colourless powder, and melts at 90°; it resembles its isomeride very closely in appearance, and has approximately the same solubilities, except that it is much more readily soluble in ether. The only notable difference in chemical properties is, that the compound of lower melting point is less stable than the other, and resinifies more readily; under certain conditions, the compound of lower melting point seems to be converted into the isomeride. F. S. K.

Formation of Rosaniline. By B. Goldberg (*Ber.*, **24**, 3552—3553).—Bidet's statement (Abstr., 1889, 595) that a mixture of pure (thiophen-free) aniline, orthotoluidine, and paratoluidine only yields traces of rosaniline on heating with arsenic acid is incorrect; the author's experiments have shown that, practically, the same quantity of rosaniline is obtained from the thiophen-free, as from the commercial bases. F. S. K.

New Method of Formation of Desaurins. By V. Meyer and H. Wege (*Ber.*, **24**, 3535—3536).—Desaurin can be easily prepared by mixing deoxybenzoïn (1 mol.) with finely-divided potassium hydroxide (4 mols.), and boiling the mixture with carbon bisulphide (15—20 parts) for 2½ hours; the carbon bisulphide is then distilled, the residue washed with alcohol and ether successively until the

washings are no longer coloured red, and then recrystallised from chloroform or xylene; the yield of the pure product is about 45 per cent. of the deoxybenzoïn employed. F. S. K.

Studies in the Induline Group. By O. Fischer and E. Hepp (*Annalen*, **266**, 249—263; compare Abstr., 1891, 1044).—When phenylinduline is heated at 160—170° for 5—6 hours with glacial acetic acid (5 parts) and 20 per cent. hydrochloric acid (20—30 parts), or dilute (1 : 5) sulphuric acid, it yields aniline, a base of the composition $C_{24}H_{19}N_3O$, benzeneindone, a hydroxy-compound of the composition $C_{18}H_{14}N_2O_2$, and a small quantity of a brownish-red substance; these products are isolated as follows:—The brownish-red solution is filtered from a considerable quantity of a brown, crystalline substance, which consists essentially of the hydrochloride of the base $C_{24}H_{19}N_3O$, but contains also a small quantity of the brownish-red substance; the last-named compound is probably a salt of carbazolefluorindine (*loc. cit.*), judging from the fluorescence of its solutions; it can be easily separated from the other hydrochloride, owing to its insolubility. The acid filtrate is then treated with excess of alkali, the precipitated benzeneindone separated by filtration, the alkaline solution treated with acetic acid, and the precipitated hydroxy-compound extracted by shaking with ether.

The *base* of the composition $C_{24}H_{19}N_3O$, obtained by decomposing the hydrochloride with alcoholic soda, crystallises from hot benzene in small, brown crystals having a steel-blue reflex; it melts at about 218° with evolution of a red vapour, and, when heated more strongly, it is converted into the brownish-red substance referred to above. It dissolves in glacial acetic acid and in dilute mineral acids yielding brownish-red, in concentrated hydrochloric acid and sulphuric acid yielding dirty-violet, solutions; when heated with concentrated hydrochloric acid, it is decomposed into aniline and the hydroxy-compound referred to above, and more fully described below.

The *hydroxy*-compound of the composition $C_{18}H_{14}N_2O_2$ is obtained in reddish-yellow crystals on evaporating its ethereal solution (see above); it crystallises from benzene or alcohol in brownish-yellow prisms or plates, gives off a brownish-red vapour when heated at 230°, and melts at about 280°; it imparts to textile materials a brownish-orange colour. It dissolves in concentrated sulphuric acid with a brownish-yellow coloration; its *hydrochloride* crystallises in thick prisms having a greenish-blue reflex, and is decomposed by water.

Benzeneindone, $C_{18}H_{12}N_2O$, crystallises from alcohol in lustrous, well-defined plates, dissolves in benzene and alcohol with a yellow, in dilute hydrochloric acid with a rose red, and in concentrated sulphuric acid with a green, coloration; when distilled with zinc-dust, it yields phenazine (m. p. 171°) and benzene.

A compound of the composition $C_{18}H_{15}N_3O_2$ is formed, together with a violet base, aniline, and a sparingly soluble, almost black compound, when amidophenylinduline sulphate is heated with dilute sulphuric acid for 4—5 hours at 160—170°; the acid solution is filtered from the sparingly soluble sulphate of the violet base, mixed with soda, again filtered, the filtrate acidified with acetic acid,

and the precipitate recrystallised from 70 per cent. alcohol, from which it separates in small, nodular crystals, or in plates, showing a green reflex. It sinters together at about 230°, and melts completely at 270—280° with evolution of brown vapours; it dissolves in benzene, yielding an orange-red solution which shows a green fluorescence, and its solution in acetic acid is rose-red, that in concentrated sulphuric acid greenish-brown. The *sulphate* crystallises from hot, dilute sulphuric acid in red needles, and is moderately easily soluble in water.

Phenylamidophenylinduline, $C_{30}H_{22}N_4$, is formed, together with much smaller quantities of anilidophenylamidophenylinduline (see below), when amidophenylinduline is heated with aniline (2 parts) at 150—160° for some hours. It crystallises from hot benzene in small nodules or plates having a green reflex, and melts at 245—250°; its solution in benzene is reddish-violet, that in alcohol, blue, and that in concentrated sulphuric acid, greenish-blue. The *hydrochloride*, $C_{30}H_{22}N_4,HCl$, forms lustrous, greenish crystals. This induline can also be obtained by heating an alcoholic solution of phenylamidoazobenzene (136 grams) with aniline (140 grams) and aniline hydrochloride (65 grams) at 150—160° for a day; the yield of the hydrochloride is about 100 grams.

Anilidophenylamidophenylinduline, $C_{36}H_{27}N_5$, is best prepared by heating a mixture of azobenzene (12 parts), aniline (48 parts), aniline hydrochloride (24 parts), and nitrobenzene (12 parts) for eight hours at 170°. It crystallises from boiling xylene in nodules or plates having a green reflex, and melting at 286—288°; it is more sparingly soluble than any other known induline. The *hydrochloride* crystallises in lustrous needles, and dissolves in alcohol with a greenish-blue coloration.

The molecular weight of phenylinduline was determined by Raoult's method in benzene solution; the results were in accordance with those required by a compound of the molecular formula $C_{24}H_{17}N_3$.

F. S. K.

Homologues of Acridine. By A. Volpi (*Gazzetta*, **21**, ii, 228—237).—*Ethylacridine*, $C_6H_4<\overset{CEt}{\underset{N}{|}}>C_6H_4$, is prepared by Bernthsen's method (Abstr., 1884, 1356) by the action of propionic acid on a mixture of diphenylamine and zinc chloride. When pure, it crystallises in lustrous, white plates with a yellowish tinge, melts at 116°, and dissolves freely in alcohol, benzene, and light petroleum, forming solutions with a blue fluorescence; it is only very sparingly soluble in water. The dilute solutions of its salts all have a green fluorescence. The *platinochloride*, $(C_{15}H_{13}N)_2,H_2PtCl_6$, forms minute, yellow crystals, which decompose at 215° without melting. The *aurochloride*, $C_{15}H_{13}N,HAuCl_4$, crystallises in needles melting at 170°. The *hydrochloride*, $C_{15}H_{13}N,HCl$, crystallises in yellow, monoclinic prisms, $a : b = 1{\cdot}5199 : 1$; $\beta = 83° 07'$. It dissolves freely in water, and the solution is brownish-yellow when concentrated, and yellow, with a green fluorescence, when dilute. It is readily soluble in alcohol, and decomposes when heated, without previous melting;

the *sulphate*, $(C_{15}H_{13}N)_2,H_2SO_4$, is pale-yellow in colour, and melts at 210°.

Propylacridine, $C_6H_4<\begin{matrix}CPr\\|\\N\end{matrix}>C_6H_4$, prepared in a manner similar to the previous compound, by the action of butyric acid on a mixture of diphenylamine and zinc chloride, crystallises from alcohol in colourless, monoclinic plates, $a : b : c = 2{\cdot}015 : 1 : 1{\cdot}998$; $\beta = 61° 07'$. It melts at 72—75°, dissolves freely in alcohol, and is almost insoluble in water; its solutions have the characteristic green fluorescence, and in other respects it has the general properties of the acridines. The *hydrochloride*, $C_{16}H_{15}N,HCl$, forms yellow crystals which, when heated, decompose without previously melting; the *sulphate*, $C_{16}H_{15}N,H_2SO_4$, forms greenish-yellow crystals, readily soluble in water and alcohol, but insoluble in ether. It darkens at 245°, and melts at 249°.

Pentadecylacridine, $C_6H_4<\begin{matrix}C(C_{15}H_{31})\\|\\N\end{matrix}>C_6H_4$, is prepared from palmitic acid by the same method as the preceding compounds. It separates from alcohol as a crystalline mass of a buttery consistency, but may be obtained in white or yellowish plates by slowly evaporating the alcoholic solution. It melts at 65°, and dissolves in alcohol, ether, benzene, and light petroleum, but not in water. The alcoholic solution of the base has a blue fluorescence, whilst the alcoholic solutions of its salts have a green fluorescence, and are decomposed by water. The *platinochloride*, $(C_{28}H_{39}N)_2,H_2PtCl_6$, forms minute, orange-yellow crystals melting at 185°. The *hydrochloride*, $C_{28}H_{39}N,HCl$, is a yellow substance which melts at 79°, dissolves in alcohol, and is decomposed by water. The *sulphate*, $C_{28}H_{39}N,H_2SO_4$, crystallises in tufts of yellowish-red needles, melts at 150—151°, and dissolves in alcohol and benzene, but is insoluble in ether, and is decomposed by water; its solutions have a feebly acid reaction.

Stearic acid also yields an acridine by Bernthsen's reaction, so that if the reaction does not apply to the entire series of fatty acids, the limit must lie beyond stearic acid. Acridines may also be prepared from lactic, succinic, and tartaric acids, and will be described by the author in a future paper. S. B. A. A.

Methylcarbazacridine. By D. Bizzarri (*Gazzetta*, **21**, ii, 158—163).—*Methylcarbazacridine*, $\begin{matrix}N—C_6H_3\\|\times|\\MeC—C_6H_3\end{matrix}$, is obtained by a method analogous to that used for the preparation of phenylcarbazacridine (Abstr., 1891, 219). A mixture of carbazole (8 grams), glacial acetic acid (7 grams), and zinc chloride (15 grams) is heated at 150—155° in a sealed tube for eight hours. The bluish-green, pitchy product is extracted with boiling absolute alcohol, the liquid filtered into concentrated ammonia solution, and diluted with water. The bright-red precipitate is collected, washed, dried, and repeatedly extracted with dilute alcohol (47 per cent.); on cooling, the solution deposits a yellowish-white substance, which, after being washed with dilute alcohol, dried, and dissolved in the least possible quantity of

glacial acetic acid, is reprecipitated by ammonia, and finally fractionally crystallised from benzene and alcohol. Minute, colourless, uniaxial rhombohedra are thus obtained, soluble in acetic acid, sparingly so in alcohol, benzene, ether, chloroform, and carbon bisulphide, and insoluble in water and light petroleum. When heated, the substance shrinks at 150°, softens at 175°, melts at 178°, and decomposes at higher temperatures. When its acetic acid solution is treated with zinc-dust, filtered, and the filtrate precipitated with water, a white, crystalline powder is obtained, melting with decomposition at 206°; this dissolves in acetic acid, yielding a colourless solution, which, on treatment with potassium dichromate, gives the characteristic cherry-red colour of the original substance. Acids also, especially hydrochloric and sulphuric, rapidly reconvert it into methylcarbazacridine, of which it is, doubtless, the hydro-derivative. The compounds of methylcarbazacridine with acids have the same instability as the corresponding phenylcarbazacridine compounds, being decomposed by water, alcohol, excess of acids, or by drying. The *hydrochloride* forms beautiful, indigo-blue plates, the *sulphate* greenish-blue plates, the *nitrate* light-blue plates, and the *chromate* brownish-green plates. Picric acid forms an unstable compound crystallising in ruby-red needles. Methylcarbazacridine is obtained in small quantity by heating acetylcarbazole with zinc chloride for two hours at 150—155°, and proceeding as above indicated. The aqueous alcohol used in the preparation of the substance retains in solution a compound melting at 137—138°, and crystallising in minute prisms, soluble in acetic acid. W. J. P.

Aromatic Nitriles. By F. J. Zinsser (*Ber.*, **24**, 3556—3557; compare Freund and Immerwahr, Abstr., 1890, 1407).—A more convenient method for preparing diphenylacetic acid than that usually adopted is to boil benzilic acid with hydriodic acid (b. p. 127°) and a little amorphous phosphorus for four hours; the nitrile of this acid is best prepared by quickly distilling a mixture of the amide and phosphorus sulphide from a small retort.

Diphenylacetonitrile does not react with fatty halogen compounds under various conditions; on reduction with sodium and amyl alcohol, it is converted into diphenylmethane and hydrogen cyanide. When phenylcinnamonitrile, CHPh:CPh·CN, is treated with sodium and amyl alcohol, it yields a large quantity of dibenzyl.

F. S. K.

1 : 3′ : 4-Dichloronaphthalenesulphonic Acid. By P. T. Cleve (*Ber.*, **24**, 3477—3479).—1 : 3′ : 4-*Dichloronaphthalenesulphonic acid* is obtained by dissolving 1 : 3′-dichloronaphthalene (m. p. 48°) in a mixture of fuming and concentrated sulphuric acid (equal parts) and gently warming, when a pasty mass is produced, which, on dissolution in water, yields microscopic needles of the acid; it is very sparingly soluble in dilute sulphuric acid. A second product, probably a disulphonic acid, is also obtained in small quantity. The *potassium* salt crystallises in flat needles and tablets of a silvery lustre with 1 mol. H_2O; the *ammonium* salt resembles it; the *sodium* salt forms thin needles with 3 mols. H_2O; the *silver* salt lustrous scales with

1 mol. H_2O; the *calcium* and *barium* salts crystallise with 3 mols. H_2O; whilst the *zinc* salt crystallises with 5 mols. H_2O. All these salts are readily soluble in boiling water, and, for the most part, sparingly so in cold water. The *lead* salt crystallises with 4 mols. H_2O; the *copper* salt with 6 mols. H_2O; whilst the *methyl* and *ethyl* salts form delicate needles and melt at 138° and 154° respectively. The *sulphonic chloride* crystallises from glacial acetic acid in needles, and melts at 151°, whilst the *sulphonamide* forms long, flat, satiny needles, and melts at 217°. 1 : 4 : 3′-Trichloronaphthalene (m. p. 65°) is formed when the sulphonic chloride is heated with an excess of phosphorus pentachloride. A. R. L.

1 : 2-Amidonaphthalenesulphonic Acid. By P. T. Cleve (*Ber.*, **24**, 3472—3477).—Landshoff and Meyer (D.-R.P. 56,563) describe a naphthylaminesulphonic acid, obtained by heating at 200—250° an alkali salt of naphthionic acid which contains the amido-group in an α-position. The sulpho-group must occupy the β-position adjacent to the amido-group, as it can be converted into 1 : 2-dichloronaphthalene (m. p. 34°). The new acid forms long, anhydrous needles or small, rhombic crystals, $a : b : c = 0{\cdot}79401 : 1 : 0{\cdot}36429$, and is more soluble than its isomeride, dissolving in 34 parts of boiling water and 225 parts of cold; if allowed to slowly crystallise at the ordinary temperature, long needles containing $\frac{1}{2}$ mol. H_2O are obtained. The *potassium* salt, sparingly soluble in cold water, the *sodium* salt, dissolving in 60 parts of cold water, the *ammonium* salt, readily soluble in water, the *silver* salt, a white, sparingly soluble precipitate, and the *calcium* salt, sparingly in water, are anhydrous, whilst the *magnesium* salt crystallises with 8 mols. H_2O, the zinc salt with 5 mols. H_2O, and the *barium*, *lead*, and *manganese* salts with 1 mol. H_2O. The *acetyl* derivative dissolves easily in water and separates in small, lustrous needles containing 1 mol. H_2O. The *diazosulphonic acid* is a greenish, crystalline powder, and yields a *hydrazinesulphonic acid* crystallising in micacous plates. The chlorosulphonic acid, obtained by boiling the diazo-derivative with cuprous chloride, crystallises in plates of a silvery lustre, and yields a *sulphonic chloride* melting at 80°, anhydrous *potassium*, *sodium*, *silver*, and *barium* salts, a *calcium* salt containing 1 mol. H_2O, and an *ethyl* salt crystallising in small, colourless needles, and melting at 104°. 1 : 2-Dichloronaphthalene passes over on distilling the chlorosulphonic acid with an excess of phosphorus pentachloride. 1 : 2-*Naphtholsulphonic acid* is produced by adding the diazo-derivative to boiling dilute sulphuric acid, and is purified by first converting it into the barium salt and then into the lead salt; it forms small, lustrous, rhombic tablets, is readily soluble in boiling water, sparingly in cold, and does not melt at 250°; its solution gives with ferric chloride an indigo-blue colour, which soon changes to dirty red. The *sodium* salt is readily soluble in water; the *lead* and *calcium* salts crystallise with 1 mol. H_2O, and are sparingly soluble in water, whilst the *barium* salt crystallises with $1\frac{1}{2}$ mols. H_2O, and is also sparingly soluble in water. Further experiments are in progress. A. R. L.

Nitrosonaphtholsulphonic Acids. By O. HOFFMANN (*Ber.*, **24**, 3741—3746).—*Sodium ferrinitrosonaphtholsulphonate*,

$$Fe(NO\cdot C_{10}H_5O\cdot SO_3Na)_3\ [O : NO : SO_3 = 1 : 2 : 4],$$

is prepared by adding ferric chloride in excess to nitroso-α-naphtholsulphonic acid and treating the solution with soda; the compound crystallises from water in dark-green plates. The corresponding *potassium salt*, $Fe(NO\cdot C_{10}H_5O\cdot SO_3K)_3$, is more unstable than the sodium compound, and does not give constant analytical results.

Cupric nitrosonaphtholsulphonate, $C_{10}H_5O\ll^{NO}_{SO_3}>Cu + 3H_2O$, is obtained from nitroso-α-naphtholsulphonic acid and cupric sulphate, and crystallises in groups of brown needles. Nitroso-β-naphtholsulphonic acid gives an insoluble, amorphous precipitate with cupric sulphate.

Cupric ammonionitrosonaphtholsulphonate,

$$C_{10}H_5O\ll^{NO\cdot NH_3}_{SO_3\cdot NH_3}>Cu + H_2O,$$

is formed from nitroso-α-naphtholsulphonic acid and cupric ammoniosulphate, or by heating the preceding copper salt with ammonia, and crystallises in small, brown plates, which exhibit an intense, bronze lustre in reflected light. The compound from nitroso-β-naphtholsulphonic acid resembles the α-derivative in properties and composition.

Zinc ammonionitrosonaphtholsulphonate, $C_{10}H_5O\ll^{NO\cdot NH_3}_{SO_3\cdot NH_3}>Zn + + H_2O$ [O : NO : SO_3 = 1 : 2 : 4], crystallises in lustrous, brownish-red needles, which are somewhat soluble in dilute ammonia. The corresponding compound [O : NO : SO_3 = 2 : 1 : 3′] is deposited in yellowish-green, lustrous plates.

The *cadmium ammonio-salts* are crystalline; the α-naphtholsulphonic acid derivative is deposited in long, orange-coloured needles, whilst that from β-naphtholsulphonic acid is obtained in yellowish-green, microscopic plates.

All the above ammonio-derivatives decompose, with evolution of ammonia, on heating in aqueous solution.

Sodium nitrosonaphtholsulphonate, $NONa\cdot C_{10}H_5O\cdot SO_3Na + 2H_2O$ [O : NO : SO_3 = 2 : 1 : 3′], is prepared by adding concentrated soda to a hot saturated solution of sodium nitroso-β-naphtholsulphonate, and crystallises in small, slender, green needles. J. B. T.

Hydroxyanthranol. By C. E. LINEBARGER (*Bull. Soc. Chim.* [3], **6**, 92—94).—Benzylhydroxyanthranol,

$$OH\cdot CH\ll^{C_6H_4}_{C_6H_4}>C(OH)\cdot CH_2Ph,$$

is best prepared by boiling for three hours a mixture of 5 parts of soda, 50 parts of water, 10 parts of zinc-dust, and 3 parts of anthraquinone, and then adding 2 parts of benzyl chloride in small portions and continuing the boiling for five hours. The product, after being purified by crystallisation from alcohol, is recrystallised from benzene. It then forms very pure but small prisms, melts at 60—61°, and

begins to decompose at 100°. It is insoluble in water, soluble in alcohol, benzene, and chloroform. Its solutions have a bluish fluorescence. Anthraquinone is obtained by oxidation with chromic acid in acetic solution. Benzylanthracene is obtained by reduction with hydriodic acid and amorphous phosphorus. The production of diacetylbenzylhydroxyanthranol, by boiling 3 parts of benzylhydroxyanthranol with 6 parts of sodium acetate and 20 parts of acetic anhydride for half an hour, proves the presence of two hydroxyl groups. The purified product forms small, greenish tables, insoluble in water, soluble in alcohol, very soluble in benzene. It melts at 126°. W. T.

Paranthracene. By K. Elbs (*J. pr. Chem.* [2], **44**, 467—469).—The paranthracene was prepared by exposing a benzene solution of 90 per cent. anthracene, saturated at 40—60°, for a week to sunshine, and then gently warming it on the water-bath to dissolve any anthracene which might have crystallised out together with the paranthracene. The precipitate was then filtered, washed with benzene, and crystallised either from boiling xylene or dimethylaniline. From xylene, paranthracene generally crystallises in colourless, lustrous needles, and from dimethylaniline in laminæ. The crystals melt, but not sharply, between 272° and 274°, and become converted into anthracene. Paranthracene does not fluoresce, whether as solid or in solution; it remains unchanged at 260°, and when a solution of it in dimethylaniline is heated; on the other hand, a solution of it in naphthalene and in diphenylamine rapidly becomes fluorescent from its conversion into anthracene, the former solution when boiled, and the latter when heated at 260°.

The solubility of paranthracene in various solvents at their freezing point is very slight; naphthalene proved the best solvent for determining the molecular weight of paranthracene by the cryoscopic method, and even this only dissolves 0·229 per cent. at its melting point. A large number of determinations were made with the solution in naphthalene, and the results showed values varying between 276 and 344 as the molecular weight of paranthracene, whose formula may, therefore, be allowed to be $(C_{14}H_{10})_2$. Graebe and Liebermann assert that paranthracene is stable towards bromine in sunlight. The author finds that a mixture of paranthracene (1 part), bromine (10 parts), and carbon bisulphide (100 parts), exposed to sunlight, rapidly evolves hydrogen bromide, and yields dibromanthracene tetrabromide. Anthracene behaves similarly under the same circumstances, although statements as to the bromination of anthracene take no account of the fact. A. G. B.

Terpenes and their Derivatives. By J. W. Brühl (*Ber.*, **24**, 3701—3737; compare this vol., p. 200).—This paper describes some of the physical constants of the compounds described in the previous communication.

The specific gravity was determined at 20° and compared with water at 4°. The refractive index (n) was usually determined for the potassium, sodium, lithium, and thallium flames, and also for the

lines in the hydrogen spectrum, Hα, Hβ, Hγ, Hδ. The term "specific dispersion" is applied to the difference in the specific refractive powers of the compounds in the region of the spectrum between Hγ and Hα. $\mathfrak{M}\alpha$ denotes the molecular refractive power for the hydrogen line α.

The sp. gr. of menthyl ethyl ether, $C_{10}H_{19}OEt$ = 0·8513; $\mathfrak{M}\alpha$ = 56·96, and the molecular dispersion = 1·38; these numbers agree closely with the theoretical values. Ethyl camphor could not be obtained quite pure; its sp. gr. = 0·9372; $\mathfrak{M}\alpha$ = 53·40; $\mathfrak{M}n_a$ = 53·64; molecular dispersion = 1·29; the compound, therefore, contains no ethylene linkage.

Ethyl camphocarboxylate, like the preceding compound, contains no ethylene linkage; the sp. gr. = 1·0563; $\mathfrak{M}\alpha$ = 59·48; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 1·45. The molecular dispersion of these compounds is thus seen to be unaffected by the closing of an open chain; in this respect it resembles molecular refraction, nor is it influenced by a para-linkage in the benzene nucleus; that is to say, by the formation of a double tetramethylene ring. Ethyl camphocarboxylate ethyl ether is represented by the formula already given, and is not a camphordicarboxylic acid; its sp. gr. = 1·0759; $\mathfrak{M}\alpha$ = 76·92; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 2·20. The theoretical values are 74·61 and 1·177, the difference is probably due to experimental error.

Bornyl ethyl ether, $C_{10}H_{17}$·OEt, was prepared by the mutual action of borneol, sodium, and ethyl iodide, and also from camphor by Baubigny's method; the sp. gr. = 0·9008; $\mathfrak{M}\alpha$ = 54·88; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 1·31.

Bornyl methyl ether, $C_{10}H_{17}$·OMe, like the preceding compound, has no ethylene linkage, the sp. gr. = 0·9162; $\mathfrak{M}\alpha$ = 50·36; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 1·26.

Bornyl methylene ether, $(C_{10}H_{17}O)_2CH_2$, crystallises in rhombic prisms, $a : b : c$ = 0·9134 : 1 : 0·565; the sp. gr. = 1·0735; $\mathfrak{M}_{H\alpha}$ = 92·77; $\mathfrak{M}_{H\gamma} - \mathfrak{M}_{H\alpha}$ = 2·16; this value was obtained indirectly; the number required by theory is 2·14, and it appears to be the first known example of a compound crystallising in any but the regular system, the molecular refraction and molecular dispersions of which agree with the values deduced from its chemical composition and constitution; for details of the measurements and calculations, the original paper should be consulted.

The constants for diethyl camphorate also agree with theoretical numbers; the sp. gr. = 1·0298; $\mathfrak{M}\alpha$ = 67·32; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 1·57. The compound contains no ethylene linkage.

On account of the extreme viscosity of ethyl hydrogen camphorate, the sp. gr. was determined by means of the vacuum pyknometer (Abstr., 1891, 520); the sp. gr. = 1·09977; $\mathfrak{M}\alpha$ = 57·84; $\mathfrak{M}\gamma - \mathfrak{M}\alpha$ = 1·37; the acid, therefore, contains no ethylene linkage, and the physical properties agree with the formula already proposed for it. The molecular heat of combustion of camphoric acid = 1243·6 cal. and of camphoric anhydride = 1252·4 cal.; the small difference between these numbers indicates that the carboxyl groups are in the ortho-position.

The author considers that the low electrical conductivity of camphoric acid is the only fact which can be urged against his formula;

after pointing out that this may be due to the presence of the basic group $CH_2{\cdot}CH_2$, he discusses the general effect of substitution on the electrical conductivity of acids, and enumerates a number of apparent anomalies; since no analogue of camphoric acid is known in the succinic acid series, it is impossible to foresee how the electrical conductivity would be affected by the introduction of the group C_2H_4. J. B. T.

Crystalline Products from Lemon and Bergamot Oils. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 30—33; compare Tilden and Beck, Trans., 1890, 323).—The residue from the distillation of lemon oil at a pressure of 10 mm. is dissolved in light petroleum, and this solution deposits nodular crystals of the composition $C_{10}H_{10}O_4$, which are purified by recrystallisation from anhydrous ether, and then form a white, inodorous powder which melts at 144°, and neither decomposes nor sublimes when heated to 240°. Sulphuric acid colours this substance, which is, perhaps, hesperetic acid, golden-yellow; a trace of nitric acid converts this to green, or a trace of potassium permanganate to blue, which subsequently becomes green. On evaporation, the light petroleum leaves a butter-like mass, melting about 50°, and this, after purification by recrystallisation from alcohol, has a lemon-like odour, and gives a dark brown coloration (this vol., p. 386) with ammoniacal manganous solutions, differing in this respect from the substance $C_{10}H_{10}O_4$. Bergamot oil, when similarly treated, affords white, crystalline needles which melt at 184°, sublime at 230—240°, and have the centesimal composition C 65·24, H 3·78, O 30·98. This substance does not appear to be the bergaptene of Mulder and Ohme, which melts at 206°. T. G. N.

Action of Hydriodic Acid and Amorphous Phosphorus on Picrotin. By A. Oglialoro and O. Forte (*Gazzetta*, **21**, ii, 213—215).—*Picrotoxic acid*, $C_{15}H_{18}O_4$, is obtained by warming a mixture of picrotin (prepared by the action of potash on picrotoxin), amorphous phosphorus, and hydriodic acid, allowing the brisk effervescence which takes place at first to subside, and then boiling for about 10 hours in a reflux apparatus. On diluting the product with water, steam-distilling, and filtering the residue, the filtrate, on cooling, leaves a white deposit of picrotoxic acid. This crystallises from dilute alcohol in lustrous, white needles, melts at 134°, dissolves readily in alcohol, but only sparingly in hot water. It has a feebly acid reaction, and dissolves in alkalis, but is reprecipitated from its solutions on the addition of an acid. The *silver* salt, $C_{15}H_{17}O_4Ag$, is a white, crystalline powder, sensitive to light. The formation of this acid affords additional proof of the formula $C_{15}H_{18}O_7$ for picrotin. S. B. A. A.

Constituents of the Buds of Chrysanthemum Cinerariæfolium. By H. Thoms (*Chem. Centr.*, 1891, ii, 670—671; *Pharm. Centralhalle*, **32**, 471—472).—Continuing his examination of the constituents of the buds of *Chrysanthemum cinerariæfolium* (see also Abstr., 1891, 333), the author describes one of the new compounds, *pyrethrosin*,

more fully. The light petroleum extract of the buds was concentrated, and a golden-yellow, soft residue obtained, which, after being washed with alcohol, remained as colourless, bitter crystals. The crystals are elongated, rhombic octahedrons, melting at 188—189°. It is readily soluble in chloroform and in hot alcohol, less soluble in ether and light petroleum, insoluble in water. Its formula is $C_{31}H_{44}O_{10}$ (?). It dissolves in concentrated sulphuric acid with yellow or weak redish-brown coloration. In 25 per cent. hydrochloric acid, the substance becomes red or violet, and the solution is violet coloured; water precipitates yellow plates. The filtrate, after treatment with hydrochloric acid, does not reduce Fehling's solution, so that pyrethrosin cannot be considered as a glucoside; but if the yellow compound be treated with concentrated hydrochloric acid, and the solution be neutralised, it then reduces Fehling's solution. The author suggests that the yellow substance is nearly related to phloroglucinol, and that pyrethrosin is a phloroglucide. J. W. L.

Agrostemma Githago (Corn Cockle). By N. Kruskal and R. Kobert (*Chem. Centr.*, 1891, ii, 545—546; *Arb. pharm. Inst. Dorpat*, **6**, 89—145, 146—148).—The sapotoxin of *Agrostemma* has the same composition as those of *radix saponariæ albæ* and of quillaja bark, but differs from them in its physiological properties. Hydrolysis with acids causes the formation of glucose (4 mols.) and sapotoxin (1 mol.). The corn cockle contains about 6·17 per cent. on the average.

Agrostemma-sapotoxin has an irritating action on the mucous membrane of the nose, mouth, and eyes; it affects the nerves similarly to that of the quillaja bark. When in solution (1 : 15000), it dissolves blood corpuscles of both carnivorous and herbivorous animals. It appears to act differently on animals when taken inwardly, the Herbivoræ being relatively unaffected, provided that the doses are not too large and not taken for too great a length of time, whilst, on the other hand, the Carnivoræ are seriously affected and readily succumb to its action. On man it has an intermediate effect, but doses of 0·1 gram are sufficient to cause illness. The author points out that the bread which the Russian military authorities provide for the soldiers may contain as much as 0·5 per cent. of corn cockle, and this corresponds with a dose of about 6 grams of corn cockle per day, a quantity which may readily produce serious toxical effects.

Kobert points out that the simple term "saponin" is not sufficient, and the source from which it has been obtained should be stated, since the several different saponins have such varying physiological actions. The several saponins appear to belong to series of compounds which have different generic formulæ. Stütz's saponin, $C_{19}H_{28}(OH)_5O_5$, belongs to a series the formula of which would be $C_nH_{2n-8}O_{10}$. The lowest member of the series is isomeric with syringin, and has the formula $C_{17}H_{28}O_{10}$. J. W. L.

Constitution of the Ethylpyrrolines. By C. U. Zanetti (*Gazzetta*, **21**, ii, 163—173).—The author applies the method given by him (Abstr., 1891, 1387) for the determination of the constitution

of pyrroline derivatives to the case of the ethylpyrrolines obtained by the various known methods.

Ethylpyrroline (1 vol.), obtained by passing a mixture of equal volumes of ethyl alcohol and pyrroline through a heated tube containing zinc-dust (Abstr., 1890, 1428), is dissolved in alcohol (10 vols.) and boiled with the calculated quantities of hydroxylamine hydrochloride and anhydrous sodium carbonate for six hours. The solvent is distilled off under reduced pressure, the residue treated with cold, dilute aqueous potash, and the unaltered pyrroline extracted with ether. The solution is now saturated with carbonic anhydride, and again extracted with ether; on evaporating the ethereal solution, a syrup is left which solidifies almost completely after a time. The resinous matter is removed from this by washing with cold ether, and the residue dissolved in boiling ether; on cooling, the solution deposits a small quantity (0·2 gram from 11 grams of ethylpyrroline) of a *dioxime*, $C_6H_{12}N_2O_2$, which, after recrystallisation from ether, forms colourless scales, and melts at 134—135°. The ethereal solution, on concentration, yields a quantity (4 grams from 11 grams of ethylpyrroline) of an isomeric *dioxime*, which, on being repeatedly recrystallised from anhydrous ether, is obtained in splendid, colourless scales melting at 84—85°; this compound is very soluble in water, alcohol, benzene, and ethyl acetate, somewhat less so in ether. The formation of these two dioximes shows that the ethylpyrroline is a mixture of two isomerides.

The oxime melting at 84—85° (2 grams), when boiled with 30 per cent. aqueous potash (30 c.c.), gives off ammonia; the brownish-red solution thus obtained is saturated with carbonic anhydride, repeatedly extracted with ether to remove the unchanged oxime, and decolorised by animal charcoal. The solution is now exactly neutralised with sulphuric acid and evaporated to dryness, first on a water-bath and then in a vacuum. On extracting the residue with anhydrous ether free from alcohol, and evaporating the ethereal solution, a syrupy acid is left; this does not solidify, dissolves with effervescence in solutions of the alkaline carbonates, gives a violet coloration with ferric chloride, and yields an uncrystallisable hydrazone. With lead acetate solution, the ammonium salt gives a white precipitate, soluble in excess; with mercurous chloride, a white precipitate, rapidly changing to metallic mercury; with mercuric chloride, an opalescence; and with silver nitrate, in concentrated solution, a yellow precipitate rapidly changing to metallic silver. The acid is probably *normal propionylpropionic acid*, $CH_2Me{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, its *silver* salt having the composition $AgC_6H_9O_3$. The dioxime melting at 84—85° has, therefore, the constitution $CH_2Me{\cdot}C(NOH){\cdot}CH_2{\cdot}CH_2{\cdot}CH{:}NOH$, and the pyrroline from which it is obtained must be α-ethylpyrroline. The dioxime melting at 134—135° is probably $NOH{:}CH{\cdot}CH_2{\cdot}CHEt{\cdot}CH{:}NOH$, and is derived from β-ethylpyrroline.

The ethylpyrroline obtained by the action of ethyl iodide on the potassium compound of pyrroline boils at the same temperature (163—165°) as the above, but, on treatment with hydroxylamine hydrochloride, yields nothing but a small quantity of the dioxime melting at 134—135°. The pyrroline obtained in this manner is,

therefore, β-ethylpyrroline, that obtained from alcohol and pyrroline being a mixture of α- and β-ethylpyrroline, boiling at the same temperature.

The above experiments fully agree with the authors' previous observation, that β-pyrroline derivatives are much more stable than α-pyrrolines. Diethylpyrroline yields no trace of oximido-compound on treatment with hydroxylamine hydrochloride. W. J. P.

Derivatives of Carbonyl Chloroplatinite. By F. Foerster (*Ber.*, **24**, 3751—3765; compare Abstr., 1891, 1162).—*Pyridine carbonyl chloroplatinite*, $COPtCl_2,C_5NH_5$, is obtained as a yellow oil by mixing an aqueous solution of pyridine with a hydrochloric acid solution of carbonyl chloroplatinite, $COPtCl_2$. It decomposes at 100°, forms a *hydrochloride*, $COPtCl_2,C_5NH_5,HCl$, and when treated with hydrobromic acid yields, not the hydrobromide, but the compound $COPtBr_2,C_5NH_5,HBr$. It also forms a very unstable *picrate*.

Dipyridine carbonyl chloroplatinosite, $\begin{matrix}COPtCl,C_5NH_5\\ |\\ COPtCl,C_5NH_5\end{matrix}$, is obtained by mixing a fairly concentrated hydrochloric acid solution of carbonyl chloroplatinite with an alcoholic solution of pyridine, shaking to redissolve the precipitate first formed, and recrystallising from alcohol the crystals that finally separate. It forms, when pure, yellowish-green needles, dissolves readily in methyl and ethyl alcohol, chloroform, and benzene, very sparingly in ether, carbon bisulphide, and light petroleum, decomposes at 60°, and is decomposed by mere traces of moisture. In the reaction mentioned above, carbonic anhydride is evolved, and out of the mother liquor from the substance last described there can be obtained, by evaporation at the ordinary temperature, first lustrous, yellowish-green crystals of a double compound,

$$C_2O_2Pt_2Cl_2(C_5NH_5)_2,2PtCl_2(C_5NH_5)_2,$$

which dissolves without decomposition in hot hydrochloric acid, and can be dried at 100°. Then separate large, colourless, oblique prisms of *platodipyridine chloride*, $PtCl_2(C_5NH_5)_4 + 3H_2O$, and small, yellowish-brown needles, consisting for the most part of *platosopyridine chloride*, $Pt(C_5NH_5Cl)_2$, but containing also a little *platosemidipyridine chloride*, $PtCl(C_5NH_5)_2Cl$. Platosopyridine chloride forms, with dipyridine carbonyl chloroplatinosite, the double compound mentioned above, and from it, with excess of pyridine, the platodipyridine chloride was doubtless derived. Dipyridine carbonyl chloroplatinosite, when treated with chlorine, yields pyridine platinochloride, $(C_5NH_5)_2,H_2PtCl_6$, and hydroplatinochloric acid, H_2PtCl_6; when it is boiled with hydrochloric acid, platinum separates, and the hydrochlorides of pyridine carbonyl chloroplatinite and of pyridine are formed. A compound $COPtCl_2,(C_5NH_5,HCl)_2$ appears to be incapable of existence.

Analogous bromine compounds were obtained in a similar manner. *Pyridine carbonyl bromoplatinite*, $COPtBr_2,C_5NH_5$, forms yellow needles or plates melting at 78—79°; it dissolves readily in benzene, carbon bisulphide, ethyl acetate, and hot alcohol, more sparingly in cold alcohol, ether, and light petroleum; it is decomposed by hot

water. It forms a *hydrochloride*, $COPtBr_2,C_5NH_5,HCl$, and a very unstable *picrate*.

Dipyridine carbonyl bromoplatinosite, $(COPtBr)_2(C_5NH_5)_2$, is insoluble in most solvents, chloroform excepted. It forms triclinic crystals, which are decomposed by water or when heated to 60°. With hydrobromic acid, it behaves like the analogous chlorine compound with hydrochloric acid. *Platodipyridine bromide*,

$$PtBr_2(C_5NH_5)_4 + 3H_2O,$$

forms lustrous, rhombohedral crystals, which are soluble in water and alcohol, but not in ether; it decomposes at 130°, forming *platosopyridine dibromide*, $Pt(C_5NH_5Br)_2$. This substance, which is also formed when an aqueous solution of platodipyridine bromide is allowed to remain, or boiled with hydrobromic acid, forms needles, or yellow aggregates of microscopic needles; it is insoluble in water, and nearly so in aqueous ammonia. As in the case of the analogous chlorine compound, small quantities of an isomeric compound, $PtBr_2(C_5NH_5)_2$, were also obtained.

Attempts to see if the carbonyl group in these compounds will react with hydroxylamine or phenylhydrazine, as it does in ketones and aldehydes, gave negative results. Hydroxylamine exercises a reducing action. With an acetic acid solution of phenylhydrazine, carbonyl chloroplatinite yields an unstable *phenylhydrazine carbonyl chloroplatinite*, $COPtCl_2,C_6H_5N_2H_3$, which crystallises from ethyl acetate in yellow plates. It is decomposed by hot hydrochloric acid, but dissolves in a hot hydrochloric acid solution of carbonyl chloroplatinite, and, on cooling the solution, the *hydrochloride*,

$$COPtCl_2,C_6H_5N_2H_3,HCl,$$

separates out in orange-yellow needles, soluble in alcohol and ethyl acetate, but not in benzene, carbon bisulphide, or ether; it is decomposed by water when heated at 100°. C. F. B.

Action of Bromine on Para- and Ortho-hydroxyquinoline. By A. Claus and H. Howitz (*J. pr. Chem.* [2], **44**, 433—451).—4 : 3-*Bromhydroxyquinoline hydrobromide* separates as a yellow, crystalline precipitate when bromine (1 mol.) is added to a solution of 3-hydroxyquinoline in 10—12 times its weight of glacial acetic acid. It is sparingly soluble in cold water, and crystallises from hot water in small, hard, lustrous granules. It has no definite melting point, but dissociates when heated. When the aqueous solution of the hydrobromide is decomposed by potassium hydroxide or ammonia, and acidified with acetic acid, 4 : 3-*bromhydroxyquinoline* is precipitated in felted, small, slender needles; it melts at 186° (uncorr.), and sublimes; the *platinochloride*, with 2 mols. H_2O, is described. By oxidation with permanganate, the base yielded pyridinedicarboxylic acid, which was converted into nicotinic acid (m. p. 227—229°) when heated; this is evidence that the bromine atom is not in the pyridine ring. The orientation given is also supported by the fact that this bromhydroxyquinoline is one of the products of the quinolisation of metabromoparahydroxaniline by Skraup's method, as will be shown

in a future memoir. The hydrobromide is also formed when a solution of bromine in chloroform is added to one of 3-hydroxyquinoline in the same solvent. But an intensely reddish-yellow precipitate is formed when the reaction takes place in a solution in concentrated hydrobromic acid, or when bromine is added to a solution of 3-hydroxyquinoline in chloroform; this compound would appear to contain more hydrogen bromide than the yellow hydrobromide, into which it changes, after a time, with evolution of hydrogen bromide.

When bromine (1 mol.) acts on 1-hydroxyquinoline, a mixture of the hydrobromides of the unaltered base, and of bromo- and dibromo-1-hydroxyquinoline is formed. The product is boiled with water, and the solution, either before or after filtration, mixed with sodium acetate; the precipitate is dissolved in hydrochloric acid, and again precipitated by sodium acetate. The bases are next dissolved in hydrochloric acid, and the solution mixed with sufficient water to render it turbid; after some hours, the dibromo-derivative separates, and is treated by the same process several times to purify it. The bromo-derivative can be obtained pure from the solution after a very small quantity of sodium acetate has been added to precipitate the remaining dibromo-derivative. The two can also be separated by fractional distillation with steam, when the bromo-derivative passes over first.

4 : 1-*Bromhydroxyquinoline* crystallises from hot water in small, colourless needles, melts at 124° (uncorr.), sublimes in various but ill-defined forms, and is practically insoluble in cold water. The *platinochloride* was obtained. When oxidised by permanganate, the base yields non-brominated pyridinedicarboxylic acid; this settles its orientation.

4 : 3 : 1-*Dibromhydroxyquinoline* crystallises in lustrous, slender, yellowish needles, melts at 196° (uncorr.), sublimes in colourless needles when heated, and dissolves easily in chloroform, acetone, benzene, glacial acetic acid, and alcohol, but only sparingly in ether, and not at all in cold water. When oxidised by permanganate, it yields pyridinedicarboxylic acid; this shows that the bromine atoms are not in the pyridine ring. When the hydrobromide is suspended in chloroform and acted on by bromine, a red additive compound is produced, which easily decomposes, like that described above.

A. G. B.

Oxidation of Piperidine and Tetrahydroquinoline Derivatives. By C. Schotten and W. Schlömann (*Ber.*, **24**, 3687—3700). —Picrylpiperidine (compare Turpin, Trans., 1891, 714) is hardly acted on at all by potassium permanganate, even on long-continued heating; on oxidation with nitric acid or chromic acid, it yields resinous products.

Phenylsulphone-δ-amidovaleric acid, $SO_2Ph{\cdot}NH{\cdot}[CH_2]_4{\cdot}COOH$, is obtained, together with small quantities of phenylsulphonamide, when phenylsulphonepiperidine (compare Hinsberg, this vol., p. 64) is oxidised with potassium permanganate. It crystallises from hot water in colourless, nacreous plates, melts at 97°, and is readily soluble in alcohol, ether, glacial acetic acid, and light petroleum, but only sparingly in benzene and chloroform; when boiled with acetic anhydride, it is converted into a crystalline anhydride. The *barium* salt

$(C_{11}H_{14}O_4NS)_2Ba$, *zinc* salt, with $2H_2O$, and *copper* salt (anhydrous) were prepared. The *silver* salt, $C_{11}H_{14}O_4NSAg$, crystallises in lustrous plates. When the acid is heated with concentrated hydrochloric acid at 180°, it yields δ-amidovaleric acid phenylsulphonate,

$$C_5H_{11}NO_2,C_6H_5\cdot SO_3H;$$

this salt begins to melt at about 105°, and is not completely liquefied until the temperature has risen to 145°; when, after it has solidified, the same portion is again heated, it melts quite sharply at 107°. When phenylsulphone-δ-amidovaleric acid is heated with concentrated hydrochloric acid and barium chloride at 250°, it seems to be decomposed into δ-amidovaleric acid, sulphuric acid, and benzene.

Phenylsulphonetetrahydroquinoline, $C_9NH_{10}\cdot SO_2Ph$, prepared by shaking tetrahydroquinoline with potash and phenylsulphonic chloride, crystallises from dilute alcohol in large, colourless plates, melts at 67°, and is volatile with steam; it is readily soluble in benzene and chloroform, but more sparingly in glacial acetic acid, ether, alcohol, and light petroleum, and insoluble in water. On oxidation with potassium permanganate, it yields very small quantities of an acid, the nature of which was not determined, and a little phenylsulphonamide; with fuming nitric acid, it yields a yellow compound which is insoluble in soda.

Methyl tetrahydroquinolinecarboxylate, $C_9NH_{10}\cdot COOMe$, is obtained when tetrahydroquinoline is treated with methyl chlorocarbonate in the cold. It melts at about 35°, and is insoluble in water, alkalis, and acids, but soluble in the ordinary organic solvents; on oxidation with boiling potassium permanganate, it gives a substance which crystallises in red needles, melts at 175°, and gives the indophenin reaction; when heated with potassium permanganate in the cold, it yields very small quantities of an acid which melts at 155—156°. The *dinitro*-derivative, $C_{11}H_{11}N_3O_6$, prepared by dissolving methyl tetrahydroquinolinecarboxylate in fuming nitric acid, crystallises from alcohol in golden needles, melts at 174° with decomposition, and is not decomposed by boiling alkalis or acids; it is insoluble in ether and light petroleum, and only sparingly soluble in alcohol, but readily in benzene.

F. S. K.

Synthesis of Phenylpyrazolidine. By A. Michaelis and O. Lampe (*Ber.*, **24**, 3738—3740).—Sodium phenylhydrazine (2 mols.), benzene, and trimethylene bromide (1 mol.) are mixed and allowed to remain for some time at the ordinary temperature, the reaction being completed by heating on the water-bath; the benzene solution is treated several times with water, and finally with dilute hydrochloric acid; the acid solution, after neutralisation with alkali, is extracted with ether. After the ether is distilled, and the residue fractionated, *phenylpyrazolidine*, $NPh<\begin{matrix}CH_2\cdot CH_2\\ |\\ NH\cdot CH_2\end{matrix}$, is obtained as a colourless, or pale-yellow, liquid with a faint, characteristic odour; it boils at 210° under a pressure of 165 mm., and at 160° under a pressure of 20 mm. The compound has well marked basic properties, reduces alkaline copper solutions on warming, and is readily oxidised either by exposure to air or on treatment with mercuric oxide,

forming phenylpyrazoline. The picrate crystallises in short, yellow needles. The above synthesis probably proceeds in two stages, an intermediate compound, $CH_2Br{\cdot}CH_2{\cdot}CH_2{\cdot}NPh{\cdot}NH_2$, being first formed; this is then condensed by the excess of sodium phenylhydrazine; the reaction is therefore analogous to the formation of pyrrolidine from δ-chlorobutylamine by the action of alkalis.

A technical product, termed "phenylpyrazine," which is formed by the action of ethyl β-bromopropionate on phenylhydrazine in alkaline solution, is 1 : 5-phenylpyrazolidone, $NPh<\begin{matrix}CO\cdot CH_2\\ |\\ NH\cdot CH_2\end{matrix}$. The compound $C_9H_8N_2O_2$, prepared by Michaelis and Burmeister from ethyl chloromalonate and phenylhydrazine (compare Abstr., 1891, 1068), proves to be 1 : 3 : 5-phenylpyrazolidone, $NPh<\begin{matrix}CO\cdot CH_2\\ |\\ NH\cdot CH_2\end{matrix}$. J. B. T.

The Osazone of Hydroxypyruvic Acid. By W. Will (*Ber.*, **24**, 3831—3834).—In a previous paper (Abstr., 1891, 542), the author described a substance obtained by the action of hydrogen chloride on an alcoholic solution of the osazone of hydroxypyruvic acid, which he regarded as its ethyl salt. After dissolving in alkali and reprecipitating with acid several times, and finally recrystallising from alcohol, it is obtained in reddish-yellow aggregates of needles, which, from the analysis and molecular weight determination, have the composition $C_{15}H_{12}N_4O$. It is therefore not the ethyl salt, as formerly supposed, but is obtained from the osazone by loss of the elements of water, and is identical with the phenylhydrazineketophenylpyrazolone obtained by Knorr by heating the osazone with acetic anhydride (Abstr., 1888, 724). Its formation is represented as follows:—

$$N_2HPh{:}C<\begin{matrix}COOH\\ CH{:}N{\cdot}NHPh\end{matrix} = N_2HPh{:}C<\begin{matrix}CO{\cdot}NPh\\ |\\ CN{:}N\end{matrix} + H_2O.$$

It is insoluble in water, readily soluble in alcohol and ether, sublimes in small quantities, and colours wool and silk yellow in alkaline solution.

The osazone of hydroxypyruvic acid differs from the similar compounds investigated by Knorr, inasmuch as the solutions of its salts do not yield the pyrazolone directly on acidification. The osazone itself yields a sodium salt, as already found by Nastvogel (Abstr., 1889, 237). The pyrazolone, however, also yields a *sodium compound*, which crystallises in slender, yellow needles, and melts at about 300° with decomposition. It also forms a *silver compound*, $C_{15}H_{11}AgN_4O$, which crystallises in reddish-yellow plates, becomes brown at 206°, and melts at 215°.

The ethyl salt of the osazone may be obtained by the action of methyl iodide and alkali on its alcoholic solution. It is a yellow, microcrystalline powder which melts at 222—223°, and is insoluble in alkalis and dilute acids. H. G. C.

Phenylguanazole. By G. Pellizzari (*Gazzetta*, **21**, ii, 141—154). —*Phenylguanazole* is prepared by heating a mixture of dry dicyano-

diamide with phenylhydrazine hydrochloride, in molecular proportion, at 150°; much ammonia is evolved during the reaction, and, as spontaneous heating occurs, the mixture must be cooled if the temperature rises above 180°. The vitreous, yellow product is crystallised from dilute hydrochloric acid, dissolved in water, and decomposed by concentrated caustic potash, when the base separates in red needles; on recrystallisation from alcohol, it is obtained in large, hard, slightly yellowish crystals melting at 174—175°. It is very soluble in alcohol and water, but only sparingly in chloroform, ether, or benzene; it is precipitated from its aqueous solutions by caustic soda and caustic potash. The molecular formula, as determined by the cryoscopic method, is $C_8H_9N_5$. The aqueous solution is neutral to test-paper. The *hydrochloride*, $C_8H_9N_5,HCl$, crystallises in thin, white scales, very soluble in water and alcohol, and melts at 240°. The *platinochloride*, $(C_8H_9N_5)_2,H_2PtCl_6$, forms yellow, prismatic needles. The aqueous solution of the base gives a white, flocculent precipitate with silver nitrate, soluble in hot water, nitric acid, and ammonia; it is a molecular compound of phenylguanazole with silver nitrate,

$$C_8H_9N_5,AgNO_3.$$

Silver sulphate and mercuric chloride give white precipitates with aqueous solutions of the base; mercurous nitrate gives a white precipitate soon turning yellow; and copper salts give a yellowish-green precipitate. These precipitates are all molecular compounds. The reaction between dicyanodiamide and phenylhydrazine hydrochloride may be carried out in alcoholic solution by heating for eight hours in a closed tube at 100°. The reaction is represented by the equation

$$NHPh\cdot NH_2 + NH\cdot C(:NH)\cdot NH\cdot C(:NH)\cdot NH_2 = \begin{matrix} C(:NH)\cdot NH \\ | \\ NH\cdot C(:NH) \end{matrix}\!\!>NPh + NH_3.$$

Anilbiguanidine is probably an intermediate product of the reaction, for if anilguanidine hydrochloride (1 part) and cyanamide (1 part) be boiled with water (8 parts) for six hours, and treated with potash, ammonia is evolved and phenylguanazole separates. Phenylguanazole is also obtained by heating together at about 160° equal parts of anilguanidine hydrochloride and guanidine carbonate; large quantities of ammonia are evolved; the product is dissolved in dilute hydrochloric acid, and filtered; on treating with solid potash, crude phenylguanazole separates, and is purified by repeated extraction with chloroform. A mixture of biguanide with phenylhydrazine in molecular proportion, when heated at 120—160°, evolves much ammonia, and, on extracting the product with alcohol, evaporating, dissolving in water, treating with a little potash, filtering, and adding excess of potash, phenylguanazole is obtained. The yield by the last two methods is small, but they show the very great analogy which exists between phenylguanazole and phenylurazole (Trans., 1888, 550).

Ethylanilbiguanidine, $NH_2\cdot C(:NH)\cdot NH\cdot C(:NH)\cdot NH\cdot NEtPh$, is prepared by heating unsymmetrical ethylphenylhydrazine hydrochloride with dicyanodiamide in molecular proportion, at 160—170°, for half

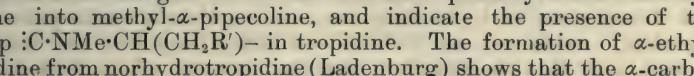
an hour. No ammonia is evolved. The product is dissolved in water, filtered, and treated with caustic potash; the base separates as an oil which is extracted by agitation with ether, and the residue left on evaporating the ethereal solution is boiled for some time with water to eliminate unaltered ethylphenylhydrazine; caustic potash is then added, and the precipitate again extracted with ether; on evaporating the ether, the base is obtained as a vitreous, friable mass which softens at about 50°. It is very soluble in alcohol, ether, and benzene, less so in water; it has a strongly alkaline reaction, and absorbs carbonic anhydride. When boiled with potash, it yields ammonia and ethylphenylhydrazine. The *sulphate*, $C_{10}H_{16}N_6,H_2SO_4$, is obtained in small, colourless crystals which are very soluble in water, but only sparingly in alcohol. W. J. P.

Tropine. By G. Merling (*Ber.*, **24**, 3108—3126).—The experiments to be described, taken in conjunction with the facts already known, prove that neither the formula proposed by the author, nor that of Ladenburg, which Liebermann has already shown to be untenable (Abstr., 1891, 749), represents the constitution of this compound. In the present research, the author commenced his experiments with Roth's methyltropidine (Abstr., 1884, 761), a compound which proves to have properties entirely different from those ascribed to it by Roth, and proceeded on the lines laid down by him for the investigation of certain bases allied to piperidine (*Annalen*, **264**, 310; Abstr., 1891, 1506).

α-Methyltropidine ($\Delta^{3:5}$-*dihydrobenzyldimethylamine*, see below), $C_6H_7\cdot CH_2NMe_2$, is prepared by distilling a dilute aqueous solution of tropidinemethylammonium hydroxide until it reaches a concentration of 1 : 10, and then driving the base over with a current of steam; it is a colourless, mobile oil, of a faint ammoniacal odour, and cannot be distilled, as it changes into *β*-methyltropidine on heating; the yield is equal to that of the tropidine employed. The *platinochloride*, $(C_9H_{15}N)_2,H_2PtCl_6$, crystallises from boiling water in orange-yellow prisms, and melts at 173—174°; the *aurochloride*,

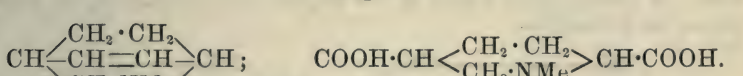
$$C_9H_{15}N,HAuCl_4,$$

is a golden-yellow, crystalline precipitate sparingly soluble in water, and decomposing when boiled with it; the *methiodide*, $C_6H_9NMe_3I$, is readily soluble in hot water, sparingly in cold, and melts at 162° with the evolution of gas. *Hydrochloro-α-methyltropidine*,



$$C_6H_7HCl\cdot CH_2\cdot NMe_2,$$

is obtained as the hydrochloride, when α-methyltropidine is allowed to remain for some days at the ordinary temperature with a solution of hydrogen chloride saturated at 0°; the *aurochloride*,

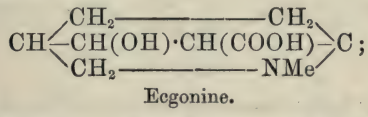


$$C_9H_{16}ClN,HAuCl_4,$$

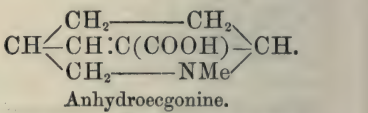
separates as a yellow, crystalline precipitate on adding auric chloride, and the free base as a colourless, mobile oil on adding sodium hydroxide to the solution; the latter changes slowly at the ordinary temperature, or quickly at the temperature of the water-bath, into a

viscid syrup which consists essentially of tropidinemethylammonium chloride. It is poured into water and distilled in a current of steam, when a small quantity of α-methylpiperidine passes over; the residue is shaken with ether to remove the resinous substances, solutions of sodium hydroxide and potassium iodide added, and the precipitated tropidinemethylammonium iodide crystallised from boiling alcohol; it is next converted into the chloride by silver chloride, and this salt yields tropidine and methyl chloride on dry distillation. These reactions are analogous to the conversion of pentallylcarbindimethylamine into methyl-α-pipecoline, and indicate the presence of the group $:C\cdot NMe\cdot CH(CH_2R')-$ in tropidine. The formation of α-ethylpyridine from norhydrotropidine (Ladenburg) shows that the α-carbon atom carries an atom of carbon not belonging to the hydrogenised pyridine nucleus; whilst that of the bibasic tropic acid, by the oxidation of tropine with chromic acid, proves that the second carbon atom of the side chain is also in combination with one of the nucleal carbon atoms. When α-methyltropidinemethylammonium iodide is converted into the hydroxide, and this is boiled with water, it decomposes into tropilidene, C_7H_8, trimethylamine, and water, a reaction which points to the presence of the group $=CH\cdot CH_2\cdot NMe_2$ in α-methyltropidine. These facts are only to be accounted for by adopting the following formulæ:—

Tropine.



Tropidine. Tropic acid.



Methyltropine is, therefore, Δ^3-hydroxytetrahydrobenzyldimethylamine, and α-methyltropidine is $\Delta^{3:5}$-dihydrobenzyldimethylamine. Tropilidene, C_7H_8, when dissolved in carbon bisulphide and treated with bromine, forms a *dibromide* which is an oil miscible with ether and having a camphor-like odour; when kept in a desiccator, it resinifies by degrees, and, when heated on the water-bath for some hours, hydrogen bromide is evolved, and it is converted into a crystalline mixture of benzyl bromide and a substance separating from alcohol in yellow tablets, which is perhaps an isomeride of the dibromide. When tropilidene (1 gram) is heated in a reflux apparatus for an hour with sulphuric acid (5 grams), water (20 grams), and potassium dichromate (3·2 grams), a mixture of benzoic acid and benzaldehyde is formed with evolution of carbonic anhydride. Tropilidene is, therefore, probably $CH_2{:}C<\begin{matrix}CH_2{\cdot}CH_2\\ CH-CH\end{matrix}>CH$.

β-Methyltropidine, $C_7H_9NMe_2$, is prepared as follows:—α-Methyltropidine is heated at 140—150° in a reflux apparatus; on now removing the source of heat, the temperature rises to 190°; the liquid is maintained at this for some minutes, and is then distilled, when

small quantities of di- and tri-methylamine pass over, and at 200° a few drops of tropylen; whilst β methyltropidine passes over at 204—205° (757 mm.), and a small quantity of a base boiling at a very high temperature remains behind as a thick, brown oil. It is a colourless, highly refractive oil, having a characteristic odour, and a sp. gr. 0·922 at 15°. When β-methyltropidine is dissolved in hydrochloric acid and the solution heated, tropylen separates as an oil and is driven over with a current of steam; whilst dimethylamine hydrochloride remains behind. The fact that Ladenburg obtained tropylen and dimethylamine by heating tropidine methiodide with potash is, therefore, explained as follows:—α-Methyltropidine is initially formed, and this changes into the β-compound, which then decomposes into tropylen and dimethylamine. When β-methyltropidine and methyl iodide are mixed in molecular proportion in methyl alcoholic solution, tetramethylammonium iodide separates: the quicker if heat is applied; whilst after removing the iodine from the solution by silver chloride, platinic chloride precipitates a *platinochloride*, $(C_7H_7Me)_2,H_2PtCl_6$, as a bright-yellow, amorphous precipitate, and on evaporating the filtrate, an oily compound at first separates, and, later, lustrous crystals of the *platinochloride*, $C_7H_7Me_3,H_2PtCl_6$. The author finds, contrary to Ladenburg's statement, that tropylen forms a crystalline compound with potassium hydrogen sulphite, and it must therefore be an aldehyde or a ketone; since it gives an acid of the composition of adipic acid on oxidation, it is probably tetrahydrobenzaldehyde, and in concordance with the above formulæ, the Δ^3-derivative. Ecgonine and anhydroecgonine must, in conformity with the above-given formulæ for tropine and tropidine, be represented as follows:—

Ecgonine.

Anhydroecgonine.

The formation of dihydrobenzaldehyde from dibromanhydroecgonine (Eichengrün and Einhorn, Abstr., 1891, 65), then, admits of simple explanation. The dihydrobenzaldehyde must be the $\Delta^{3:5}$-derivative. A. R. L.

A Violet from Codeïne. By P. Cazeneuve (*Compt. rend.*, **113**, 747—749).—10 grams of codeïne is heated with 10 grams of paranitrosodimethylaniline in presence of a litre of ethyl alcohol of 93° for 300 hours. When the liquid cools, it deposits tetramethyldiamidoazobenzene. The alcohol is distilled off and the residue boiled with water; after cooling, the liquid is filtered and agitated with amyl alcohol, which dissolves out the violet colouring matter, whilst a beautiful blue colouring matter remains in the water. When the amyl alcohol is evaporated, the violet compound separates in amorphous, lustrous flakes, somewhat soluble in water, but especially soluble in alcohols and in ether, forming dichroic solutions. When the aqueous solution is poured on to strong sulphuric acid, it gives, like the safranines, a green zone, changing to blue, and then to violet,

which indicates the presence of poly-acid combinations. The morphine violet gives a similar reaction.

Codeïne violet dyes silk, wool, and gun-cotton directly, but the colour alters somewhat when exposed to light.

When the amyl alcohol solution of the compound is mixed with alcohol and ether, and treated with platinic chloride, a platinochloride is obtained with a paler colour than the platinochloride of the analogous morphine compound. It has the composition

$$NMe_2\cdot C_6H_4\cdot N:C_{17}H_{18}MeNO_4,H_2PtCl_6,$$

and hence codeïne violet has the composition

$$NMe_2\cdot C_6H_4\cdot N:C_{17}H_{18}MeNO_4.$$

The yield is small, but better results were not obtained by varying the proportions of the reacting substances. Heating in a sealed tube gave a smaller yield (compare Abstr., 1891, 1220).

C. H. B.

An Alkaloïd from Javan Coca Leaves. By F. Giesel (*Chem. Centr.*, 1891, ii, 488, from *Pharm. Zeit.*, **36**, 419—420).—From 20 kilos. of a small-leaved Javan coca, the author obtained 1 kilo. of cinnamylcocaïne, whilst about three times this amount, besides some cocaïne, remained uncrystallisable. From the mother liquors an alkaloïd was separated as hydrobromide, which resembled dextrococaïne. The *hydrobromide* melted at 49°.

The hydrochloride is more readily soluble in water, and less soluble in alcohol, than is the hydrochloride of dextrococaïne. The salts of the new alkaloïd are precipitated crystalline from quite dilute solutions by potassium dichromate, which is not the case with the salts of cocaïne or dextrococaïne; moreover, the polarised ray is not perceptibly deviated.

Concentrated hydrochloric acid splits it up into benzoic acid and ecgonine hydrochloride, without the formation of an intermediate product, as in the case of dextrococaïne.

The alkaloïd could not be detected in the leaves of American truxillo; at the same time, an alkaloïd, somewhat resembling Hesse's hygrine, but different from it, was obtained from them. It differs from Hesse's hygrine in its solubility in solutions of the alkalis, and is destroyed by potassium permanganate; whilst Hesse's remains unchanged. It occurs in the leaves in quantities up to 0·2 per cent, and is a constituent of the plant, and not a product of decomposition.

J. W. L.

Cyanmethæmoglobin and Detection of Hydrogen Cyanide. By R. Kobert (*Chem. Centr.*, 1891, ii, 591, from *Apoth. Zeit.*, **6**, 386).—Researches carried out by the author indicate that hydrogen cyanide forms with methæmoglobin a red compound *cyanomethæmoglobin*, which differs from oxyhæmoglobin and its modifications in that its spectrum is not characterised specially by any band. The remarkably bright-red colour of the blood, after poisoning with hydrogen cyanide, in places where the formation of methæmoglobin

has taken place, is caused by the formation of the cyanogen compound.

Blood which contains the cyanogen compound may be detected thus:—1 c.c. of the blood is diluted with 99 c.c. of water and a 1 per cent. solution of potassium ferricyanide is added drop by drop. If cyanogen is absent, the colour of the solution passes from red to yellow, owing to the formation of methæmoglobin, and it shows the corresponding spectrum. In the presence of cyanogen, the colour only becomes brighter red, and shows no absorption band. Hydrogen cyanide may be detected by means of this test. Healthy blood is employed, and, after diluting with water (1 c.c. of blood to 99 c.c. of water), it is shaken with a small crystal of potassium ferricyanide until the red colour has just changed to yellow, and a little of the liquid under investigation is poured on to the surface. The presence of hydrogen cyanide causes a bright-red coloration to form. The solutions must not be alkaline, but should be just acid.

If blood contains cyanogen, a 1 per cent. solution retains its colour for some time; whereas healthy blood becomes darker at the end of a few hours or days, and shows the spectrum of hæmoglobin.

J. W. L.

Transformations of Albumins. By G. Patein (*Compt. rend. Soc. Biol.*, 1891, 207—212).—From experiments on egg-albumin and serum-albumin, it is shown that the action of acetic acid and alkalis produces changes in the albumin which render it no longer coagulable by heat or precipitable by certain reagents. The same sometimes occurs in the albumin which passes into the urine in cases of disease.

W. D. H.

Physiological Chemistry.

Digestive Ferments in Crustacean Eggs. By J. E. Abelous and F. Heim (*Compt. rend. Soc. Biol.*, 1891, 273—275).—Various crustacean eggs were found to contain an amylolytic, an inverting, and a tryptic ferment. Their amount and activity probably varies with the degree of maturity of the eggs. These are regarded as enzymes, not as organised ferments. W. D. H.

Formation of Sugar in the Organism when Oxygen is deficient. By A. Dastre (*Compt. rend. Soc. Biol.*, 1891, 681—684).—The recent experiments of Araki (Abstr., 1891, 1125—1392) and by Zillessen (*ibid.*, 1126) are merely confirmatory of some of a more com-

plete nature made by the author some years ago (*Glycémie asphyxique*, 1879); these are not alluded to by the authors just mentioned.

W. D. H.

Gases of Peptone Blood. By Blachstein (*Arch. f. Anat. u. Physiol., Physiol. Abth.*, 1891, 394—401).—In dogs, Labousse (Abstr., 1889, 531) has shown that injection of "peptone" lessens the amount of carbonic anhydride in the blood, whilst the oxygen remains normal, or rather over the normal. It is now shown that in the rabbit, an animal whose blood is not rendered incoagulable by peptone, the same change in the blood gases occurs. Moreover, the amount of carbonic anhydride in the lymph is not lessened, and so the diminution is not explicable on the ground of lessened metabolism. W. D. H.

The Specific Gravity of the Blood of Europeans living in the Tropics. By M. Glogner (*Virchow's Archiv*, **126**, 109—113).—The specific gravity of the blood was estimated by Hammerschlag's method. A drop of blood is placed in a mixture of benzene and chloroform, and then benzene or alcohol, as the case may be, is added until the drop of blood swims. The mixture is filtered through linen, and its specific gravity, taken with the hydrometer, gives that of the blood.

The persons, 20 in number, on whom the observations were made were Europeans who had lived for varying periods in the East India Islands (six months to 29 years), and were suffering from varying degrees of "tropical anæmia." The average number of corpuscles was found to be normal; but the sp. gr was 1·053 instead of the normal 1·062. The anæmia thus appears to be due to loss in the constituents (probably proteïds) dissolved in the blood plasma. W. D. H.

Tropical Anæmia. By C. Eijkman (*Virchow's Archiv*, **126**, 113—124).—This investigation resembles that in the preceding abstract, but is rather more extensive. The specific gravity of blood was estimated by Schmaltz' capillary pycnometer (*Arch. Klin. Med.*, 1890); the corpuscular richness by counting; the percentage of hæmoglobin by Fleischl's hæmometer. Observations were made both on Malays and Europeans, the latter being classified according to their length of residence in the tropics. The blood on the average gave throughout practically the same number of corpuscles, and the same percentage of hæmoglobin. The average specific gravity was 1·057, length of stay in the Indies making no difference. Schmaltz gives the normal specific gravity as 1·059; so there is a slight fall, but nothing like so great as in the more familiar forms of anæmia. W. D. H.

Disappearance of Sugar from the Blood. By V. Harley (*J. Physiol.*, **12**, 391—408).—In view of Schenk's statement (Abstr., 1891, 350, 504) that a considerable amount of sugar is lost when it is estimated in albuminous mixtures such as serum, a number of investigations were made on this subject. A known amount of dextrose was mixed with defibrinated calf's blood, the proteïds removed by acetic acid, heat, and filtration, and the sugar estimated in the filtrate and washings; the loss varied from 0 to 4·8 per cent. The reason of the

variation appears to be the behaviour of the proteïd on heat coagulation; if the coagulum formed is dense and firm, the loss of sugar is great. If the proteïd separates in loose, flocculent curds, the precipitate is more readily washed, and the loss of sugar reduced to a minimum.

Similar results followed experiments made with blood drawn directly from an artery in a living animal, and also when other methods of precipitating the proteïds (potassio-mercuric iodide, mercuric chloride) were employed; and the general conclusion is drawn that the loss of sugar is due to mechanical retention by, not chemical combination with, the coagulated proteïd. In addition to this, however, the element of time has to be taken into account; the longer the blood, if fresh, and sugar solutions are mixed, the greater is the loss of the sugar; this is not due to bacteria. The glycolysis is of a progressive character. W. D. H.

Glycolytic Power of Blood and Artificial Production of Diabetes. By R. Lépine and Barral (*Compt. rend.*, **113**, 729—730).—Moderate bleeding of a dog at first (after a short time) increases the glycolytic power of the blood, but repeated bleeding reduces it. Ligature of Wirsung's canal causes a great increase of the glycolytic power of the blood. Grützner found that under the same conditions there was an increase in the saccharifying power of the urine, and the authors find that this is true also of the blood. Section of the nerves of the pancreas is followed by a great increase in the glycolytic and saccharifying power of the blood. Electrification of the lower end of the pancreatic nerves produces diabetes after a short time.

C. H. B.

Influence of Muscular Work on the Elimination of Creatinine. By J. Moitessier (*Compt. rend. Soc. Biol.*, 1891, 573—574).—After muscular work (walking), no increase in the amount of creatinine in the urine was observed. The experiments were made on the author's own person. W. D. H.

Xanthocreatinine in the Urine. By G. Colosanti (*Gazzetta*, **21**, ii, 188—192).—The urine of the lion is very rich in urea, which, when extracted by Hoppe-Seyler's method, crystallises in thin, snow-white scales, not in needles as does that obtained from the urine of the dog. The alcoholic mother liquor from the crystallisation and washing of the urea when concentrated is of a syrupy consistency, and has an aromatic odour; it contains, besides much creatinine, xanthocreatinine, which may be separated as a yellow, crystalline powder.

Monari (Abstr., 1886, 613) has shown that if large quantities of creatine, or creatinine, are introduced into the circulation, either by intravascular injection or as the result of excessive muscular effort, the bases are partly eliminated as xanthocreatinine. As the rich meat diet of the lion introduces into the system large quantities of creatine, the author supposes that part of the base is secreted as xanthocreatinine. W. J. P.

Is Alcohol Eliminated by the Milk? By F. Klingemann (*Virchow's Archiv*, **126**, 72—80).—By administering fairly large doses of alcoholic liquors to nursing women, none was ever found in the milk. In animals in which proportionally larger doses were given, minute traces were occasionally found. W. D. H.

Action of Pilocarpine on the Excretion of Milk. By C. Cornevin (*Compt. rend. Soc. Biol.*, 1891, 628—630).—Pilocarpine is a drug which increases the amount of many secretions, such as sweat and saliva. By experiments on cows, it was, however, found that it does not increase the amount of milk secreted. Analysis of the milk showed a slight increase in the amount of lactose. There is no glycosuria. W. D. H.

Excretion of Uric Acid and Urea. By W. P. Herringham and H. O. Davies (*J. Physiol.*, **12**, 475—477).—Haig states that the proportion of uric acid to urea varies inversely with the daily total acidity of the urine. Haig estimated uric acid by Haycraft's method. In the present research, uric acid was estimated by Ludwig's modification of Salkowski's process, and urea by the hypobromite method. Two experiments were made, one of 16 days on a mixed diet, one of eight days on a vegetable diet. The proportion of uric acid to urea varied, but bore no fixed relation to the total acidity of the urine. W. D. H.

Excretion of Uric Acid, Urea, and Ammonia. By W. P. Herringham and E. W. Groves (*J. Physiol.*, **12**, 478—484.)—A series of experiments similar to the preceding, but performed more carefully, the composition of the diet being noted. The results obtained showed that the excretion of uric acid does not vary inversely with the daily acidity of the urine, and that uric acid may be passed to the amount of $\frac{1}{24}$th of the urea without bad effects. On three occasions sodium salicylate was given; these coincided with large excretions of uric acid. This may, however, have been due to the salicyluric acid in the urine; or it may have been accidental, as on other days, when no drug was given, the excretion was as large. W. D. H.

Heat Production in Nerves during Excitation. By G. N. Stewart (*J. Physiol.*, **12**, 409—425).—In the nerves of rabbits and dogs there is not even a rise of temperature of the general nerve sheath of $\frac{1}{2000}$th of a degree during excitation. On theoretical grounds, the statement of Rolleston (Abstr., 1890, 536), that a frog's nerve gives off heat when it dies, is considered to be erroneous. W. D. H.

Physiological Action of Nickel Carbon Oxide. By M. Hanriot and C. Richet (*Compt. rend. Soc. Biol.*, 1891, 185—186).—This compound is extremely poisonous. The blood shows the spectrum of carbonic oxide hæmoglobin. (Compare McKendrick and Snodgrass, Abstr., 1891, 1130.) W. D. H.

Physiological Action of Nickel Carbon Oxide. By P. Langlois (*Compt. rend. Soc. Biol.*, 1891, 212—213).—The oxygen of

oxyhæmoglobin is displaced by this substance, but it is regarded as unsettled whether the compound formed is carbonic oxide hæmoglobin, or hæmoglobin united to the nickel compound.

W. D. H.

Physiological Action of Trimethylamine. By Combemale and Brunelle (*Compt. rend. Soc. Biol.*, 1891, 175—178).—Inhalation of the vapour of trimethylamine produces an increased secretion of saliva. The same effect follows its administration by the mouth, or under the skin. The alkalinity of the saliva is greater than normal. Occasionally vomiting is produced, also increase of the nasal mucus and of tears. There is always slight albuminuria. After subcutaneous administration, there is local inflammation at the point of injection, leaving a wound which takes a long time to heal. A dose of 3 centigrams per kilo. of body weight causes a lowering of body temperature.

W. D. H.

Physiological Action of Dinitrobenzene. By A. Huber (*Virchow's Archiv*, **126**, 240—270).—The main effects of dinitrobenzene, as tested on both cold- and warm-blooded animals, are changes in the blood, paralysis, and intense dyspnœa. The blood becomes of a dark chocolate colour; the red corpuscles are largely deprived of their pigment, which in frogs partly collects round the nucleus. Spectroscopic investigation showed an absorption band in the red, reminding one of the similar band of acid hæmatin, and of methæmoglobin, but not identical with either. It is spoken of as the dinitrobenzene band, and it is considered that this compound acts in a specific manner on the blood pigment. After large doses, the urine was found to be brown in colour, and to contain a strongly reducing substance, and sometimes dinitrobenzene was itself present. The body temperature is lowered. The illness which workers in roburite factories suffer from appears to be caused by dinitrobenzene fumes.

W. D. H.

Relation between the Chemical Constitution and Physiological Action of Compounds of the Aromatic Series. By G. Oddo (*Gazzetta*, **21**, ii, 237—258).—

Benzene Nucleus.—I. *Triazobenzene.*—This compound, prepared by the author's method (Abstr., 1891, 696), has a very energetic antipyretic and analgesic action on mammals, both in the normal and febrile conditions. Its antipyretic action is probably more powerful than that of any other known substance, the temperature in mammals falling almost to the point of collapse with complete anæsthesia; these effects last for 24 or more hours, paralysis and death often supervening. The action is accompanied by a rise in the pulse rate, and does not commence until some hours after administration, probably owing to its insolubility; the acidity of the stomach also affects the rapidity and extent of the action. It is probably eliminated from the body by the skin and lungs. Frogs, on the other hand, exhibit convulsive movements and depressed pulse. It thus appears that azoimide does not retain its physiological properties (*Ber.*, 1890, 1023; Abstr., 1891, 56 and 524) when in combination with organic radicles.

II. *Benzamide* acts as a gentle antipyretic; its action is rapidly developed, and soon ceases. It probably passes from the system through the skin and lungs.

Naphthalene Nucleus.—*Ethyl α-naphthylazoacetoacetate*,

$$C_{10}H_7{\cdot}N_2{\cdot}CHAc{\cdot}COOEt$$

(Abstr., 1891, 1381), gave negative results in experiments on dogs and frogs. *α-Acetonuphthalide*, which resembles some well-known antipyretics of the benzene group in constitution, likewise gave rise to no noteworthy symptoms. This behaviour is attributed by the author to the physiological inactivity of the naphthalene nucleus. The phenanthrene nucleus appears to be similarly inactive, a subcutaneous injection of 0·04 gram only feebly affecting a frog. In conclusion, the author ascribes the antipyretic properties of benzene compounds to the presence of the benzene nucleus, and regards the absence of these properties from naphthalene compounds as indicative of the absence of a preformed benzene nucleus from these substances and hence as confirmatory of Bamberger's centric formulæ.

Chemistry of Vegetable Physiology and Agriculture.

Nitrification of Organic Nitrogen. By T. Leone and O. Magnanini (*Gazzetta*, **21**, ii, 206—208).—The authors have instituted experiments to determine whether organic nitrogen is completely converted into nitric acid by the nitrifying organism. A quantity of gelatin solution containing 0·04—0·07 gram of nitrogen was dissolved in 2—3 litres of water, and kept at 32° for 45 days, after which time neither ammonia nor nitrous acid was present in the solution, so that the action may be considered to have ended. On determining the nitric acid, a deficit of 17·4—19·0 per cent. on the amount of nitrogen originally present was observed. This nitrogen must either have been evolved in the free state or remained in the solution as organic matter not convertible by the organism. W. J. P.

The Sources of the Nitrogen of our Leguminous Crops. By Sir J. B. Lawes and J. H. Gilbert (*Jour. Roy. Agri. Soc.* [3], **2**, 657—720).—Both the scientific interest and practical value of leguminous crops depend largely on the amount of nitrogen they contain and on the sources of this nitrogen; also on the great difference in these respects between them and the agricultural plants of other orders. Grain and root crops and potatoes cannot be successfully grown without the application of nitrogenous manure, whilst the direct effect of such manure is to increase not so much the nitrogenous as the non-nitrogenous constituents of the plants—the carbohydrates. This is well illustrated by the results of field experiments made at Rothamsted; the results show that when nitrogenous

manures are applied in conjunction with minerals, there is an enormous increase in the carbon assimilation and carbohydrates formed as compared with the amounts assimilated under the influence of minerals only. On the other hand, leguminous crops, grown without nitrogenous manure, contain a higher percentage of nitrogen than non-leguminous crops, and yield also a much greater amount of nitrogen over a given area of land; nitrogenous manures have little or no effect when given to them, and the carbon assimilation is not materially increased.

Boussingault's experiments, and the earlier experiments made at Rothamsted (this Journal, 1863, 100), showed that, under conditions of sterilisation and enclosure, there was no gain from free nitrogen in the growth of either *Gramineæ*, *Leguminosæ*, or other plants. The results obtained by Hellriegel and others, and especially those obtained at Rothamsted in 1888 (Abstr., 1890, 814), are next discussed. They show that, under non-sterilised conditions—in fact, with suitable microbe infection of the soil—there was nodule formation on the roots and considerable fixation of free nitrogen. These results have received confirmation from still more recent Rothamsted experiments, and also from the direct experiments of Schloesing, jun., and Laurent (Abstr., 1891, 353), who determined the loss of nitrogen which took place in the confined air in which their plants were grown.

In 1889, and since, quantitative experiments have been made with peas, beans, vetches, lupins, white clover, red clover, sanfoin, and lucerne; that is to say, with four annuals and four plants of longer life. The results, as far as they are available, show that without soil-extract seeding, and with no nodules, there was no gain of nitrogen; whilst with soil extract, and with nodule formation, there was a considerable gain of nitrogen, in fact, very many times as much nitrogen in the products of growth as in the seeds sown.

The difficulty at first experienced by Hellriegel in obtaining good results with lupins, and at Rothamsted with yellow and blue lupins in 1888, seems to be due to the infecting soil which was used being unsuitable. Nobbe's experiments (Abstr., 1891, 1533) indicate that there are a variety of leguminous nodule-organisms, which have very different effects with the different plants (compare also Beyerinck, Abstr., 1891, 1539). This would also be consistent with the observations made at Rothamsted with various plants, showing that the external appearance and distribution of the nodules were very different in the case of peas, vetches, lupins, and other plants.

A series of experiments was commenced at Rothamsted in 1890, with a view to the more detailed examination of the roots of the plants than was possible in the case of the strictly quantitative series. The plants were grown in pits, so arranged that some of the plants of each description could be taken up and their roots examined at three (or four) successive periods of growth. Each plant was grown in sand supplied with minerals and soil extract, and in a mixture of soil and sand. Generally speaking, in sand, the area of infection was limited, but the nodules were of great size; in soil with much greater distribution of the infecting organisms, there was a far greater number of nodules, which were, however, smaller than those grown in sand. The results of determinations of dry matter and nitrogen in

the nodules of the plants taken up at different periods indicate that in the case of the annual, when the seed is formed and the plant more or less exhausted, both the actual amount of nitrogen in the nodules and its percentage in the dry substance are greatly reduced; but that with the plant of longer life, although the earlier-formed nodules become exhausted, others are constantly produced, thus providing for future growth. And the results of these experiments, taken together with those of the quantitative series, show further an intimate connection between the gain of nitrogen by the *Leguminosæ* and the development of the nodules on their roots.

As to the manner in which nitrogen is fixed, it has been suggested that, under the conditions of the symbiosis, the plant is enabled to fix the free nitrogen of the atmosphere by its leaves; but there is little or nothing in the evidence we have which leads to this conclusion. It is also suggested that the bacteria of the nodules become distributed in the soil and there fix nitrogen, which is subsequently taken by the plants from the soil. In the Rothamsted experiments, however, no gain of nitrogen was observed in the soils. Berthelot found that soils both free from higher vegetation, and soils in which leguminous plants were growing, gained in nitrogen; and Schloesing, jun., and Laurent also found fixation to take place in soils under the influence of lower plants—lichens and algæ. Nevertheless, neither experience in practical agriculture, nor the nitrogen statistics of soils and crops, indicate any material fixation of free nitrogen under the agency of microbes within the soil, independently of leguminous growth. There is, however, evidence that, in soils and subsoils containing combined nitrogen, lower organisms may serve the higher by bringing the organic nitrogen into an available form. As examples may be mentioned the fungus of fairy rings, the fungus mantle observed by Frank on the roots of certain trees, and especially the nitrifying organisms. To return to the question of fixation, the most probable explanation seems to be that free nitrogen is fixed in the course of the development of the organisms within the nodules, and that the resulting nitrogenous compounds are absorbed and utilised by the plant. It may be mentioned that Loew (Abstr., 1890, 1052), viewing the question in the light of his own results with platinum in presence of alkali, suggested the possibility that the vegetable cell, with its active protoplasm, if in an alkaline condition, may fix free nitrogen with formation of ammonium nitrite. It was frequently found at Rothamsted that the contents of the nodules, when apparently in an active condition, showed a weak alkaline reaction.

Although much of the nitrogen of leguminous crops is sometimes obtained under the conditions described, from the free nitrogen of the air, a good deal is taken up from the subsoil, chiefly as nitric acid derived from the organic matter present in the soil. A difficulty in the way of the assumption that much of the greater assimilation of the Leguminosæ than by other plants is due to nitrification of the subsoil is the fact that the direct application of nitrates has but little effect on the growth of such plants. The two cases are, however, different—nitrates, when applied, percolate more or less alone through the soil, whilst nitrates formed as a result of action on the organic nitrogen

will probably be associated with other constituents liberated at the same time.

With regard to the more practical aspects of the subject, reference is made to the experiments of Schultz, of Lupitz, who has, for some years, grown leguminous crops over large areas of poor sandy soil, using kainite and phosphatic manures; he finds the lands thereby much benefited for subsequent cereal and other crops. The system is extending in other parts of Germany, and in this country Mr. Mason, of Eynsham Hall, Oxon, is making extensive experiments on the subject.

"The experimental results which have been brought forward clearly established that there is great gain of nitrogen under some conditions. It has also been clearly shown that due infection of the soil and of the plant is an essential to success. The evidence at the same time points to the conclusion that the soil may be duly infected for the growth of one description or some descriptions of plant, but not for some other descriptions. The field experiments on leguminous crops at Rothamsted have further shown, so to speak, that land which is quite exhausted, so far as the growth of one leguminous crop is concerned, may still grow very luxuriant crops of another description of the same family, but of different habits of growth, and especially of different character and range of roots. This result, though undoubtedly more or less due to other causes also, is, nevertheless, in some cases doubtless dependent on the existence, the distribution, and the condition, of the appropriate microbes for the due infection of the different descriptions of plant. In fact, it is pretty certain that success in any system involving a more extended growth of leguminous crops in our rotations will not be obtained without having recourse to a considerable variation in the description of leguminous plant grown. Other essential conditions of success will generally be the liberal application of potash and phosphatic manures, and sometimes chalking or liming, for the leguminous crop. Then, the questions would arise—how long the leguminous crop should occupy the land; to what extent it should be consumed on the land, or the manure from its consumption be returned; or, under what conditions the whole, or part, of it should be ploughed in? Lastly, it is probable that more benefit would accrue to the lighter and poorer than to the heavier or richer soils by any such extended growth of leguminous crop." N. H. M.

Assimilation of Free Nitrogen by Plants in its Dependence on Species, on Nutrition, and on Soil. By B. Frank (*Landw. Jahrb.*, **21**, 1—44).—1. *Dependence on Species.* (*a.*) *Cryptogams.*—Earlier investigators ascribed to the non-chlorophyllous cryptogams the power of assimilating free nitrogen (Jodin, *Compt. rend.*, **55**, 612; Hallier, *Gährungsercheinungen*, Leipzig, 1867), whilst more recently this has been denied (Nägeli, *Sitzungsber. kgl. bair. Akad.*, 1879). The author's experiments with a form of penicillium, with pure cultivations of the fungus of leguminous root-nodules, and with chlorophyllous algæ, show that, when grown in non-nitrogenous media and in air free from combined nitrogen, they will develop, although only slowly, and take up elementary nitrogen. (*b.*) *Phanerogams.*—The experiments with phanerogams were, like those previously de-

scribed (Abstr, 1891, 353), made in glass pots or in glass dishes and exposed to air. The first experiments were made with buckwheat and spurrey in sandy soil (12 kilos.); a fallow experiment with heavy loam was also made. The following results were obtained (compare results with oats and rape in loam and with yellow lupins in sandy soil, *loc. cit.*):—

TABLE I.

Kind and number of plant.	Dry produce.	Nitrogen.				
		At commencement.		At conclusion.		
		Seeds.	Sand.	Produce.	Soil.	Gain.
	grams	gram	grams	gram	grams	grams
1. Buckwheat (18) ..	10·354	0·007	1·15	0·082	(2·14)*	(1·065)
2. Corn spurrey	16·755	0·012	1·15	0·111	1·21	0·159

* Assuming the percentage given (1·0178) to be a misprint for 0·0178.

The gain in the soil was greatest in the case of yellow lupins (*loc. cit.*), and is there much too great to be due to the small amount of roots left in. In no case was there any material loss in the soil, showing that the nitrogen of the plants was derived from the air.

2. *Influence of Nutrition.*—In order to ascertain the effect of different nitrogenous manures on the amount of nitrogen fixed, experiments were made with yellow lupins which were grown in ignited sand supplied with minerals: some pots had no nitrogen, others had 0·12 gram of nitrogen, either as calcium nitrate, as ammonium sulphate, or as urea. In each case there were two sets of experiments, one microbe-seeded and the other not. There were four pots (one plant in each) for each experiment. In most cases, there were no nodules formed in those pots which were not intentionally infected, and there were generally nodules on the roots of the plants to which soil was added for seeding. The total produce, &c., was determined in each experiment (the plants of the several pots of one set being taken together). As there were some failures, the average amount of produce for the successful pots and the amount of nitrogen in it and in the seed sown is given in Table II, p. 372. The actual gain, if any, cannot be ascertained, as, with the exception of the experiments with nitrates, the final amount of nitrogen in the sand was not determined.

The results show that yellow lupins and peas, without the help of soil, develop organisms when supplied with nitrogenous manure, but there is better development when the plants are infected and are not supplied with combined nitrogen than when the plants are not infected but are supplied with combined nitrogen. In the case of yellow lupins growing in symbiosis with soil organisms, the application of nitrogenous manures (at least, as nitrate, ammonia, and urea) seems to act injuriously. Peas grow best under the simultaneous action of the symbiosis and nitrate.

TABLE II.

	Dry produce (grams).	Nitrogen.				
		At commencement.		At conclusion.		
		Seed (gram).	Nitrate, &c. (gram).	Produce (gram).	As nitrate (gram).	In produce. N in seed = 1.
Yellow Lupins.						
1. Seeded	7·859	0·009	—	0·112	—	12·3
2. Seeded calcium	6·869	0·009	0·12	0·094	0·002	10·3
3. Not seeded nitrate	5·826	0·009	0·12	0·078	0·007	8·6
4. Seeded ammon.	4·890	0·009	0·12	0·051	—	5·5
5. Not seeded sulph.	7·088	0·009	0·12	0·049	—	5·4
6. Seeded urea ..	5·598	0·009	0·12	0·092	—	10·1
7. Not seeded	10·071	0·009	0·12	0·111	—	12·3
Peas.						
8. Seeded	2·264	0·009	—	0·039	—	4·2
9. Seeded calcium	6·480	0·009	0·12	0·057	0·0015	13·4
10. Not seeded nitrate	4·350	0·009	0·12	0·052	0·0010	5·5
11. Seeded ammon.	4·971	0·009	0·12	0·071	—	7·5
12. Not seeded sulph.	5·468	0·009	0·12	0·048	—	5·1

3. *Influence of Soil.*—With regard to non-leguminous plants, a great difference in development was observed when oats and rape were grown in loamy soil (with 0·118 per cent. of nitrogen) and in sandy soil (containing 0·0035 per cent. of nitrogen). The results with loam have already been given (*loc. cit.*). The results given in Table III were obtained with the sandy soil.

TABLE III.

	Dry produce (grams).	Nitrogen (grams).					
		At commencement.			At conclusion.		
		Soil.	Seed.	Total.	Soil.	Produce.	Total.
1. Fallow	—	0·30	—	0·30	0·40	—	0·40
2. Oats	8·26	0 30	0·014	0·314	0·39	0·037	0·427
3. Rape	2·13	0·27	0·003	0·273	0·37	0·022	0·392

The next experiments were made with yellow lupins and with peas grown in humous soil and in peaty soil, and the results are compared with those previously obtained with the same plants grown in sandy soil (*loc. cit.*). With regard to lupins, the plants grown in sterilised, rich soil (No. 2, in Table IV) were entirely free from nodules, and lupins can, therefore, in a good soil, assimilate free nitrogen without the help of the symbiosis; the power of assimilating free nitrogen is less in good soils than in poor, light soils, but in the poor soils this action is almost entirely due to the co-operation of the fungus.

Peas can also do without the symbiosis in good soil—the plants grown in sterilised soil (No. 5) were quite free from nodules—and take up free nitrogen from the air which is collected in the crop itself and in the crop-residue in the soil. But the symbiosis is of use even in humous soil, and increases the nitrogen assimilation. Peas did not grow very well in the peaty soil; although there were nodules on the roots of plants grown in both the infected and the non-infected pots, the growth in the pot which was infected (with lupin soil) was much the greater.

The next experiments were with red clover in sand (with minerals) in humous soil, and in peaty soil. The numerical results, together with those obtained with lupins and peas, are given in Table IV (p. 374).

In the case of the sterilised red clover plants, several of the better plants grown in sand and many of those grown in soil had nodules when taken up. The results indicate that red clover, grown in sand, can only develop and take up free nitrogen when in symbiosis with the nodule fungus; otherwise, practically no nitrogen will be assimilated. In humous soil, red clover assimilates free nitrogen very readily, and enriches the soil in which it grows; the symbiosis plays an important part in the assimilation. At the same time, in spite of the symbiosis and of the presence of the necessary minerals, the growth of red clover is, in sand, far less than in a good soil. In fact, in good soil, completely or nearly sterilised, the growth is greater than in suitably infected sand. The experiments with peaty soil showed a much greater development with clover than with peas.

Summary.—All plants assimilate free nitrogen, but some of them require nitrogenous manures. There is only one plant (yellow lupin) which assimilates more nitrogen when grown in nitrogen-free soil than in presence of combined nitrogen. Peas, and probably most *Leguminosæ*, yield large amounts of nitrogen only when supplied with combined nitrogen (especially nitrates), but the amount required is less than is generally supposed. Lupins should only be grown in poor soils; peas, red clover, and probably many other *Leguminosæ* give better results when grown in good soils; the more these plants are strengthened by the application of combined nitrogen, the more free nitrogen they will be able to assimilate. Non-leguminous plants can only be made to recover from the state of hunger when grown in nitrogen-free soil by the application of combined nitrogen; when they have thus gained strength, they assimilate free nitrogen. Leguminous plants, on the other hand, recover from this period of nitrogen hunger, not only when they are supplied with combined nitrogen,

N. H. M.

Nitrogen Question. By H. IMMENDORFF (*Landw. Jahrb.*, **21**, 281—339).—With regard to losses of nitrogen, there is no reason to suppose that when nitrogen compounds free from nitrites and nitrates decompose without access of oxygen, free nitrogen will be liberated. This view is supported by the experimental results of Kellner (*Zeit. physiol. Chem.*, **12**, 95), Tacke (*Landw. Jahrb.*, **16**, 917), and Ehrenberg (Abstr., 1887, 172 and 746), and more recently of Schloesing (Abstr., 1890, 282). The case is, however, different when nitrites and nitrates are present in the decomposing matter; reduction takes place, free nitrogen is liberated, and all the intermediate oxy-

compounds will be formed (Tacke, *loc. cit.*). In Tacke's experiments, the reduction was diminished, but not altogether prevented, by the presence of air, and it is possible that with still better ventilation the reduction might have been stopped altogether. Losses of nitrogen during the process of nitrification was observed by Dehérain (Abstr., 1887, 993), and Tacke (*Landw. Jahrb.*, **18**, 439), whilst in Ehrenberg's experiments (*loc. cit.*), in which, however, ventilation was deficient, no evolution of free nitrogen was detected, and Schloesing's results (Abstr., 1889, 638 and 1239) indicated that a loss of free nitrogen is not necessarily a consequence of nitrification.

The power of fixing nitrogen, which Berthelot ascribes to some especially poor soils, was in no case confirmed by Schloesing (Abstr., 1888, 1330); not even after two years exposure of a soil to air. On the other hand, Berthelot's results are supported by those of Gautier and Drouin, Dehérain, Pechard and Tacke (*loc. cit.*). Inasmuch as no constituent of soils is known to have the power of fixing nitrogen, the fixation, if admitted at all, is ascribed to bacteria; and it seems not unlikely that the soil bacteria which fix nitrogen are identical with those which, as has been shown by the indirect experiments of Hellriegel and others, and the direct experiments of Schloesing and Laurent, have the same power when living in symbiosis with leguminous plants. It may be mentioned, however, that in Berthelot's experiments, sterilised soils and soils infected with the contents of leguminous nodules, showed no material difference with regard to the amount of nitrogen they fixed.

In the first series of the author's experiments, mixtures of blood meal, garden soil, and chalk, and of bone meal, soil, and chalk respectively were kept for some months, at a temperature of 28—30° in glass tubes, from which all the air had been expelled and replaced by oxyhydrogen mixture (prepared by electrolysis). The different parts of the apparatus, of which a sketch is given, were fused together, so as to avoid the use of joints or corks; and it was so arranged that samples of the gas could be obtained as often as desired for analysis, without interrupting the experiment. In the first weeks, no appreciable amount of nitrogen was evolved, but subsequently there was a loss in Experiment 1 (with 14·856 grams of substance, containing 0·3151 gram of nitrogen) of 20 miligrams of nitrogen. In Experiment 2 (with 14·3969 grams of soil, &c., containing 0·2208 gram of nitrogen) the loss of nitrogen was 11 milligrams. No nitrous oxide was given off.

In the other series of experiments, layers of soil or other substances were put in alternate layers with pieces of glass rod in upright cylinders, so constructed that air free from combined nitrogen could be passed through from below, and any ammonia which might be given off absorbed by acid, and the quantity determined at the end of the experiment.

The following table shows the nature and amounts of the substances experimented on, the total initial and final nitrogen; the nitrogen as nitric acid, and the nitrogen as ammonia, found at the end of the experiments. The experiments 1—6 extended over nearly a year, whilst the others lasted from 16 to 22 weeks.

* Containing 33·7 per cent. of soluble phosphoric acid.
† Containing 8·6 per cent. of soluble phosphoric acid.

With regard to loss of free nitrogen, the results show that it may take place during decomposition in presence of plenty of oxygen, both when nitrification takes place and when ammonia is formed. Gain of nitrogen took place (Experiments 10, 11, 12) in substances containing plenty of nitrogen, and coincidently with large production of ammonia. As other experiments indicate that under these conditions loss of free nitrogen takes place, this was probably also the case in these three experiments, and the gain must therefore have been still greater than the numbers indicate. The last six experiments are of further interest as showing the retentive power, or want of such a power, for ammonia of various substances. The superphosphate retained the whole of the ammonia; the superphosphate-gypsum, and gypsum kept back some, but allowed very much to escape. Kainite, on account of its greater solubility, acts more strongly in fixing ammonia than either superphosphate-gypsum or gypsum. Calcium carbonate assists the volatilisation of ammonia. When phosphoric acid was used, there was no loss of free nitrogen, whilst when other substances, especially kainite, were employed, the loss of free nitrogen was considerable. The author is, however, not prepared to say that the non-evolution of nitrogen was due to the presence of phosphoric acid (compare v. Krause, Abstr., 1890, 1340).

In the course of the first series of experiments, it was noticed that when the tube containing soil was filled with electrolytic gas, the gas disappeared entirely in a few days. In order to ascertain whether this was due to the physical and chemical properties of the soil, or to micro-organisms, the following experiments were made:—25 grams of moderately moist arable soil was put into the apparatus (similar to that used in the first set of experiments already described), which was exhausted and filled with the oxyhydrogen mixture. In the first four weeks there was only a slight absorption, but a good deal of carbonic anhydride was evolved; afterwards the absorption was more rapid, and in about five weeks almost the whole of the gas was absorbed, and nearly a vacuum produced. A similar experiment in which a few drops of chloroform were introduced into the apparatus showed that under these conditions only a trace of carbonic anhydride was given off, and that no absorption of the oxyhydrogen mixture took place. Two more experiments were made in which blood meal (5 grams) was mixed with the soil; similar results were obtained. The absorption of oxygen and hydrogen is therefore probably due to micro-organisms in the soil. The author considers this power of uniting oxygen and hydrogen to be more remarkable than the power of fixing nitrogen, and refers to the processes studied by Winogradsky, in which bacteria oxidise ferrous oxide to ferric oxide, hydrogen sulphide to sulphur, and finally to sulphuric acid, &c.

Experiments were also made to see if pure cultivations of bacteria from pea and bean nodules have the power of assimilating free nitrogen, but they always failed to develop well in nutritive solutions free from nitrogen.

The following conclusions are drawn from the above results:—(1.) Loss of nitrogen can take place in decomposing nitrogenous

matter, independently of nitrification; whilst it does not take place when air is excluded. (2.) It is not established whether free nitrogen is eliminated during the nitrification of ammonia with sufficient ventilation. (3.) Free nitrogen is fixed not only in poor soils, but in materials rich in nitrogen. (4.) Superphosphates are excellent preservatives for farmyard manure, even when air has access. Superphosphate-gypsum is of less value, whilst gypsum and kainite are far less effective still. (5.) Arable soil, after undergoing a process of decomposition, has the power of uniting oxygen with hydrogen, the union being probably accomplished by bacteria. (6.) No kind of bacteria has as yet, with certainty, been isolated which has the power of fixing free nitrogen; although it is established that the *Leguminosæ*, with the help of certain known bacteria, are in a position to employ free nitrogen to their advantage.

Sketches are given of the apparatus employed, which was similar to that used by Tacke.

After the above investigation was completed, the author found that the absorption of oxygen and hydrogen by soils had been discovered by de Saussure, in 1834. Liebig (*Annalen*, **153**, 142) considered the process to be a purely chemical one. N. H. M.

Fixation of Free Nitrogen by Plants. By T. Schloesing, Jun., and E. Laurent (*Compt. rend.*, **113**, 776—778).—An extension of the work on the Leguminosæ (Abstr., 1891, 353) to other classes of plants. Two experimental methods were employed, the first consisting in measuring the decrease in volume of the nitrogen of the atmosphere in which the plants were confined, the other in estimating the increase of the total nitrogen in the soil, seeds, and crop during the experiment. The results yielded by the two methods agree well. As the conditions under which nitrogen might be absorbed were unknown, it was necessary to employ natural soil, for which purpose a poor sandy earth was enriched with calcareous earth, and with garden soils in which grass, trefoil, lupin, and beans had been grown; it was watered with nutritive mineral solutions also, and, after the seeds had been sown, with an aqueous extract of the mixture of garden soils.

In the first set of experiments, which extended over $3\frac{1}{2}$ months, the results were obscured by the growth of mosses and algæ on the surface of the soil, and although it was found that the nitrogen absorbed was markedly greater in the case of the leguminous plants (peas) than in those of the others (Jerusalem artichokes, oats, and tobacco plants), yet it could not be ascertained to which vegetation the absorption was due. That nitrogen was assimilated during the growth of the cryptogams was evident, since in one of the blank experiments in which no appreciable growth appeared on the surface of the soil, no sensible amount of absorption took place, whilst in other blank experiments in which the lower growths had developed freely, a considerable amount of nitrogen was taken up.

In a second set of experiments, which extended over three months, the lower growth was prevented by covering the soil with a layer of calcined quartz sand, and it was found that neither with soil alone,

nor with growing plants of oats, mustard, cress, or asparagus, was there any sensible absorption, whilst with peas, a very considerable amount of nitrogen was found. In the last case it was remarked, too, that nodosities had formed on the roots.

Berthelot (*ibid.*, 778—779), in calling attention to the above note, points out the confirmation which the results bring to his own researches and views on this subject. Jn. W.

Proteïds of the Maize-kernel. By R. H. Chittenden and T. B. Osborne (*Amer. Chem. J.*, **13**, 453—468; compare Abstr., 1891, 1285). —The authors propose to investigate, first, the proteïds which are soluble in salt solution, but insoluble in water; secondly, those which are soluble both in water and in salt solution, and, thirdly, those which are insoluble in water and salt solutions, but soluble in alcohol. The present paper relates to the first class.

When fine freshly-ground maize-meal is extracted in the cold with 10 per cent. sodium chloride solution, it yields a yellow solution, from which the proteïds may be precipitated either by removing the salt by dialysis or by adding ammonium sulphate to saturation. The precipitate is purified by redissolving in sodium chloride solution and again dialysing, and then separates in small spheroïds, which adhere to the walls of the dialyser, and closely approximate to crystals in character. The ammonium sulphate precipitate is partially soluble in water, and may therefore be treated with that solvent before digesting with sodium chloride, the two solutions being mixed before dialysing. 5 per cent. ammonium chloride solution may be substituted for the sodium chloride, the proteïds being precipitated as before by ammonium sulphate. The products obtained in this way were of practically identical composition:—C, 51·65; H, 6·82; N, 17·69; and S, 0·93. The yield of pure product obtained by the first method was 0·2 per cent.

When the sodium chloride solutions of the proteïds are heated, they become turbid, and at a somewhat higher temperature form a flaky coagulum; if this is filtered off, the clear filtrate undergoes the same changes when raised to a still higher temperature, and so on, several distinct fractions being obtained; even when the solution has been boiled for some time, the filtrate often yields a precipitate with acetic acid. The temperatures of coagulation are not, however, very constant, as they are considerably altered by slight variations in the methods of extracting and purifying the proteïds. From a consideration of these phenomena it appears that the proteïd matter either consists of several distinct globulins, or is itself a simple globulin capable of being split up by the action of heat. It may, for instance, be a mixture of variable proportions of vitellin and an uncoagulable globulin. Phytomyosin cannot be present in quantity since very little precipitate is thrown down when the sodium chloride solution of the proteïd is saturated with that salt.

An attempt was made to fractionate the proteïd matter based on the facts that it is not entirely redissolved by sodium chloride solution, and that the soluble portion is only partially reprecipitated by the addition of a large quantity of water. The fractions soluble in

sodium chloride were of practically the same composition as the original proteïds, but the insoluble fraction contained appreciably less nitrogen (15·59 per cent.). The formation of the insoluble proteïd may be explained by supposing that the globulin is partially converted into an albuminate. Another attempt was based on the varying solubility of the proteïd in sodium chloride solutions of different strengths; but the fractions obtained were unaltered in composition. Jn. W.

Choline and Betaïne in Cotton Seed Foods. By W. Maxwell (*Amer. Chem. J.*, **13**, 469—471).—The bases were extracted from finely ground cotton-seed cake with 70 per cent. alcohol, and purified by means of the mercurochlorides. The hydrochlorides prepared from the latter were separated by means of absolute alcohol, in which the betaïne salt is very sparingly soluble. The relative amounts of choline and betaïne hydrochloride thus obtained were as 1 to 5·7. The relative amounts obtained from cattle food prepared from a sample of the same cotton seed was as 1 to 4·7. Jn. W.

Occurrence of Gums which yield Xylose. By A. Voswinkel (*Chem. Centr.*, 1891, ii, 655; from *Pharm. Centralhalle*, **32**, 505—507).—The author found these gums in several fungi, *Cantharellus cibarius*, *Hydnum repandum*, *Clavaria flava*, *C. botrytis*, *Psaliota campestris*, *Boletus edulis*, and *B. granulatus*. It was separated by extracting the ground fungus with soda; the extract was then precipitated with alcohol and the precipitate washed with alcohol containing a little hydrochloric acid. The product gave the phloroglucinol and furfuraldehyde reactions, and was converted into xylose by dilute sulphuric acid. J. W. L.

The Poisonous Constituent of the Ethereal Fern Extract. By E. Poulson (*Chem. Centr.*, 1891, ii, 673; from *Arch. expt. Path. Pharm.*, **29**, 1—24).—The author's experiments show that the poisonous properties of fern extract are due to an amorphous substance which is the true *filicic acid*. The acid is readily converted into its lactone, by simply boiling its ethereal solution. The lactone is named *filicin* by the author. The filicic acid melts at 184·5°; filicin melts at 125°. The pure acid may be obtained from filicin by dissolving the latter in cold dilute soda, and filtering the solution into dilute hydrochloric acid. The white precipitate is then dried over sulphuric acid. Determinations of the molecular weights of the two compounds by Raoult's method gave for filicin 642 and 654, which, in conjunction with the analysis, indicates the formula $C_{35}H_{40}O_{12}$, whilst, for filicic acid, the numbers 663—699 were obtained, and this, in conjunction with the analysis, indicates the formula $C_{35}H_{42}O_{13}$. The author considers filicic acid to be suitable for therapeutical purposes; it is readily soluble in the alimentary canal, but difficultly reduced and either kills parasitic organisms or expels them, without damaging the canal. It appears to be more readily absorbed if taken with oil than if taken alone. J. W. L.

Ammonia in the Atmosphere and Rain Water of the Tropics. By V. Marcano and A. Muntz (*Compt. rend.*, **113**, 779—781).—The observations, which extend over several years, were made near Caracas, Venezuela, in 10° N. latitude, at an altitude of 922 metres above sea-level. The temperature of this locality is constant, the rains very intermittent, and the storms violent and numerous. It has already been shown (Abstr., 1889. 923) that the nitric and nitrous nitrogen in the air of this region is ten times more abundant than in that of more temperate climates, and it is now found that the ammonia is distinctly less, a surface of acidified water 1 square metre in area absorbing in 24 hours an average of 0·01252 gram of ammonia, as against 0·02 and 0·024 in France. This unexpected result is probably due to the formation of solid ammonium nitrite and nitrate in the air, a theory borne out by the excessive amount of ammonia found in the rain water, 0·00155 gram per litre on an average, as against 0·00052 gram in Alsace (Boussingault) and 0·00097 at Rothamsted (Lawes and Gilbert). (Compare, however, next abstract.) Jn. W.

Ammonia in Rain Water. By Albert-Lévy (*Compt. rend.*, **113**, 804—805).—The author points out that the figures of Lawes and Gilbert quoted by Marcano and Muntz (preceding abstract) varied considerably from year to year, and that, in 1856 for example, they found 0·00143 gram of ammonia per litre, an amount quite comparable with those obtained by the authors criticised. He also quotes various other data to show that the amount of ammonia in the rain water of Venezuela is not excessive; the mean amount, for instance, in the rain water of Montsouris, France, where he has estimated the ammonia in every downpour for upwards of 16 years, is as much as 0·0022 gram per litre. Jn. W.

Analytical Chemistry.

Test for Hydrogen Peroxide. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 22—23; compare Abstr., 1891, 1549).—The author claims priority over Denigés for the use of the ammonium molybdate and sulphuric acid test for hydrogen peroxide (Abstr., 1890, 1185). He further states that the test is not trustworthy, as it is coloured yellow by faint traces of organic matter and by hydrogen phosphate and silicate, and yields a blue coloration when the test is made on alcoholic or aldehydic derivatives. The following test is without these disadvantages:—To the suspected liquid, 3 or 4 c.c. of ammonium molybdate solution (10 per cent.) is added, and subsequently a few drops of citric acid solution (25 per cent.); if hydrogen peroxide be present, a yellow coloration ensues. This test is capable of detecting 1/10 milligram hydrogen peroxide in 400 c.c. water. The author notes that commercial paraldehyde contains notable quantities of hydrogen peroxide. T. G. N.

Standardising Iodine Solution for the Determination of Sulphur in Steel and Pig Iron. By J. M. Wilson (*Chem. News*, **64**, 252).—Using a standard steel, the author standardises his iodine solution by the same process as he uses for the determination of sulphur in the samples of pig-iron and steel submitted for analysis, and finds the result satisfactory. D. A. L.

Estimation of Sulphur. By G. Craig (*Chem. News*, **64**, 266—267).—20 grains of slag, finely ground, is heated with 1 oz. of water, in a flask furnished with a tap funnel, with a nitrogen bulb partially filled with glass beads and charged with ammonia and hydrogen peroxide for outlet, and with a Liebig's bulb charged with potash and hydrogen peroxide for inlet through which coal gas is now admitted to expel air; the heating is continued, and hydrochloric acid is run in from the funnel, the whole is agitated until the slag is decomposed, boiled, and finally coal gas is aspirated through. The nitrogen bulb is now washed out, and the sulphur determined as barium sulphate. To make the estimation in pyrites, the finely pulverised ore, well mixed with zinc-dust in a small Bohemian glass tube, is covered lightly with the disc-like end of a flattened glass rod, which is packed round with asbestos, the tube is heated at first gently, finally for 30 seconds at a red heat; it is then, when cool, dropped into a flask like that employed above, but fitted at the outlet with a reflux condenser, a U-tube containing calcium chloride, and finally, a U-tube filled with glass beads and sodium hydroxide. The operation proceeds as described above, but the hydrogen sulphide is not oxidised. D. A. L.

Estimation of Sulphur in Organic Substances. By A. Angeli (*Gazzetta*, **21**, ii, 163—165).—Some organic substances containing sulphur resist the oxidising action of nitric acid when heated with it in a sealed tube for determination of the sulphur by Carius' method. The author finds that the addition of bromine very considerably assists the oxidation; for example, sulphonal, which offers great resistance to oxidation by nitric acid alone, is completely oxidised when heated with nitric acid of sp. gr. 1·52 and bromine for six hours at 210°. W. J. P.

Estimation of Phosphoric Acid in Slags. By V. Edwards (*Chem. News*, **64**, 275).—A slag which resisted aqua regia succumbed satisfactorily to the action of boiling concentrated sulphuric acid in the presence of some mercury; the resulting liquid, when cold, was diluted, and an aliquot part filtered, and precipitated directly with citro-magnesic solution and ammonia. The precipitate was dissolved in nitric acid and titrated with uranium solution. D. A. L.

Estimation of Arsenic in Wall-paper. By C. R. Sanger (*Amer. Chem. J.*, **13**, 431—453)—To avoid the waste of time, the inconvenience of using large quantities of material, and the introduction of large percentage errors in weighing which are involved in the ordinary form of the Marsh process, it is modified in order that the

mirror obtained under standard conditions may be compared with a set of standard mirrors obtained under the same conditions from known amounts of arsenious anhydride.

20, 50, or 100 sq. cm. of the paper, according to the size of the pattern and the amount of arsenic present, as judged by the colour of the paper and its smell when burned, is cut into small pieces and charred by heating with 1—5 c.c. of strong nitrosulphuric acid (1 : 30), the excess of nitric acid being afterwards expelled. The use of an oxidising agent is essential, owing to the presence of chlorides, which would cause the volatilisation of 12—60 per cent. of the arsenic, and of sulphur compounds such as ultramarine, which would cause its retention as insoluble sulphide. Nitric acid is recommended, as it is simple and speedy in action; the oxidation of the arsenic is immaterial, as arsenic salts are found to yield the same results as arsenious salts; and the presence of small quantities of nitric acid in the Marsh flask does not cause the retention of the arsenic, as stated by Blondlot (*Compt. rend.*, **57**, 596).

The charred mass is moistened, and then thoroughly broken up with 5 c.c. of water; the sulphurous anhydride is expelled by boiling, as otherwise arsenious sulphide may be formed during the subsequent operations, the liquid is filtered into a tared test-tube, and the residue is repeatedly washed with hot water. If a filter-pump is used, the filtrate and washings need not amount to more than 35 c.c. The extract is now ready for reduction in the modified Marsh apparatus.

This consists of a wide-mouthed, india-rubber-stoppered bottle of 75 c.c. capacity, provided with a funnel-tube for introducing liquids, and connected on the one hand with a continuous hydrogen apparatus, and on the other with a tube of fused calcium chloride leading to a hard glass reduction-tube. Sulphuric acid cannot be used as a desiccating agent, as it dissolves the hydrogen arsenide. The reduction-tube, of 7 mm. bore, is drawn out at the end to 1·5—2·0 mm. bore, and bent up and sealed. At the commencement of each operation, the bottle is charged with 3 grams of finely-granulated zinc, and, the tightness of the apparatus having been tested, the end of the reduction-tube is broken, 20 c.c. of dilute (1 : 8) sulphuric acid is run into the flask, and hydrogen is turned on from the generator, and burned at the end of the reduction-tube in a flame 1—2 mm. high. By the use of an additional hydrogen generator the necessity for stimulating the evolution of hydrogen in the Marsh flask is obviated; it may be necessary even to cool the liquid. The use of hydrochloric acid in either the generator or the flask is inadmissible, as the mirror is then liable to be contaminated with zinc chloride. The air having been thoroughly expelled, the constricted part of the reduction tube is heated by a Bunsen flame kept steady by an iron cone. No mirror should appear in the course of 20 minutes.

The prepared extract is now gradually introduced through the funnel-tube, the lower end of which is constricted to avoid the mechanical introduction of air. The amount added, which should not contain more than 0·06 milligram of arsenious anhydride, is determined by weighing the test-tube before and after. After 25 minutes, the whole of the arsenic has been transferred to the

reduction-tube, as if the action is continued until all the zinc has dissolved there is no increase in the density of the mirror.

The mirror is now compared with a standard set, made in a similar way from quantities of arsenious anhydride varying from 0·005 to 0·06 milligram. These standards, which must be kept in the dark to avoid oxidation, are best mounted in frames which, together with a frame containing the specimen under examination, can be mounted horizontally in a box resembling a stereoscopic camera, so that the comparison may be made by transmitted light. As small an amount as 0·001 milligram of arsenious anhydride can be detected by the process.

As a check on the results obtained, the arsenic in the various samples of paper examined was estimated by titration with iodine, after solution and reduction with sulphurous anhydride. The organic matter was separated by igniting the paper with potassium nitrate, by charring it with nitrosulphuric acid, or by distilling it with hydrochloric acid. The results agree well. JN. W.

Estimation of Boric Acid. By O. HEHNER (*Analyst*, 1891, 141—145).—Stolba long ago proposed to fix boric acid in solution by adding a known excess of borax and igniting the residue. The author finds that very good results may be obtained, but that the greatest caution is necessary to avoid loss by spirting during the ignition of the residue.

After unsuccessfully attempting to fix the boric acid by means of ammonia or sodium carbonate, the author has succeeded in getting excellent results by the addition of a known weight of sodium pyrophosphate in the shape of disodium hydrogen phosphate.

L. DE K.

Estimation of Combined Alkali in Soap. By J. A. WILSON (*Chem. News*, **64**, 205).—The total alkali having been determined in the usual manner, the alkali as soap is ascertained in the following way:—A weighed quantity of soap is decomposed, on a water-bath, with dilute sulphuric acid, cooled in ice, filtered, and the fatty acids washed three times successively with 250 c.c. of boiling water, cooling and filtering each time. Then, to determine the proportion of the alkali of the soap in combination with the soluble fatty acids, the united filtrates are made up to 1 litre and 500 c.c. of the solution titrated with decinormal alkali, using methyl orange as indicator in the first instance, and finishing off with phenolphthalein; the latter numbers, calculated to caprylic acid, are those required. The insoluble fatty acids are dried, weighed, dissolved in alcohol, and the alkali originally combined with them estimated by titrating with semi-normal alkali.

Or the acid, equivalent to the alkali existing in all forms, is obtained by decomposing the soap with standard sulphuric acid, titrating the excess with methyl orange and deducting it from the total quantity of acid employed. D. A. L.

Separation of Manganese and Zinc. By E. DONATH (*Ber.*, **24**, 3600—3602).—A question of priority.

Estimation of Manganese in Slags and Ores. By G. L. Norris (*Chem. News*, **64**, 242—243).—A gram of finely powdered slag, moistened with water, is mixed with 50 c.c. of nitric acid (sp. gr. 1·420), heated to boiling, treated with 3 or 4 c.c. of hydrofluoric acid and boiled for a few minutes, when the decomposition is complete. More nitric acid is added, the whole heated to boiling, and the manganese precipitated with potassium chlorate. The precipitate, collected on an asbestos filter, is either finally weighed as pyrophosphate, or is dissolved in standardised ferrous sulphate or oxalic acid, and the excess of solvent titrated with potassium permanganate.

With ores, tartaric acid is added before the hydrofluoric acid, or when much iron is present in the ore these acids are added together; the excess of the latter being boiled off and of the former decomposed, and the estimation proceeded with as above. D. A. L.

Quantitative Separation of the Metals of the Hydrogen Sulphide Group by Means of Bromine Vapour. By P. Jannasch and P. Etz (*Ber.*, **24**, 3746—3748).—The quantitative separation of bismuth and cadmium may be readily effected by precipitating the metals with hydrogen sulphide, and after drying and weighing the mixed sulphides, transferring them to a porcelain boat, which is placed in a combustion tube and gently heated in a rapid stream of air and bromine vapour; the bismuth volatilises, and is condensed in an absorption apparatus containing dilute hydrochloric acid. The operation occupies about half an hour. The residual cadmium bromide may be dissolved in a small quantity of hydrochloric acid and precipitated with sodium carbonate. The bismuth solution is treated with nitric acid and evaporated to dryness, and this operation repeated until all the hydrochloric acid has been eliminated; the bismuth is then precipitated with ammonium carbonate solution containing a little ammonia.

The analytical results agree very closely with the theoretical numbers. J. B. T.

Separation of Bismuth from Lead. By W. Remmler (*Ber.*, **24**, 3554—3556).—The author has studied the method of separating bismuth from lead, based on the volatility of bismuth chloride, and finds that the two chlorides can be easily and accurately separated by heating the mixture at the boiling point of sulphur.

For this purpose he employed a small apparatus consisting of two test-tubes placed one inside the other, the space between them containing the sulphur; the mixture of the two chlorides is placed in a much smaller tube, and is introduced into the apparatus by means of a glass rod, which is bent into a ring at its lower extremity; during the heating, which lasts an hour, a stream of dry chlorine is passed into the small tube containing the substance.

When the two metals are obtained as sulphides, as is usually the case, the mixture is first heated for an hour in a xylene bath, and then for a like period in the sulphur bath, a stream of chlorine being passed during both operations; by this means the sulphides are first

converted into chlorides, and then the bismuth chloride is completely volatilised. An analysis of a mixture of the metals containing 42·17 per cent. of lead gave in this way 42·09 per cent.; another sample containing 43·74 per cent. of lead gave 43·43 per cent.

F. S. K.

Reaction of Certain Essences with Manganous Salts. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 25—29).—When turpentine is shaken with an ammoniacal manganous solution, and a current of air is passed through the mixture, the hydrocarbon becomes coloured dark brown. Although this reaction occurs with both dextro- and lævo-gyrate varieties, it does not obtain with pinene or fresh steam-distilled turpentine. Pure pinene exposed to dry or moist air for a day or two gives the reactions of hydrogen peroxide, and also reacts as an aldehyde with alkaline potassiomercuric iodide solution, with magenta in sulphurous acid, and with metamidobenzene hydrochloride, but does not give the above described reaction unless it has been kept for two to three months in half-filled vessels, when it gradually acquires the property; this is probably due to the formation of acids by partial oxidation of the pinene, since traces of fatty acids dissolved in pinene or freshly distilled thyme, lemon, or turpentine oil at once determine the reaction described. Turpentine and lemon oils which have resinified do not react, since they are deficient in pinenes, which are necessary both as solvents of the manganese salt and as sources of hydrogen peroxide. To determine the nature of the brown substance, 10 kilos. of French turpentine oil were treated with ammoniacal manganous solution, and a current of air passed through the warmed emulsion. The brownish-black essence, after distillation at a pressure of 10—15 mm., was treated with alcohol, when it formed a brownish-black mass; this, after washing with alcohol, was taken up with chloroform (in which it was freely soluble), and reprecipitated from this solvent by alcohol. As thus obtained, it forms a greyish powder which is insoluble in water, and only slightly soluble in alcohol, but freely so in carbon bisulphide, ether, and chloroform, yielding brownish-black solutions.

Analysis points to the formula $Mn_2C_{18}H_{28}O_6$, and the author considers the substance to be the manganese salt of an acid $C_9H_{14}O_2$, produced together with formic acid by oxidation of the turpentine molecule, since he finds that formic acid is a constant product of turpentine oil distillation, and turpentine solutions of the brown product deposit crystals of manganous formate. The solution of the brown substance in ether is decomposed by hydrogen chloride with formation of anhydrous manganous chloride, but evaporation of the residual ether gave no defined result. The brown substance, treated with hot sodium hydroxide solution, filtered, acidified, and extracted with ether, yielded odorous pitchy substances, which did not crystallise.

T. G. N.

Detection of Turpentine and other Impurities in Essences. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 29—30; compare preceding abstract).—Hydrogen potassium tartrate (20 grams) is neutralised with manganous carbonate (5—6 grams), and dissolved in a litre of water.

5 c.c. of the essence to be tested, 3 c.c. of the above solution, and 5 drops of ammonia solution (sp. gr. 0·925) are well shaken together in a test tube, which is then placed in a water bath, and a current of air passed through the contents for 30 seconds; the tube is then removed, its contents well shaken, and allowed to separate. With the exception of the oils of lemon and bergamot, which are coloured dark brown, the majority of pure essences are but faintly tinged with yellow, whereas the addition of turpentine determines a coloration varying from brown to intense brown-black in the supernatant essence. T. G. N.

Analysis of Spirits. By J. Bell (*Analyst*, 1891, **185**, 171—174).—*Estimation of the Free Acids.*—50 c.c. of the spirit, previously reduced to proof strength, is distilled to dryness in a glass retort. The distillate is titrated with N/10 barium hydroxide, using phenolphthalein as indicator. To ascertain the nature of the acid, the liquid is evaporated to dryness, and the barium salt weighed. Its combining weight is then found by converting it into sulphate.

Estimation of Ethereal Salts.—50 c.c. of the spirit at proof strength (redistilled if necessary) is directly neutralised with N/10 barium solution. The spirit is then placed in a glass retort, and distilled to dryness, the first 30 c.c. being collected separately. The distillates are now heated, in a closed flask, with a known volume of N/10 barium hydroxide, the excess of which is afterwards titrated. 1 c.c. of the barium solution corresponds with 0·0088 gram of ethyl acetate. The true nature of the compound may be ascertained by an analysis of the dry organic barium salt.

Estimation of the Higher Alcohols.—100 c.c. of the spirit at proof strength is digested with an excess of barium hydroxide, and then distilled almost to dryness. The distillate is then further diluted until it is 70 u. p., and repeatedly shaken out with chloroform. The latter, after having been repeatedly washed with water to remove any ethyl alcohol, is oxidised with a mixture of sulphuric acid and potassium permanganate, in a closed flask, at a temperature of 80° F. This operation takes about three days, and the mixture must be repeatedly shaken during that period. When the oxidation is complete, the excess of permanganate is reduced by a few drops of sulphurous acid, and the liquid rendered distinctly alkaline with normal soda. After removing any chlorine with silver sulphate, the aqueous filtrate is distilled with 10 c.c. of normal sulphuric acid, and the distillate received into a solution of N/10 barium hydroxide.

From the amount of barium neutralised, and the subsequent examination of the organic barium compound, the quantity of the higher alcohols may be calculated by employing the usual factors.

L. de K.

Estimation of Sugars by Means of Ost's Copper Solution. By M. Schmoeger (*Ber.*, **24**, 3610—3620).—A number of quantitative experiments were made in order to ascertain whether sugars can be accurately estimated with the copper solutions described by Ost (Abstr., 1891, 125, 1298), for which he claims many advantages over Fehling's solution; the experiments confirmed Ost's statements

in all respects except, perhaps, as regards the stability of the more concentrated copper solution, because, on long keeping in glass vessels, a deposit of copper silicate is formed in this solution.

Sugar, in solutions containing calcium, cannot be directly estimated by Ost's method because, on boiling, calcium carbonate is precipitated and the weight of the copper oxide is thereby increased considerably; in such cases, the calcium may be removed by precipitation with potassium oxalate, and the analysis then carried out as usual, as the presence of a small quantity of oxalic acid does not affect the results.

F. S. K.

Analysis of Sugar, Molasses, and Syrup. F. W. Babington (*Analyst*, 1891, 181—185).—*Saccharimeter Readings.*—The author dissolves 13·024 grams of the sample in 50 c.c. of warm water in a flask of 100 c.c. capacity, adds 1 gram of purified animal charcoal, and after agitating occasionally for half an hour, mixes with 30 c.c. of alumina cream. After making up to 100 c.c. and filtering through a dry filter, the liquid is examined in the 20 cm. tube in a Soleil-Ventzke-Scheibler apparatus.

Clerget Inversion.—50 c.c. of the same solution is mixed with 2·5 c.c. of fuming hydrochloric acid and heated during 20 minutes at a temperature of 60—70°. After cooling and making up to a volume of 55 c.c., the liquid is examined in the 22 cm. tube. The following formula is then applied:—

$$\frac{(\text{Direct reading} + \text{invert reading})\ 200}{142{\cdot}7 - \frac{1}{2}\ \text{temperature of inverted solution}} = \text{p. c. of cane sugar.}$$

Reducing Sugars.—The author prefers the gravimetric estimation by means of Fehling's solution. The cuprous oxide is collected on a weighed asbestos filter and weighed as such. If 2·5 grams of the sample has been used, the percentage of reducing sugars will be found by multiplying first by 0·4861 and then by 40. If it is desired to also estimate the cane sugar gravimetrically, 0·25 gram of the sample must be inverted as in Clerget's process, and then again carefully neutralised with sodium carbonate.

Moisture and Water.—The moisture in ordinary moist sugars is estimated by drying 2 grams to constant weight, but in the case of syrups or molasses, 20 grams of the sample is dissolved in water and made up to 100 c.c. 20 c.c. of this solution (= 4 grams of sample) is put into ordinary asbestos fibre contained in a milk tube, the tube and contents having been previously dried and weighed. The tube is then placed in a water-bath and dried for 48 hours at a temperature of 90—100°. The increase of the weight of the tube and contents gives the amount of dry substance contained in 4 grams of the sample, water being found by difference.

L. de K.

Estimation of Furfuraldehyde and of Pentoses. By A. Günther, G. de Chalmot, and B. Tollens (*Ber.*, **24**, 3575—3585).—After replying to some observations of Stone (this vol., p. 247), the authors describe two methods for the estimation of pentoses in vegetable products (compare Abstr., 1891, 769). In the first method, the

finely-divided substance (5 grams) is distilled from a flask with hydrochloric acid of sp. gr. 1·06 as long as the distillate gives a red coloration with aniline acetate paper, fresh hydrochloric acid being added from time to time as that in the flask passes over; this process generally occupies 4—6 hours. The distillate is neutralised with solid sodium carbonate, then acidified with acetic acid, and titrated with a solution of phenylhydrazine of known strength until a drop of the mixture no longer gives a reaction with aniline acetate paper; the quantity of furfuraldehyde in solution being thus determined, the percentage of arabinose or xylose is calculated by multiplying by factors which are obtained by ascertaining the quantity of furfuraldehyde formed from the pure pentoses under the same conditions. If, for example, 5 grams of a substance containing arabinose gives 0·75 gram or 15 per cent. of furfuraldehyde, this quantity must be multiplied by 100/51·7, which gives 29 per cent. of arabinose; in the case of xylose, the factor would be 100/52·3. As, however, the percentage of furfuraldehyde obtained depends on the quantity of substance taken, and on other conditions, the factors are different for different cases, varying from 100/53·5 to 100/47·2 in the case of arabinose, and from 100/55·2 to 100/50·4 in the case of xylose, as the percentage of furfuraldehyde rises from 5 to 20 per cent. It must also be remembered that pentoses are not actually present in the vegetable substances, but are the products of hydrolysis of the pentosans; to calculate the percentage of the last-named substances, the percentage of the pentoses should probably be multiplied by 0·88.

In the second method, the quantity of furfuraldehyde is estimated gravimetrically, instead of volumetrically, by weighing the precipitated hydrazone after it has been washed with water and dried at 50—60°; the quantity of furfuraldehyde in the 5 grams of substance taken is obtained by multiplying the weight of the hydrazone by 0·516 and then adding 0·025 gram, which represents, on the average, the amount of furfuraldehyde in the filtrate and washings.

F. S. K.

Detection of Hydrogen Cyanide. By R. Kobert (*Chem. Centr.*, 1891, ii, 591; from *Apoth. Zeit.*, **6**, 386).—See this vol., p. 362.

Estimation of Rosin in its Mixtures with Fatty Acids. By E. Twitchell (*Analyst*, 1891, 169—171; from *J. Anal. and Appl. Chem.*, **5**, 379).—When fatty acids are dissolved in absolute alcohol and treated with hydrogen chloride, their ethereal salts are formed. Rosin treated in the same way undergoes no change. On this principle the author has based his process, which may be conducted either gravimetrically or volumetrically.

The gravimetric method is carried out as follows:—2 or 3 grams of the mixture of fatty acid and rosin is dissolved in ten times its volume of absolute alcohol, and dry hydrogen chloride is passed through in a moderate stream, the flask being placed in a vessel with water to keep it cool. The gas is rapidly absorbed, and after about 45 minutes, the ethereal salts separate and float on the solution. After waiting for half an hour longer, the liquid is diluted with five times its bulk of water and boiled until the acid solution is clear, the

ethereal salts, with rosin in solution, floating on top. To this is added some light petroleum, and the whole transferred to a separating funnel, the flask being washed out with light petroleum. The acid liquid is then run off, and the light petroleum solution washed once more with water and then treated in the funnel with a solution of 0·5 gram of potassium hydroxide and 5 c.c. of alcohol in 50 c.c. of water. The rosin is immediately saponified, and the two layers separate completely. The rosin soap solution can then be run off and the rosin recovered as usual by the addition of an acid. The first stages of the volumetric method are similar to those of the gravimetric, with the exception that the contents of the flask are washed into the separating funnel with ether instead of light petroleum, and the ethereal solution is then thoroughly washed with water until all soluble acidity is removed. 50 c.c. of neutral alcohol is then added and the solution titrated with standard solution of sodium hydroxide.

The test analyses are satisfactory. L. DE K.

Estimation of Gallotannic and Gallic Acids and Tannin in Barks. By S. J. HINSDALE (*Chem. News*, **64**, 51—52; compare Abstr., 1890, 1348).—To estimate the gallotannic acid, 8 grams of the bark is extracted with boiling water, the infusion is made up to 500 c.c., and 50 c.c. of this is diluted again to 500 c.c. Five drops of the solution thus obtained is mixed with 5 c.c. of a fresh solution of ferric ferricyanide (1·5 c.c. of *liquor ferri chloridi* added to a solution of 0·04 gram of potassium ferricyanide in 500 c.c. of water); after one minute, water (20 c.c.) is added; and then, within three minutes, the colour is compared with that given by freshly-made standard tannin solution (0·008 per cent.) simultaneously treated in the same way. The solutions are so graduated that the number of drops of tannin solution required to match the colour equals the percentage of gallotannic acid in the bark. If the percentage is greater than 10, or less than 1·5, it becomes difficult to match the colour accurately, and it is therefore well in such cases to alter the strength of the infusion to the extent necessary to obtain a manageable colour.

The gallic acid is estimated in a similar way, after the precipitation of the tannin by alum and gelatin (50 c.c. of original infusion, equal to 0·8 gram of bark, 0·2 gram of alum, 20 c.c. of 3 per cent. gelatin solution, the whole made up to 250 c.c.). The colour produced by 5 drops of the filtered solution is compared with that yielded by a freshly-prepared standard solution of gallic acid, the strength of which (0·002 per cent.) is such that one-eighth of the number of drops required to match the colour equals the percentage of gallic acid in the bark.

The difference between the percentages of gallotannic and gallic acids is stated to be equal to the percentage of tannin present.

JN. W.

The Werner-Schmid Method of Milk Analysis. By T. E. HILL (*Analyst*, 1891, 67—70).—The author was inclined to be dissatisfied with this process, as his results were anything but accurate, owing chiefly to the fluffy layer below the ether being disregarded, which consists mainly of ether mixed with a little hydrochloric acid

and decomposed caseïn. No directions for washing the ether are given. The author, however, obtained more satisfactory results by following the details of Stokes' modified process, which is as follows: —10 c.c. of the sample is measured or weighed into special tubes and mixed with 10 c.c. of strong hydrochloric acid. The mixture is boiled with frequent shaking until it turns brown, and, after cooling, ether is added up to the 50 c.c. mark. After settling for five minutes, 20 c.c. of the ether is pipetted off and evaporated in a tared dish. The number of c.c. of ether remaining in the tube is then read, together with three-fourths of a fluffy-looking stratum immediately beneath the ether, and these, added to the 20 c.c. of ether evaporated, give the total number of c.c. of ether to be considered in calculating the percentage of fat. A correction for sp. gr. has, of course, to be made in each case.

By always weighing the milk, instead of measuring, and using washed ether, and also only pipetting off 15 instead of 20 c.c., the author has succeeded in obtaining results which compared satisfactorily with those obtained by Adams' method. L. DE K.

Fat Extraction from Milk Solids. By A. W. STOKES (*Analyst*, 1891, 92).—The process to be described does not lay claim to any originality, but may come in handy when an analyst has to deal with a very small quantity of a sour sample.

Five grams of the milk is dried to constant weight in a platinum, porcelain, or glass dish, and the total solids are weighed. The mass is now moistened with 5—8 c.c. of strong hydrochloric acid, and, after putting a cover-glass on the dish, heated on the top of the water-bath for three to five minutes. The contents of the dish are now well broken up with a rubber-covered glass rod and washed with water into the well-known Schmid tube.

The fat is then extracted in the usual way by shaking out with ether. L. DE K.

Detection of Coco-nut Fat in Butter. By J. MUTER (*Analyst*, 1891, 88—90).—Although coco-nut fat contains less volatile, fatty acids than butter fat, it is still possible to mix a comparatively large quantity of this fat with butter without seriously interfering with the popular Reichert's distillation process. On the other hand, where that excellent instrument the oleorefractometer is used, it is very easy to compound a mixture of margarin with coco-nut fat which will give the normal refraction of butter. It is, therefore, only by a joint use of the refractometer and Reichert's titration process that the fraud can be detected.

A sample of butter which has an abnormally high refraction, say, —36, must still be pronounced as pure when it gives a Reichert figure of 16 (working on 2·5 grams of butter fat), but if the refraction should be —37 and the Reichert only 12, it may be safely reported as adulterated with 20 per cent. of coco-nut fat. L. DE K.

Estimation of Fat in the Products from Milk. By LEZÉ and ALLARD (*Compt. rend.*, **113**, 654—656).—A definite quantity of the

substance to be examined (cream, cheese, margarin, &c.) is placed in a flask with a graduated neck, mixed with 4 or 5 times its volume of pure hydrochloric acid, and heated at a moderate temperature with occasional agitation. The substance gradually disappears, and a liquid is obtained which becomes brown on heating. Tepid water is then added in quantity sufficient to bring the liberated fat into the neck of the flask, where it is measured (compare Abstr., 1890, 837). Pasty substances may be treated with acid in a dish and afterwards transferred to the flask with a graduated neck. A sample of Gruyère cheese gave the following percentages of fat: with ether, 31·84; with carbon bisulphide, 32·04; by the new process, 31·75. 5 grams of the cheese was treated with 50 c.c. of hydrochloric acid for 15 to 30 minutes, and heated on a water-bath until it acquired a brownish colour.

Instead of multiplying the volume found by 0·9, 9 grams of matter may be weighed out instead of 10, and the volume of the fat will then represent the percentage by weight.

The separation of the fat is complete at 25—30°, and heating on the water-bath simply serves to produce agglomeration of the fat globules. The hydrochloric acid must contain no free chlorine. The fat undergoes no chemical changes; its weight remains practically the same in a drying oven, and it leaves no ash when burned.

C. H. B.

Assay of Aconite Preparations. By A. H. Allen (*Pharm. J. Trans.* [3], **22**, 230—235).—Assuming that the physiological activity of a mixture of aconite alkaloïds is represented by the amount of saponifiable base present, the author describes a delicate and ingenious volumetric method for the determination of the latter, applicable to very minute quantities. The alkaloïd is titrated with N/50 hydrochloric acid; after hydrolysis, &c., the benzoic acid formed is determined by N/50 baryta-water, the indicators being methyl-orange and phenolphthaleïn respectively. The results adduced are fairly accordant for pure samples of aconitine and of japaconitine taken separately, and there is a presumption of the same being the case for pseudaconitine from the roots of *A. ferox*. But when the method is applied to several specimens of mixed aconite alkaloïds extracted from the root (of *A. napellus?*), the results are stated by the author to be "somewhat erratic."

In a discussion following the reading of the paper, J. C. Umney pointed out that Jürgens had shown that nearly half the alkaloïds of *A. napellus* consist of an amorphous inert base, also saponifiable and capable of yielding benzoic acid (as are aconitine and japaconitine). A gummy base in aconitine had, moreover, been noticed by Wright, Groves, and others; on all hands it was admitted that the process would be invalid if this base were proved to be capable of hydrolysis.

R. R.

General and Physical Chemistry.

Electromotive Force of Gas Batteries. By G. Markovsky (*Ann. Phys. Chem.* [2], **44**, 457—472).—The author has made measurements of the E.M.F. developed in elements consisting of platinum wholly immersed in dilute, carefully boiled-out sulphuric acid, and of platinum partially immersed in this liquid and partially exposed to an atmosphere of pure hydrogen and oxygen. Experiments were also performed when the dilute acid contained platinum sulphate in varying quantities, and in one or two instances carbon electrodes were substituted for platinum electrodes. His results are as follows:—

The electromotive force of a platinum plate in hydrogen against a platinum plate in gas-free sulphuric acid is 0·646 volt. When oxygen is substituted for hydrogen, the current is in the opposite direction and the electromotive force is 0·372 volt.

Electrolytic hydrogen, and hydrogen prepared from zinc and sulphuric acid, give the same value for the electromotive force. The same thing holds for electrolytic and chemically prepared oxygen.

The electromotive force of an oxygen cell is diminished by the addition of platinum sulphate to the solution, whilst that of a hydrogen cell increases, the sum of the two remaining constant.

The electromotive force is independent of the density and temperature (up to 70°) of the gas.

Carbon electrodes behave quite differently from platinum electrodes.

J. W.

Electrical Behaviour of Metals in Salt Solutions. By H. Pellat (*Ann. Phys. Chem.* [2], **44**, 550—554).—In this paper the author replies to objections raised by Braun against his law, that the normal difference of potential between a metal and the solution of one of its salts into which it is immersed is zero. J. W.

Electrostenolysis. By F. Braun (*Ann. Phys. Chem.* [2], **44**, 473—500).—The name "electrostenolysis" is applied by the author to the phenomenon of the decomposition of an electrolyte in a narrow crack through which a current passes (Abstr., 1891, 778). Electrostenolysis is best observed in the case of solutions of salts of heavy metals, for these metals are deposited in the crack, as on an electrode. The following substances in solution were decomposed in this way:—Silver nitrate, lead acetate, lead nitrate, auric chloride, cobalt nitrate, palladium nitrate, platinum chloride, ferrous sulphate. Salts of zinc, nickel, bismuth, the alkalis, and hydrogen showed no action. Electrostenolysis, in the case of copper salts, was only observed in ammoniacal solutions.

The material in which the crack is made seems to have no influence on the result. In order to obtain the action, the diameter of the crack and the current density must be less than a definite amount.

No electrostenolysis appears in animal or vegetable membranes, in porous cells, or in hydrophane. J. W.

Electrocapillary Reactions. By F. Braun (*Ann. Phys. Chem.* [2], 501—509).—Becquerel observed that if a crack (about 0·06 mm. in breadth) is made in a glass tube which is filled with a strong solution of sodium sulphide and dipped into a concentrated solution of cupric nitrate, metallic copper is, after some time, deposited on the edges of the crack. This is covered later by a layer of cuprous oxide, which gradually grows into the crack and may eventually burst the tube.

Ostwald has given an explanation of this phenomenon on the basis of the properties of semi-permeable membranes towards various ions (Abstr., 1890, 1355). The author, on the other hand, concludes that a galvanic element is formed by the following substances:—$CuS|Cu(NO_3)_2|$basic salt + $NaNO_3|NaHS|CuS$, which occasions the deposition of copper at the crack. J. W.

Electrolytic Preparation of Metallic Alloys, &c. By H. N. Warren (*Chem. News*, **69**, 302).—The metal to be alloyed and the compound containing the alloying element are melted together in a deep, conical crucible, having a pointed graphite rod projecting an inch through the bottom. The external portion of this rod is protected by an iron tube, coated with borax to avoid oxidation, and is connected with the negative electrode of a battery; when the mass in the crucible has become liquid, a stout platinum wire, connected with the positive electrode, is arranged so as just to touch the upper surface of the liquid, and decomposition then proceeds, the metallic ion alloying with the molten metal below. D. A. L.

Basicity of Phosphoric Acid. By D. Berthelot (*Compt. rend.*, **113**, 851—854).—When ammonia, sodium hydroxide, or potassium hydroxide is added in gradually increasing quantity to a dilute solution of phosphoric acid, the decrease in electrical conductivity is represented by a right line up to the point at which one of the basicities of the acid is neutralised, and it follows that the three monobasic phosphates are not dissociated even in dilute solutions. At this point, there is a well-marked angular deflection of the curve, but with further addition of alkali the increase in conductivity is represented by a right line up to the point corresponding with the formation of a bibasic phosphate, and it follows that the bibasic alkaline phosphates are stable, even in dilute solutions. With further addition of alkali, there is again a change in the direction of the curve, but the change of conductivity is no longer represented by a right line, and there is no change in direction at the point corresponding with the tribasic phosphate. The tribasic alkaline phosphates are almost completely dissociated in dilute solutions. With stronger solutions, it can be seen that the formation of the tribasic phosphate does correspond with a distinct, although slight, angular deflection of the curve. It is clear that phosphoric acid differs markedly from the true tribasic acids (tricarballylic, aconitic, citric, &c.), for with the latter

the monobasic and bibasic salts are partially dissociated in solution, and the tribasic salt is stable.

Lenz has shown that the salts of ammonium and potassium with strong acids show equal conductivities in dilute solution, and the author has shown that with feeble acids the two conductivities are distinctly different, although remaining approximately the same, whilst with phenol they are very different. In this paper, it is shown that the conductivities of the monobasic potassium and ammonium phosphates are identical; with the bibasic phosphates, the conductivity of the ammonium salt is about 6 per cent. lower than that of the potassium salt, whilst, with the tribasic phosphates, the two conductivities are widely different, that of the potassium salt being much the higher.

The first acid function of phosphoric acid is analogous to that of strong acids, the second to that of feeble acids, and the third to that of phenols. Phosphoric acid is, in fact, not a true tribasic acid, but a monobasic acid with a complex function. It is noteworthy that these conclusions agree with those deduced from thermochemical data.

Recent Developments of the Mechanical Theory of Heat. By M. Planck (*Zeit. physikal. Chem.*, **8**, 647—656).—This report of a lecture given by the author before the German Naturforscherversammlung at Halle gives a connected account of the recent applications of thermodynamics to the study of solutions. J. W.

Thermochemistry of Bibasic Organic Acids. By G. Massol (*Compt. rend.*, **113**, 1047—1048).—The heat of neutralisation of tartaric acid with potash is +25·45 Cal. The heats of formation of various salts, calculated for the solid state throughout, are:—Potassium hydrogen succinate, 26·26 Cal.; dipotassium succinate, 46·40 Cal.; sodium hydrogen succinate, 20·19 Cal.; disodium succinate, 40·02 Cal.; dipotassium tartrate, 53·26 Cal.; sodium hydrogen tartrate, 26·01 Cal.; disodium tartrate, 45·82 Cal. From a comparison of these data with others previously given by himself (Abstr., 1891, 968, 1062; this vol., p. 260) and others (Berthelot, *Mécanique Chimique*, **1**, 539; Chroustchoff, *Ann. Chim. Phys.* [5], **19**, 422), the author concludes that the addition of alkylic hydroxyl to the carbon atom next a carbonyl group increases the heat of neutralisation, and that in the succinic series the heat of neutralisation increases with the number of alkylic hydroxyl groups; the increase, however, occurring entirely in the neutralisation of the first carbonyl group.

Jn. W.

Distillation of Coal. By P. Mahler (*Compt. rend.*, **113**, 862—864).—The sum of the heats of combustion of the products of distillation of Commentry coal was found to be 96·5 per cent. of the heat of combustion of the original coal. The following table gives the heat of combustion at constant volume of some samples of coal gas:—

	Heat of combustion per cubic metre.	Sp. gr.	Heat of combustion per kilo.
Gas made at Villette..	5601·9 Cal.	0·4033	10744 Cal.
Gas from Commentry coal.....	5804·0 „	0·4040	11111 „
Gas from Cannel coal from Niddrie.....	6365·5 „	0·6367	7735 „

C. H. B.

The Freezing Point of Isomorphous Mixtures. By F. W. Küster (*Zeit. physikal. Chem.*, **8**, 577—600).—In a former paper (Abstr., 1890, 1209), the author studied the freezing points of mixtures of hexachlor-α-keto-γ-pentene and pentachlorobrom-α-keto-γ-pentene, which crystallise together in all proportions. He has now extended his observations to other pairs of isomorphous substances, and finds that in their case also the relations are similar to those already found. The freezing point, namely, does not obey Van't Hoff's law for the depression, but lies in the neighbourhood of the point calculated from the freezing points of the components by the mixture formula of simple proportion to the quantity of each present; sometimes it is a little above this point, sometimes a little below it. In the case first investigated, the solid crystallising out had the same composition as the liquid; but this is not so for all mixtures. The author gives the following rule:—In the first crop, the substance with higher melting point predominates; but if the melting points lie close together, then apparently there is a preponderance of the substance which crystallises more readily. The temperature, therefore, is not always constant, but gradually diminishes.

The isomorphous mixtures investigated were metachloronitrobenzene and metabromonitrobenzene, trichloracetamide and tribromacetamide, α-chlorocinnamaldehyde and α-bromocinnamaldehyde, chloroquinol diacetate and bromoquinol diacetate. Mixtures of naphthalene and dihydronaphthalene were also studied, although these substances are probably not isomorphous. Acetanilide and paranitracetanilide when melted together do not crystallise homogeneously, and the freezing point very nearly obeys Van't Hoff's law. Their isomorphism is somewhat doubtful. J. W.

Pressure of Saturated Water Vapour. By G. Hinrichs (*Zeit. physikal. Chem.*, **8**, 680—681).—The author points out that the results recently obtained by Cailletet and Colardeau agree with the values calculated from his theoretical formula for the vapour pressure of water. J. W.

Vapour Tension of Homologous Compounds. By G. C. Schmidt (*Zeit. physikal. Chem.*, **8**, 620—646; compare Abstr., 1891, 969).—The author has made measurements of the vapour pressure of the alcohols of the fatty series at various temperatures. He finds that Dalton's rule is not verified, as may be seen from the following tabulation of his results:—

	Boiling points for the pressure in mm.									
	1600.	Δ.	1000.	Δ.	400	Δ.	100.	Δ.	10.	Δ.

J. W.

Rapid Method of Solution in the Cold. By J. B. Coleman (*J. Soc. Chem. Ind.*, **10**, 231—233).—The author found that by simply passing a current of air through the coarsely powdered solid suspended in water complete solution is obtained, in some cases in the space of 15 minutes, and in most cases before the expiration of an hour. The solid is put into a glass cylinder half filled with distilled water. The mouth of the jar is tightly stoppered with an india-rubber cork through which pass two glass tubes. One tube has inserted in the upper end a plug of cotton wool to keep out dust, whilst the lower end is drawn out and bent, and passes to the bottom of the cylinder; the other tube just passes through the cork. Before use, the cylinder is surrounded by a vessel containing water of the temperature at which the solubility is to be taken; the short tube is then connected with a water aspirator. The advantages of this process consist in the comparatively short time required for solution, and in the circumstance that no expensive apparatus, such as water motors and revolving agitators, are required. In places where high-pressure water is not available, steam may be substituted by attaching a flask of boiling water to the aspirator. The objections to the process are that the solution may be supersaturated by the air causing evaporation during its passage through the liquid; and, secondly, that readily oxidisable substances cannot be examined in this way. The first objection may be overcome by the use of moist air, whilst the second difficulty can usually be met by employing coal gas in place of air, care being taken that the oxygen and carbonic anhydride present in the gas are thoroughly absorbed by alkaline pyrogallol solution. D. B.

Analogies between Solutions of a Gas and of a Salt in an Indifferent Salt Solution. By J. Setschenow (*Zeit. physikal. Chem.*, **8**, 657—660).—The author finds from Bodländer's numbers (Abstr., 1891, 795) that the solubility of one salt in the solution of another indifferent salt obeys the same law as he had observed to hold good for the solubility of carbonic anhydride in salt solutions, provided the concentration of the solution is not too great.

J. W.

State of Salts in Solution: Sodium Sulphate and Strontium Chloride. By A. Étard (*Compt. rend.*, **113**, 854—857).—It is well

known that the solubility of sodium sulphate increases from 0° to 33°, at which point the saturated solution contains 34·5 per cent. of the anhydrous salt. As the temperature rises, the solubility decreases, and part of the sulphate separates in an anhydrous form. According to Tilden and Shenstone, the solubility attains another minimum at 130°, and then again increases. The author finds that the solubility decreases from 33° to 80°, the percentage of anhydrous sulphate in a saturated solution at the latter temperature being 30·0 per cent. Beyond this point, the solubility remains constant up to 230°, the composition of the solution corresponding with the formula $Na_2SO_4 + 18H_2O$. Beyond 230°, the solubility rapidly decreases, and a solution saturated at 320° contains only 17·8 per cent. of the salt.

There is no proof that when a hydrated salt is dissolved in water a solution of the particular hydrate is formed; there may be interaction between the solvent and the salt, with formation of hydrates of different composition.

The author has redetermined the solubility of strontium chloride, $SrCl_2 + 6H_2O$. Between −15° and 40°, the solubility increases, and is represented by a right line; then the rate of increase of solubility changes, the curve becomes convex towards the axis of temperature, and a maximum is reached at 61°. Beyond this point, the solubility decreases up to 80°, the curve being convex towards the axis of temperature, and, between 80° and 250°, the solubility is represented by a right line. The cause of the perturbation between 40° and 80° is easily established. Below 40°, the solution deposits only needles of the composition $SrCl_2 + 6H_2O$: between 90° and 130°, it deposits lamellæ of the hydrate $SrCl_2 + 2H_2O$; at 75°, it deposits both needles and lamellæ. At 145°, a saturated solution deposits needles, probably of a monohydrate, and then lamellæ of the dihydrate, and the right line represents the sum of the solubility of the two hydrates.

C. H. B.

Supersaturation. By L. de Boisbaudran (*Compt. rend.*, **113**, 832—835).—The author quotes certain passages from a paper read before the Academy in 1866, but not previously published. Supersaturation is a general phenomenon common to all substances, superfusion being essential to the crystallisation of a fused substance, and supersaturation of a vapour to the crystallisation of a sublimed substance. Each change can take place at various temperatures, two of which are especially noteworthy and limit the phenomenon. The change of state takes place at the higher limit if the change is inverse, and at the lower limit if the change is direct, only when the substance is in contact with some of the product of the change of state or an analogous product capable of mixing with it intimately. The term *direct* change denotes the fusion of a solid or the volatilisation of a liquid; whilst the term *inverse* change denotes the condensation of a gas or the solidification of a liquid. Crystallisation will take place at the higher temperature limit only when the liquid is in presence of previously-formed crystals of the same substance, or some isomorphous substance. Condensation will take place at the higher temperature limit only when the gas is in contact with some of the product formed by previous condensation or some liquid capable of

mixing intimately with it. Both these changes will, however, take place at the lower temperature limit, even in absence of products of the change or analogous substances. Similar phenomena are observed in the case of the inverse changes, except that it is at the higher temperature limit that the change will take place in absence of products of the change. In the author's view, substances that mix intimately or dissolve in one another, may be regarded as isomorphous, or approximately isomorphous; but, as shown in 1875, this isomorphism no longer exists when the lower limit of supersaturation is reached.

C. H. B.

Velocity of the Reaction between Alcoholic Potash and Alkyl Halides, &c. By M. Wildermann and S. Aisinmann (*Zeit. physikal. Chem.*, **8**, 661—676).—The authors investigated the rate at which hydrogen halide was split off from the halogen derivatives of the fatty hydrocarbons by alcoholic potash. They found that the coefficient of velocity, C, is greatest for iodides and least for chlorides.

		C.	
(*a*.)	Ethyl iodide	0·00162	(38·5°)
	„ bromide	0·00092	(39°)
(*b*.)	Propyl iodide	0·00051	(38·5°)
	„ bromide	0·00022	(39°)
(*c*.)	Ethylene bromide.....	0·00120	(18°)
	„ chloride.....	0·00017	(40°)

The constant for the removal of the first halogen atom from a dihalogen derivative is greater than the constant for the corresponding mono-halogen derivative, thus:

Propyl bromide	C = 0·00022 at 39°
Propylene bromide	C = 0·00084 at 18°

although the constant increases with the temperature. The constant is less for unsaturated than for saturated derivatives. J. W.

Molecular Dissymmetry. By P. A. Guye (*Chem. Centr.*, 1891, ii, 909—912).—Pasteur has shown that all chemical compounds may be divided into two classes: those with dissymmetrical and those with homohedral arrangement of the atoms in the molecule. The first includes all optically active substances, and to every dextrorotatory there is a corresponding lævorotatory variety. The tetrahedron representing any asymmetrical carbon atom CRR′R″R‴ may have either dextro- or lævo-dissymmetry. If the masses of RR′R″R‴ are nearly equal, the dissymmetry of the molecule will be much smaller than if the masses are very different; so that in the first case the optical activity will be almost nothing; but in the second it will be large. The optical activity is therefore a measure of the dissymmetry of the molecule. Any expression of the dissymmetry must fulfil these two conditions: that its value is *nil* when the carbon atom is symmetrical, and that it changes sign with the passage from dextro- to lævo-symmetry. An asymmetrical tetrahedron has no plane of symmetry; but a symmetrical one has several: six for the

compound CR_4, three for $CR'R_3$, and one for $CR'R''R_2$. As long as the carbon atom is symmetrical, the centre of gravity will lie in one of the above six planes, but, as soon as it becomes asymmetrical, the centre of gravity will lie out of these planes. If the distance of the centre from each of the planes is denoted by d_1, d_2, d_3, d_4, d_5 d_6, the product P of these distances is a measure of the dissymmetry of the tetrahedron, and, consequently, of the optical activity.

The factors d_1, d_2, &c., will have the positive or negative sign, according to the side of the plane of symmetry on which they lie. If one of the factors becomes nothing, P will be nothing, and the carbon atom becomes symmetrical. With regard to the position of the centre of gravity, it will be necessary to assume either that the masses RR'R''R''' are concentrated at the angles of the tetrahedron or not. The distances of the centres of gravity of these masses from that of the tetrahedron may be estimated from the theories with regard to the molecular volume. The molecular refraction is proportional to the spherical volume of the molecule, and is also made up of the sum of the atomic refractions. The square root of the atomic refraction gives, therefore, a number which may be termed the atomic diameter, and which represents the mean sphere of action of the atom. By thus obtaining values for the relative distances of RR'R''R''' from the centre of gravity of the tetrahedron, it is possible to estimate the position of the latter with regard to the planes of symmetry. If by the substitution of one element or radicle for another in the molecule of an active substance, the centre of gravity remains on the same side of the planes of symmetry, the optical rotation of the new product will be of the same sign as that of the parent substance. If the position of the centre of gravity with regard to the planes of symmetry changes, the sign of the rotation will also change. The author quotes experimental evidence in support of these theories.

H. C.

Levelling Instrument for Gasometric Investigations. By G. Lunge (*Ber.*, **24**, 3948—3949).—In gasometric investigations it is frequently necessary to place the tops of two mercury columns at the same level; this end may sometimes be attained by aligning them against the top of a roof, wall, or similar horizontal object. In many cases, however, such an object is not available, and the author has, therefore, devised a little instrument by means of which the levelling may be readily carried out. It consists of a brass rule, to the front of which a small spirit level is attached, and to the back a long brass rod, which passes accurately into a brass tube, the end of which can be fixed on a retort stand in the same manner as an ordinary retort-stand ring. This is then placed on the stand holding the gas-measuring tubes, and, after the mercury columns have been approximately levelled, is raised to about the same height, and the rule moved until the spirit level shows it to be exactly horizontal; the tops of the two columns can then be readily levelled by a comparison with the upper edge of the brass rule. H. G. C.

New Condenser for Laboratory Purposes. By F. Evers (*Ber.*, **24**, 3950—3951).—The condenser described by the author is a

modification of the ordinary Liebig's condenser, in which the inner tube is replaced by a cylinder of moderate width, containing within it a third narrower cylinder. The latter is connected by means of small transverse tubes with the space between the second and first cylinders, thus enabling the tap-water to cool the opposed surfaces of the two inner cylinders. A very great increase is thus obtained in the extent of cold surface to which the vapours passing the condenser are exposed, without materially increasing the dimensions of the condenser itself. H. G. C.

Lecture Experiment: Dissociation of Phosphonium Bromide. By G. S. Newth (*Chem. News*, **64**, 301).—A Liebig's condenser in miniature is constructed, in which the inner tube consists of a tobacco pipe (or pieces of tobacco piping joined with rubber tube), fixed by small pieces of rubber tube into an outer glass tube 30 cm. long and 10 mm. bore. A stream of hydrogen is passed into one of the side tubes of this glass tube, and is burnt at a fish-tail burner screwed into lead pipe and attached to the other side tube. A small U-tube, containing phosphonium bromide, is connected to one end of the clay pipe, then, almost as soon as a slow stream of hydrogen is passed (especially if the U-tube is warmed by the hand), the flame of the hydrogen indicates the presence of phosphorus, due to the diffusion through the clay pipe of the hydrogen phosphide arising from the dissociation of the phosphonium bromide, whilst the acidity of the gas issuing from the end of the clay pipe is due to the hydrogen bromide, the other product of the decomposition. D. A. L.

Inorganic Chemistry.

Direct Combination of Chlorine with Metals. By U. Kreusler (*Ber.* **24**, 3947—3948).—The author has observed that if in the well-known experiment of burning a spiral of thin brass wire tipped with Dutch metal in chlorine gas, the latter be dried, no combustion takes place, but that the addition of a little moisture brings about an immediate combination. The simple drying brought about by passing the gas through a single flask of sulphuric acid is quite sufficient to prevent the combustion taking place. H. G. C.

Note.—The fact that dry chlorine does not act on Dutch metal and other metals was shown some time ago by Cowper (Trans., 1883, 154). —Ed.

Sulphuryl Holoxide. By M. Traube (*Ber.* **25**, 95—97; see also Abstr., 1891, 978).—The paper is an answer to the criticisms of Berthelot (*Compt. rend.*, **112**, 1481) and Marshall (Trans., 1891, 771). The author has repeated the experiments formerly described, and maintains the existence of the compound SO_4. E. C. R.

Free Hydroxylamine. By C. A. Lobry de Bruyn (*Rec. Trav. Chim.*, **10**, 100—112).—This note has been published by the author in consequence of the appearance of a paper by Meyer on the stability of hydroxylamine (*Annalen*, **264**, 126). Lossen's experiments were all made in presence of water. The author considered that the presence of the water may, at least, have favoured the decomposition of the hydroxylamine, if it were not even the prime cause of the want of success attending the efforts to isolate that substance. As hydroxylamine hydrochloride is more soluble in methyl alcohol than in ethyl alcohol, absolute methyl alcohol has been employed as solvent.

The first preparations made showed that hydroxylamine is not a gas, and that a dilute solution in methyl alcohol becomes more concentrated by spontaneous evaporation in the air.

Further attempts to prepare larger quantities of material resulted in the explosion of the residue after the methyl alcohol, together with a small proportion of hydroxylamine, had been distilled off at atmospheric pressure.

The method of preparation finally adopted was as follows:—100 grams of hydroxylamine hydrochloride was dissolved in 600 c.c. of absolute methyl alcohol at a gentle heat. The calculated quantity (to leave the hydrochloride in slight excess) of a titrated concentrated solution of sodium methoxide was then added while the solution was still hot, the sodium chloride filtered off, and the filtrate distilled at a pressure of 160—200 mm. The alcohol carried over less hydroxylamine at this reduced pressure. When most of the alcohol had distilled over, dry ether was added to the residue; this separated into two layers, the upper containing 5·5 per cent. of hydroxylamine, and the lower 53·5 per cent.

A portion of the lower layer was separately distilled under a pressure of 165 mm., until a temperature of 86° was reached; the residue contained 70 per cent. of free hydroxylamine.

After an interval of six weeks, during which some decomposition took place, all the solutions were mixed and distilled under a pressure of 60 mm. The first portions of the distillate contained ammonia and methyl alcohol; then a fraction containing 32 per cent. of hydroxylamine was collected. The residue, containing 80 per cent. of free hydroxylamine, was fractionally separated into three parts. The first contained 27·2, the second 60 per cent. of hydroxylamine. The last portion solidified in the cooled receiver, forming long needles. The last part of this passed over at 70° under 60 mm. pressure. The solid substance, after pressing twice between filter paper, gave a hard, crystalline mass, containing 99·4 per cent. of free hydroxylamine. Free hydroxylamine is a very hygroscopic substance which rapidly liquefies in the air. The melting point was ascertained, by placing a thermometer in the melting crystals, to be 27·5°; for the pure substance, it is somewhat higher, the sample used had been prepared some hours, and kept in a badly stoppered bottle.

Sodium chloride is readily dissolved by hydroxylamine, and powdered potassium nitrate liquefies the solid. In these properties it resembles water (ice). Sodium attacks the solid violently. Free

hydroxylamine is inodorous, and rather denser than water. When heated rapidly on platinum foil, it explodes with a fine, clear, yellow flame. It dissolves very little, or not at all, in chloroform, benzene, ether, ethyl acetate, or carbon bisulphide; with carbon bisulphide, it, however, reacts with the separation of sulphur. Exposed to the air, it first liquefies, and then disappears by evaporation. It acts to some extent on paper and cork. The pure substance appears to be stable, as are certainly its concentrated aqueous solutions free from salts. Hydroxylamine, when melted, forms a rather thick liquid. Its dilute aqueous solutions remain stable at a high temperature. The 60 per cent. solution shaken with methyl iodide and methyl alcohol forms a white, crystalline mass after some hours. Bromine and iodine attack it with great violence. W. T.

Reduction of Nitric Acid to Ammonia by the Galvanic Current. By A. Becker (*Chem. Zeit.*, **14**, 1557).—Vortmann's recent process for the quantitative estimation of nitric acid by electrolysis is, according to the author, based on the formation of a hydrogen alloy.

Vortmann electrolyses the nitrate in presence of sulphuric acid and a metallic salt, such as cupric sulphate. During the electrolysis, metallic copper is deposited, and hydrogen is evolved, but neither of these are capable of effecting the reduction. As there is, however, in Vortmann's process, no doubt about the reduction, the author concludes this is caused by an alloy of copper and hydrogen. In his opinion, the reduction would take place instantaneously in presence of the compound of palladium and hydrogen. L. de K.

Some Hypophosphates. By C. Rammelsberg (*Chem. Centr.*, 1891, ii, 790; from *Math. Naturwiss. Mitt. Sitz. Akad. Wiss. Berlin*, 1891, 369—376).—*Lithium hypophosphate*, $2Li_2PO_3,7H_2O$, is obtained as a crystalline precipitate when a solution of lithium chloride is mixed with a solution of sodium hypophosphate. It dissolves in 120 parts of water, and may be obtained in lustrous crystals of the above composition if crystallised from acetic acid solution. 5 mols. H_2O are separated at 120°, and 6 mols. H_2O at 200°. The same salt is obtained if lithium carbonate be added to hypophosphoric acid in such quantity as to leave the solution strongly acid, whilst from the mother liquor the acid salt, *lithium hydrogen hypophosphate*, $LiHPO_3 + H_2O$, may be obtained in hygroscopic crystals.

Thallium hypophosphate, Tl_2PO_3, is obtained by neutralising the hot solution of hypophosphoric acid with thallium carbonate. It separates as slender, silky needles. The *acid salt*, $2TlHPO_3,Tl_2PO_3$, is obtained by adding half the quantity of thallium carbonate. It forms small, lustrous crystals.

Barium hypophosphate, $BaPO_3$, is precipitated from the solution in acids by the addition of ammonia. After drying over sulphuric acid, it still retains 1·62 per cent. of water. If the neutral salt be dissolved in hydrochloric acid and the solution allowed to evaporate, the acid salt, $BaH_2(PO_3)_2 + 2H_2O$, crystallises out; it loses the water of combination at 200°.

Magnesium hypophosphate, $MgPO_3 + 6H_2O$, is obtained as a fine, crystalline precipitate when normal sodium hypophosphate is added to a solution of magnesium sulphate; it is sparingly soluble. If heated with acetic acid and a little hydrochloric acid, it dissolves, and the salt $MgPO_3 + 12H_2O$ is obtained from the solution by concentration; 6 mols. H_2O separate at 200°. An acid magnesium salt could not be obtained.

Beryllium hypophosphate, $2BePO_3 + 3H_2O$, is obtained as a precipitate by adding a hot solution of beryllium sulphate to a solution of sodium hypophosphate; at 230—250°, about half the combined water separates.

When heated, the anhydrous hypophosphates are resolved into a mixture of phosphide and pyrophosphate, according to the equation $7R''PO_3 = 3R''_2P_2O_7 + R''P$. The change occurred quantitatively in the case of the silver salt. The lead and barium salts, after drying at 200°, still retained some water, and, consequently, when heated, small quantities of phosphorus and hydrogen phosphide separated from them. J. W. L.

Metallic Borates. By H. Le Chatelier (*Compt. rend.*, **113**, 1034—1036).—The author considers that many compounds of boric acid, such as fused borax, which are usually regarded as definite salts, are really mixtures, and that all known metallic borates may be looked on as salts of orthoboric or metaboric acid. It is possible to include the natural calcium borates, colemanite and perseïte, as well as the acid salts, such as borax, in this classification, by regarding part of the water of crystallisation as an essential constituent of the salt, a view which is justified by the tenacity with which this water is held.

A re-examination of the compounds prepared by Ebelmen, and described by Mallard (*Ann. des Mines*, 1887), has resulted in their resolution into constituents in a manner according with these views; *trimagnesium orthoborate*, $Mg_3B_2O_6$, can, for example, be isolated by means of methylene iodide or boiling water from the melts obtained by fusing magnesia with boric anhydride in various proportions. That the clean and uniform appearance of crystals is no criterion of purity was shown by fusing zinc oxide with boric anhydride in proportions varying from 1·5 to 2·75 mols.; the crystals obtained, although apparently homogeneous, were invariably found to be coated with a thin, transparent layer of boric anhydride. *Trizincic orthoborate*, $Zn_3B_2O_6$, crystallises in rhomboïdal dodecahedra, and can be easily separated from the melt by means of mineral acids, in which it is insoluble. *Calcium metaborate*, $CaBO_2$, is prepared by immersing a fragment of boric anhydride in a mixture of calcium chloride and alkali chloride, which is fused and exposed to moist air in an open crucible. Jn. W.

Silicon Thiochloride. By A. Besson (*Compt. rend.*, **113**, 1040—1041).—The reaction which results in the production of silicon chloride and sulphur from sulphur dichloride and silicon at a temperature below redness extends at a higher temperature to the

formation of silicon thiochloride. A current of chlorine saturated with sulphur dichloride vapour is led over a quantity of crystalline silicon heated to bright redness in a porcelain tube, the silicon sulphide which rapidly chokes the tube being removed from time to time by allowing the chlorine to pass alone. The liquid product is fractionated from excess of sulphur chloride, and is purified from oxychloride by recrystallisation from carbon tetrachloride, and subsequent sublimation in a current of dry air at 100°.

Silicon thiochloride, $SiSCl_2$, is a white solid which crystallises in white needles, melts at 74°, and boils at 185°. It is unstable in moist air, and is violently decomposed by water with the formation of hydrogen sulphide and chloride, and silica. JN. W.

Allotropic States of some Elements. By E. PETERSEN (*Zeit. physikal. Chem.*, **8**, 601—623).—The object of this investigation was to determine the relation between the changes of volume and of energy in passing from one allotropic modification of an element to another. True allotropic varieties differ, according to the author, in

	Heat of oxidation.	Atomic volume.
Carbon—	(C,O_2).

the quantity of energy they contain, in specific gravity, in specific heat, and in solubility. Colour and crystalline form he considers of secondary importance.

His results are summed up in the preceding table (p. 405):—

On the basis of these results, the author divides the various cases of allotropy into three groups:—

Group I.—The transition from one modification to another is accompanied by a contraction and a slight evolution of heat. To this group belong the modifications of sulphur and selenium.

Group II.—The heat evolution is considerable, and accompanied by a change of volume. Phosphorus and arsenic, crystalline and amorphous carbon, are examples.

Group III.—The thermal effect is accompanied by no change of volume. Gold and silver are examples. J. W.

Graphite. By W. Luzi (*Ber.*, **24**, 4085—4095).—It has been observed by Schafhäul, Marchand, and Brodie that, when finely-pulverised graphite is boiled with concentrated sulphuric acid, a mixture of sulphuric and nitric acids, sulphuric acid and potassium dichromate, or sulphuric acid and potassium chlorate, and subsequently washed and ignited, it swells up and assumes a characteristic vermiform or moss-like appearance. The author finds that concentrated nitric acid, or a solution of potassium permanganate in sulphuric acid, also effects the change, which likewise takes place when the coarsely pulverised graphite is simply moistened with concentrated, red, fuming nitric acid, and ignited in a flame on platinum foil, worm-like forms being obtained in this way, 2 cm. in circumference and 15 cm. in length; they are capable of being pressed into any form, are extremely light, and float upon water, alcohol, and ether. In the inner portions of these masses, lamellar crystals are found which have a brown or greenish appearance under the microscope in reflected light. In continuing his experiments, the author found that certain specimens of graphite do not undergo this change; graphites may, therefore, be divided into two groups, according as they do or do not exhibit this phenomenon, which he designates the "nitric acid reaction." Rocks containing graphite may be examined by this method with the aid of the microscope to determine to which group their graphite belongs. A mixture of the two kinds of graphite may be separated, after treatment with nitric acid and ignition, by adding the product to water, when that which remains unchanged sinks to the bottom, whilst the modified graphite floats upon the surface.

The author is unable to offer any explanation as to this difference of behaviour, as all the specimens of the two groups experimented with were morphologically identical, and, so far as could be ascertained, had the same specific gravity; they were also practically pure. Those specimens giving the "nitric acid reaction" contained, for the most part, large crystals, and it is proposed to retain the name graphite for such as these, reserving that of "graphitite" for the others.

According to the author, molten silicates serve as crystallisation

menstrua for carbon; better results are obtained, however, by mixing the silicates with a fluoride and some water, thus:—When potassium silicate (2 parts) and fluorspar (1 part) is pulverised with so much amorphous carbon that the mixture is of a mouse-grey colour, moistened with water, and heated in a well-closed porcelain crucible under a clay hood with the blast lamp for about three quarters of an hour, and slowly cooled down, graphite-like crystals are formed. The same result is obtained by fusing together a mixture, moistened with water, of sodium silicate (6 grams), colourless fluorspar (3·5 grams), and soot from a luminous gas flame. The last-mentioned discovery appears to throw light on the natural formation of graphite by contact metamorphosis (Beck and Luzi, Abstr., 1891, 989).

A. R. L.

Analysis of the Products of Incomplete Combustion. By V. B. Lewes (*J. Soc. Chem. Ind.*, **10**, 413—417).—In this paper, a successful attempt has been made to utilise the property which finely divided palladium has, of causing the oxidation of hydrogen, but not of methane, when a mixture of these gases with air is passed over it, experiments having shown that a separation between these gases is possible, owing to the fact that the carbonic oxide is oxidised into carbonic anhydride under the same conditions. For the combustion of hydrogen, palladium asbestos was used, the gas being passed through a small, V-shaped combustion tube, 10 inches in length, containing the palladium asbestos, and heated in a bath of melted paraffin wax at 200—220°. This arrangement was employed for the determination of the composition of the gases escaping into the atmosphere when the flame of an atmospheric burner is brought into contact with the bottom of a vessel, which is kept cool by water between 0° and 100°. The experiments, which are described in detail in the paper, show that the extreme tip of an atmospheric burner is the only portion of a flame which can be utilised for heating substances cooler than itself without giving rise to deleterious products of incomplete combustion, this circumstance being confirmed by analyses of the gases escaping unburnt from the outer zone of a luminous flame and an atmospheric burner flame respectively. It is further shown that the air mixed with coal gas in an atmospheric burner produces a far more complete combustion than in the case of a luminous flame, where the air, mixing with the partially burnt coal gas, so dilutes it and cools it down at the edge of the flame, that large quantities of even the inflammable hydrogen escape unburnt. In the analyses of the products of incomplete combustion, the large proportion of carbonic oxide in the outer tip of the luminous flame is due to the reduction of carbonic anhydride by the deposit of red-hot carbon on the bottom of the vessel.

Calcium Phosphate from Solution in Acetic Acid. By H. E. Davies (*Chem. News*, **64**, 287).—Bright, glittering, prismatic crystals, giving, on analysis, numbers corresponding with the formula CaH_5PO_6, are obtained by slow crystallisation from solutions of freshly-precipitated tricalcium phosphate in acetic acid. The fact that these crystals only lose water at high temperatures, and not at 100°, is accepted by

the author as indicating absence of water of crystallisation, and the compound is therefore regarded as a derivative of phosphorus penthydroxide, of the formula $P(OH)_4 \cdot O \cdot Ca \cdot OH$. D. A. L.

Action of Carbonic Anhydride and Ferric Hydroxide on Tricalcium Phosphate. By G. v. Georgievics (*Monatsh.*, **12**, 566—581).—When carbonic anhydride is passed through water containing tricalcium phosphate in suspension, some of the calcium is withdrawn by it to form calcium carbonate, whilst dicalcium hydrogen phosphate is simultaneously produced. At the same time, a portion of the tricalcium phosphate appears to dissolve as such in the solution of hydrogen calcium carbonate which results from the presence of a large excess of carbonic anhydride.

Freshly precipitated ferric hydroxide in presence of carbonic anhydride is capable of withdrawing phosphoric acid from tricalcium phosphate, and under certain circumstances, namely, the presence of a sufficiently large proportion of the hydroxide and carbonic anhydride, the reaction becomes quantitative. G. T. M.

Action of Barium Peroxide on Metallic Salts. By H. Kwasnik (*Ber.*, **25**, 67—70).—Kassner has observed (Abstr., 1891, 245) that barium peroxide is acted on by potassium ferricyanide with evolution of the whole of the oxygen and formation of potassium ferrocyanide, the oxygen being free from ozone or hydrogen peroxide. The author then observed that ferric chloride also causes a copious evolution of oxygen from barium peroxide, but that in this case no reduction to ferrous salt takes place, only half the total oxygen being evolved, according to the equation

$$6BaO_2 + 4FeCl_3 + 6H_2O = 3O_2 + 4Fe(OH)_3 + 6BaCl_2.$$

Here also the oxygen evolved is free from ozone and hydrogen peroxide.

All ferric salts have the same action on the peroxide, and likewise the ferrous salts, these being first oxidised to ferric salts. The salts of potassium, sodium, lithium, ammonium, calcium, strontium, and barium are without action; magnesium salts give a reaction after some time; zinc and cadmium salts more rapidly; whilst those of nickel and cobalt give an immediate evolution of gas, the solutions assuming the colour of the hydroxides. Manganese, aluminium, chromium, and copper salts behave in a manner similar to the ferric salts. The salts of mercury, silver, and gold are reduced to the metallic state, with evolution of all the oxygen in the form of gas; a solution of chloroplatinic acid, on the other hand, although it causes the evolution of oxygen, does not yield metallic platinum, but unites with the barium, forming barium platinochloride. If silver nitrate be added to the solution of chloroplatinic acid, a precipitate of silver chloride and silver platinochloride is formed, and platinic chloride remains in solution; this mixture, on treatment with barium peroxide, gives a mixture of metallic silver and platinum. The reduction of the insoluble silver chloride led the author to examine the action of barium peroxide on other insoluble salts, and it was found that the reaction takes place readily with various insoluble sulphates, carbonates, phosphates, and arsenates. H. G. C.

Magnesium Nitride. By V. Merz (*Ber.*, **24**, 3940—3944).—It has been shown by Briegleb and Geuther (*Annalen*, **123**, 228) that magnesium filings are converted into magnesium nitride, Mg_3N_2, by strong ignition in a current of nitrogen. The author finds that the combination may be readily demonstrated in the following manner:—1·5—2 grams of well-dried magnesium powder is introduced into an eprouvette of hard glass, about 20 cm. in length and 12—13 mm. in diameter, which is connected on one side with a long tube passing vertically downwards and dipping under coloured water, and on the other hand with an apparatus for the preparation of pure and dry nitrogen. As soon as the air is completely driven out by nitrogen, the magnesium is heated by two or three large Bunsen burners, and, after two or three minutes, the current of nitrogen stopped by means of a pinch-cock. The water is then observed to rise rapidly in the vertical tube, and attains a height of about 3 metres in 2—3 minutes; the gas may then be again passed into the apparatus, and the absorption repeated several times. After an ignition of 40—60 minutes, almost the whole of the magnesium is converted into the nitride, the remainder having acted on the glass, blackening it, owing to the formation of silicon. The magnesium nitride thus obtained may be readily detached from the glass, and forms a light, loosely aggregated, pale-yellow, brittle mass, which has generally a greenish-grey tinge, and sometimes shows an orange surface colour; on warming, it assumes first a darker yellow colour, and then becomes reddish-brown, or brick-red, if in the form of powder. The moisture of the air rapidly decomposes it, with evolution of ammonia and formation of magnesium hydroxide; on treatment with a small quantity of water, it behaves in a very similar manner to quicklime, whilst, with a larger quantity of water in a flask, the ammonia is evolved almost explosively. The evolution of ammonia with water may also be shown with the mixture of magnesia and magnesium nitride prepared by burning magnesium in a limited supply of air.

Briegleb and Geuther state that magnesium and ammonia only act on one another at temperatures which cause a dissociation of the latter into its elements; the author finds, however, that magnesium powder readily withdraws the nitrogen from ammonia at a much lower temperature. Thus, when 1 to 1·25 grams of magnesium powder is heated with a single Bunsen burner in a current of ammonia gas, thoroughly dried and free from air, a sudden ignition is observed, which rapidly spreads through the whole mass, a gas being simultaneously evolved which has all the properties of hydrogen. It was found that after 15—20 minutes' ignition, about 90 per cent. of the magnesium had been converted into the nitride, the remainder having acted on the glass with formation of silicon. By this method, much larger quantities of the nitride may be prepared without difficulty.

The formula Mg_3N_2 requires 28 per cent. of nitrogen; the samples prepared by the above methods gave, in the best instances, 24·8, 25·2, and 25·3 per cent. H. G. C.

Supposed Copper Nitride. By P. L. Aslanoglou (*Chem. News*, **64**, 313).—Grove stated, in 1841, that a nitride of copper, sp. gr. 5·9,

was produced by the action of an electric current when metallic copper forming the positive electrode and platinum the negative electrode were immersed in a solution of ammonium chloride. The author, having repeated the experiment many times, finds that the product has a specific gravity of 5·6, that it does not contain nitrogen, but really consists of cuprous oxide and metallic copper in the proportions of $Cu_2O + Cu$. D. A. L.

Copper Phosphides. By Granger (*Compt. rend.*, **113**, 1041—1042).—The product which Abel obtained as a hard, brittle, steel-grey mass by passing phosphorus vapour over red-hot copper, is not a pure substance, but it may be converted into a crystalline phosphide by repetition of the treatment. *Pentacupric diphosphide*, Cu_5P_2, crystallises in bright, steel-grey, hard, brittle, hexagonal prisms, of which the crystallographic data are given. It dissolves easily in hot nitric acid. When heated to dull redness in air, it is oxidised to copper phosphate, but if the air is replaced by an inert gas, phosphorus is given off, and a residue of *tricuprous phosphide*, Cu_3P, is left; at a higher temperature, however, still more phosphorus is lost.

Jn. W.

Chemical Changes between Lead and Nitric Acid. By V. H. Veley (*J. Soc. Chem. Ind.*, **10**, 206—210).—The main conclusions to be drawn from the experiments described by the author are briefly summed up as follows:—(1) The behaviour of lead towards nitric acid is different, except in the production of nitrous acid, from that of silver, mercury, copper, and bismuth; (2) lead is attacked less by very dilute or by concentrated nitric acid than by an acid of intermediate strength; (3) lead is attacked less by nitric or nitrous acid taken separately than by mixtures of the two acids, the action in the latter case being greater the more nearly equal is the proportion between the nitric and nitrous acids; (4) in constructing vessels through which nitric acid or mixtures of nitrous and nitric acids might pass, no advantage appears to be obtained by alloying the lead with small portions of antimony. D. B.

Composition of Glass suitable for Chemical Utensils. By R. Weber and E. Sauer (*Ber.*, **25**, 70—75).—The authors have determined the weight lost by flasks made of various glasses when water, sulphuric acid, hydrochloric acid, ammonia, sodium phosphate, and sodium carbonate are boiled in them for 3—5 hours.

The loss of weight is found to increase with the temperature, and is greater when the flask is heated over a bare flame than when heated in a water-bath.

In the experiments described, the flasks were heated under the same conditions on an iron plate covered with asbestos, with distilled water for five hours and with the other reagents for three hours. The authors give a table of the results obtained. They find that the best glass for chemical purposes contains silica, lime, and alkali in the proportion 8 : 1 : 1·5. They confirm the observations of other investigators, that the glass is attacked to a greater extent by water than by acids, and to a much greater extent by alkalis.

E. C. R.

Examination of Glass for Chemical Purposes. By F. Mylius and F. Foerster (*Ber.*, **25**, 97—99).—The authors have examined flasks made of 22 kinds of glass, and find that the most suitable glass contains silica, lime, and alkali in the proportion 7·2 : 1 : 1·1 (Weber and Sauer obtained the proportion 8 : 1 : 1·5; see preceding abstract). The experiments were carried out as follows:—The flask, after three days' treatment with water, was allowed to remain for three days with water at 20°, and the loss determined. It was then treated with water at 80°, and the loss again determined. From the similarity in composition of the glasses found to be most suitable for chemical purposes by the authors and by Weber and Sauer, the authors conclude that the determination of the action of water alone on glass is a criterion of its quality. E. C. R.

Green Chromic Sulphate. By A. Recoura (*Compt. rend.*, **113**, 857—860).—In presence of excess of sulphuric acid, a green chromium hydrogen sulphate is formed. A green modification of the normal sulphate is, however, obtained by reducing chromic anhydride with alcohol and sulphuric acid in presence of a quantity of water insufficient to dissolve the anhydride. 50 grams of chromic anhydride is mixed with 13 grams of water, and a mixture of 40 c.c. of concentrated sulphuric acid and 35 c.c. of alcohol of 95° is added drop by drop, care being taken that the temperature does not exceed 30°. The product is triturated with glacial acetic acid to remove organic matter, and then washed with anhydrous ether until all acid is removed. A pale-green chromium sulphate of the composition $Cr_2(SO_4)_3 + 11H_2O$ is thus obtained. It is extremely hygroscopic and deliquescent, rapidly forming a deep-green liquid when exposed to the atmosphere. It differs from the ordinary sulphate in that it gives no precipitate with lead or barium salts until after about half an hour. Precipitation is accelerated by heating, but is not complete until ebullition has been prolonged for several hours. If the solution has been prepared for some time, it gives an immediate precipitate in consequence of a partial spontaneous change into the violet modification. It is already well known that the green solution obtained by heating a solution of the violet chromium sulphate is only partially decomposed by barium chloride.

The green salt obtained by Étard by heating the crystallised violet sulphate at 100° has the composition $Cr_2(SO_4)_3 + 6H_2O$, but dissolves very slowly in water. If the violet sulphate is only heated at 90°, the residue has the composition $Cr_2(SO_4)_3 + 8H_2O$, dissolves readily in water, and seems to be identical with the green salt obtained in the manner described above. C. H. B.

Isomeric Forms of Chromic Sulphate. By A. Recoura (*Compt. rend.*, **113**, 1037—1040).—The green chromic sulphate which is prepared from the hydrated violet sulphate (preceding abstract) forms an aqueous solution which is quite distinct from the green solution obtained by heating that of the violet sulphate, and previously shown to contain a basic sulphate, $2CrO_3,5SO_3$ (Abstr., 1891, 1430). The new substance is not precipitated by barium

chloride or lead nitrate, but is thrown down by alkalis as a hydroxide, $Cr_2O(OH)_4$, which is shown by calorimetric measurements to be identical with that obtainable from chromium oxytetrachloride, Cr_2OCl_4. The solution changes spontaneously into that of the violet sulphate when kept, and may be transformed into that of the above-mentioned basic sulphate by adding in succession soda (2 mols.) equivalent to one-third of the acid present, and sulphuric acid (1 mol.).

Jn. W.

α-Orthostannic Acid. By G. Neumann (*Monatsh.*, **12**, 515—523; compare Löwenthal, *J. pr. Chem.* **77**, 324).—When a 5 per cent. solution of stannic chloride (2 parts) is mixed with a saturated solution of ammonium sulphate (1 part), a white precipitate is obtained, which, after washing and long-continued exposure to the air, gives, on analysis, numbers corresponding with the formula $Sn(OH)_4$. Saturated solutions of potassium and sodium sulphates may be substituted for the ammonium sulphate with production of the same substance; and it appears that the presence of hydrogen sulphide in the solution in no way alters the composition of the product. α-Orthostannic acid is readily soluble in hydrochloric acid, and may therefore be regarded as an isomeride of the hydrate of metastannic acid obtained by Fremy. It is, perhaps, identical with the acid obtained by Fremy and Weber, to which those authors ascribed the composition $3SnO_2,7H_2O$.

G. T. M.

Preparation of Pure Zirconium Chloride from Zircons. By F. P. Venable (*Chem. News*, **64**, 315—316).—The author has considerably modified Linnemann's method. The zircon is pulverised roughly in an iron mortar, and then ground in an agate mortar until the powder will pass through a 100-mesh sieve; the powder is boiled repeatedly with strong hydrochloric acid and washed with water. The fusion is conducted in a nickel crucible; 400 grams of sodium hydroxide are first fused, then 20 grams of dry sodium fluoride are added, and when the mass is highly heated, the 100 grams of zircon powder is dropped in; any boiling over of the mass is prevented by the temporary removal of the flame. When the action ceases, the molten mass is poured on to a sheet of nickel, and as soon as it solidifies is plunged into water; the sodium silicate and a negligible amount of the zirconate pass into solution, but the bulk of the latter remains behind, and is dissolved in hydrochloric acid, being then subjected to repeated evaporation to dryness and treatment with hydrochloric acid, to remove silica and hydrofluoric acid; the zirconium being ultimately precipitated as hydroxide by means of ammonia. The hydroxide, after thoroughly washing by decantation, is dissolved in the smallest possible quantity of strong hydrochloric acid, the solution evaporated to dryness, and the zirconium chloride obtained washed in a funnel with a mixture of strong hydrochloric acid with four parts of alcohol; any zirconium chloride passing into solution can be recovered. The white mass in the funnel is then repeatedly crystallised from strong hydrochloric acid, the zirconium oxychloride being obtained in well-formed crystals of glistening whiteness.

The author used North Carolina zircons, and found they contained

sodium, potassium, magnesium, calcium, aluminium, iron, lead, tin, uranium, erbium, silicon, and zirconium, the mean percentage of $Fe_2O_3 = 3{\cdot}29$, of $ZiO_2 = 62{\cdot}83$, of $SiO_2 = 33{\cdot}98$. Linnemann found 16 elements in his zircons, and does not mention tin as one.

D. A. L.

Solution of Antimonious Chloride in Saturated Solutions of Sodium Chloride. By H. Causse (*Compt. rend.*, **113**, 1042—1045).—When excess of antimonious oxide is added to cold hydrochloric acid, a state of equilibrium is established after a time between the oxide, the acid, the water, and the oxychloride resulting from the interaction of the water and the chloride. The amount of chloride formed increases with the strength of the acid, but the amount of the latter left uncombined is constant for all solutions containing more than 15 per cent. of hydrogen chloride. If the acid is saturated with sodium chloride, the curve representing the ratio of uncombined to total acid is not altered in character, but is brought nearer the abscissa, the proportion of free acid being less in every case; on the other hand, the amount of oxide dissolved is practically constant. A considerable amount of the acid in the solution thus saturated with sodium chloride may be neutralised with sodium carbonate without precipitating the antimony, and actual titration shows that the amount of alkali added is exactly equivalent to the free acid, so that antimonious chloride can remain dissolved in an aqueous solution of sodium chloride.

Jn. W.

Antimony Thiophosphate. By E. Glatzel (*Ber.*, **24**, 3886—3888).—*Antimony thiophosphate*, $SbPS_4$, is obtained by the action of antimony trichloride or antimony trisulphide on phosphorus pentasulphide. Finely powdered phosphorus pentasulphide (40 grams) and antimony trichloride (80 grams) are mixed together by shaking in a retort and warmed for one hour on the sand-bath with the neck of the retort pointing upwards; when the reaction is ended, the phosphorus thiochloride and excess of antimony trichloride are distilled off. The antimony thiophosphate which remains in the retort is bright-yellow; it melts when the temperature is raised, and solidifies on cooling in radiating, fibrous crystals of brilliant, silky lustre; when ground up, it yields a straw-coloured felted mass which smells of hydrogen sulphide, is insoluble in water, alcohol, ether, carbon bisulphide, hydrochloric acid, dilute sulphuric acid, benzene, and acetic acid, but is decomposed when boiled with strong nitric acid, aqua regia, strong sulphuric acid, and potassium or sodium hydroxides, and burns with a pale flame when heated in the air. When heated at its melting point for some time, decomposition takes place, a part of the phosphorus pentasulphide distils off, and a ruby-red, amorphous mass is left in the retort.

The preparation from antimony trisulphide is carried out in the same way as described above from the trichloride.

The author is preparing other thiophosphates.

E. C. R.

Bismuthic Acid. By G. André (*Compt. rend.*, **113**, 860—862).—20 grams of bismuth bromide and 40 grams of potassium brom-

ide are dissolved in 60 grams of water and mixed with excess of bromine. The solution is then poured drop by drop into an almost boiling solution of 100 grams of potassium hydroxide in 150 grams of water, the alkali remaining in excess at the end of the reaction. A very dense, red-brown precipitate forms immediately. This is washed repeatedly with boiling water by decantation, and after a long time part of the product forms a brown emulsion with the water, whilst a red-brown compound remains at the bottom of the vessel. The emulsion is decanted off, and can be precipitated by addition of a few drops of nitric acid. The non-emulsified product was washed with hot water until no longer alkaline, and one portion was washed for several days longer. Both portions, when dried at 100°, had the composition $4KBiO_3,3HBiO_3$. The same product is obtained from bismuth chloride. It dissolves easily in hydrochloric acid, with evolution of chlorine, but is soluble only with difficulty in warm nitric acid. When heated, it becomes pale-yellow, loses oxygen, then becomes brown, melts, and, on cooling, is pale-yellow.

Prolonged washing with boiling water yields a product which, after being dried at 100°, has the composition $KBiO_3,HBiO_3$.

All these products when treated with warm, dilute nitric acid, lose the whole of their potassium and yield brick-red bismuthic acid, $HBiO_3$. Very often the residue dried at 100° has the composition $HBiO_3,Bi_2O_5$. C. H. B.

Mineralogical Chemistry.

Determination of the Melting Points of Minerals. By J. Joly (*Chem. News*, **65**, 1—3, 16—18, 30—32, and 41—44).—Up to the present, no serious attempt has been made to measure accurately the melting points of minerals. The scale of fusibility of Van Kobell constitutes a comparative method, but is full of errors even as a means of identification. Whether a splinter of a mineral will melt in the flame of the blowpipe depends as much on the shape, conductivity, and dimensions of the splinter as on its melting point. In order to avoid these sources of error and to obtain an accurate measure of the melting points of minerals, the author has designed an instrument which he terms a "meldometer"; it is constructed as follows:—A ribbon of pure platinum, having a width of about 1·2 mm., is stretched between forceps, furnished each with a binding screw, and insulated from each other so that on connecting the binding screws with a battery a current can be passed through the ribbon. Upon the surface of this ribbon the substance to be examined is placed. It is necessary first to reduce the mineral to a fine powder in an agate mortar, and finally grind it with a little water in the form of a fine fluent paste; a speck of this is spread over a small area of the ribbon. The best condition for observing melting is when a

few particles are thinly spread here and there upon the platinum. A quantity invisible to the unassisted eye may be dealt with, for in all cases the phenomena of melting are observed through a microscope. The microscope having been brought to bear upon the thin coating of the powdered mineral upon the platinum, a current of gradually increasing intensity is passed through the ribbon until the mineral melts or volatilises. In this process the mineral often exhibits very characteristic phenomena, so that a substance may be identified in this way by comparing its behaviour with that of accredited specimens of the material in question. By this method, also, sublimates may be readily obtained, even from substances which treated in the blowpipe would appear to afford none. A circular cover-glass, not too thin, grasped in a forceps, is held horizontally above the platinum ribbon, as the temperature is being raised. If the sublimate is one which oxidises, we obtain the oxidised sublimate alone, or the unoxidised sublimate bordered by the oxide, according as we hold the glass further or nearer to the ribbon.

In order to measure the exact melting points of the substances dealt with, the author, after trying different methods for the estimation of the temperature, has adopted one which depends on the thermal expansion of the ribbon. The increase in length of the ribbon is determined when a salt of known high melting point is seen to melt upon its surface, and again when two or more other substances differing from each other as much as possible in melting point are melting. With several such points, a curve can be constructed for the extension of the ribbon with temperature, from which the temperature of melting of any unknown substance can be at once ascertained, when the extension of the ribbon at the time of melting is known. Full details of the method of measuring the extension of the ribbon are given in the paper. H. C.

Natural Classification of Minerals. By T. Sterry Hunt (*Systematic Mineralogy*, New York, 1891).—In a volume of 391 pages, the author describes a method of classification of minerals designed with the object of reconciling the natural history method and the chemical method, between which the antagonism in former years was the subject of much debate. His primary division, based on chemical grounds, is into four classes: (1) The non-oxidised metallic minerals, (2) the haloïd minerals, (3) the oxidised minerals, and (4) the carbonaceous combustibles. The further subdivisions are chemical and physical, use being made of the periodic law, and of the law of polymerism. By dividing the calculated value of the chemical unit for each species by its specific gravity, the author obtains a constant which he terms the reciprocal of the coefficient of condensation, and this figure furnishes a means of classification with which hardness and other physical properties coincide to a remarkable degree.

B. H. B.

Paramelaconite and Footeïte. By G. A. Koenig (*Zeit. Kryst. Min.*, **19**, 597—603).—At the Copper Queen Mine, at Bisby, in

Arizona, Mr. A. E. Foote found two interesting specimens, which probably once were portions of the same piece. The specimens consist of black crystals with an adamantine lustre planted on a matrix composed of acicular, indigo-blue crystals. The black crystals, termed *paramelaconite* by the author, are of the tetragonal system, closely resembling the black anatase of Brazil. The colour of the crystal faces is violet-black, whilst that of the fractured surface is raven-black. The hardness is 5, and the sp. gr. 5·833. Analysis yielded 100·68 per cent. of CuO, and 0·64 per cent. of Fe_2O_3, or, if the excess is taken to be oxygen, the material analysed consisted of—

CuO.	Cu_2O.	Fe_2O_3.	Total.
87·66	11·70	0·64	100·00

This represents, therefore, an undoubted case of dimorphism of black cupric oxide, a mineral hitherto found to crystallise in the asymmetrical system. On the conclusion of the investigation, the author discovered another specimen of this mineral, described as melaconite or tenorite from South Arizona, in the collection of the University of Pennsylvania.

The small, acicular crystals, termed *footeïte* by the author, are of the monosymmetrical system, and gave on analysis results corresponding with the formula $8Cu(HO)_2,CuCl_2 + 4H_2O$. The mineral approaching most closely to this composition is Church's blue thallingite. B. H. B.

Samarskite from Colorado. By W. F. Hillebrand (*Zeit. Kryst. Min.*, **19**, 638—640; from *Proc. Colorado Sci. Soc.*, **3**, 38—47).—The mineral examined was obtained from the Devil's Head Mountain, Douglas Co., Colorado. It occurs in small fragments without crystalline form. It has a hardness of 5·5 to 6, a sp. gr. of 6·18, a pitch-black colour, a dirty-brown streak, and a conchoidal fracture. A second specimen had a salmon-coloured streak and a sp. gr. of 6·12, whilst a third specimen was so highly altered that the original colour and lustre could no longer be observed. Analyses of the three specimens are given by the author.

With this mineral, there occurs another, which appears, according to analyses given by the author, to consist of a mixture of a mineral resembling cyrtolite and of a phosphate. B. H. B.

Formation of Melilite during the Burning of Portland Cement. By G. Bodländer (*Jahrb. f. Min.*, 1892, i, Mem. 53—56).—On emptying the chamber of an annular kiln at the Ascania Cement Works, at Nienburg, there was found, with the compact cement clinkers, a porous mass, about the size of the fist, which was filled with tabular, tetragonal crystals about 3 mm. in diameter and 1·5 mm. in height. The crystal planes are of light-brown colour, and the fractured surfaces are greyish-yellow. On analysis, it was found that this mineral was melilite. It appears to have been formed by the action of the acid fire-bricks, with which the kiln was lined, on the basic mass of cement. B. H. B.

Relation between Minerals of the Heulandite and Desmine Groups. By F. Rinne (*Jahrb. f. Min.*, 1892, i, Mem. 12—44).—The heulandite group consists of the minerals heulandite, brewsterite, and epistilbite, and the desmine group consists of desmine, harmatome, and phillipsite. From a consideration of the geometrical relations of the crystals of these minerals, it is shown that heulandite, brewsterite, and epistilbite may, in view of their external form, be regarded as one group of isomorphous minerals, bearing a relation to the group of isomorphous minerals composed of harmatome, phillipsite, and desmine. The mean axial ratios of the minerals of these groups are:—

Heulandite group..	$a:c:b = 1:0{\cdot}8611:1{\cdot}7520$; $\beta = 56°\ 2'$
Desmine group....	$a:c:b = 1:0{\cdot}8479:1{\cdot}3811$; $\beta = 53\ \ 52'$

With regard to the composition of these minerals, W. Fresenius has shown that harmatome, phillipsite, and desmine are members of a series of silicate mixtures. In the case of the heulandite group, the author proposes the following formulæ, based on analyses made by Jannasch:—

Heulandite	$RAl_2Si_6O_{16} + 6H_2O$.
Epistilbite	$RAl_2Si_6O_{16} + 5\frac{1}{2}H_2O$.
Brewsterite	

In heulandite R represents Ca, Sr, Na_2, K_2, Li; in epistilbite, Ca, Na_2, K_2, Li_2; and in brewsterite, Si, Ba, Ca, Na_2, K_2.

Interesting relations are also pointed out in the physical properties of these minerals. The individuality of the six minerals is rendered evident, and they may well be classed together as one great natural group of zeolites. B. H. B.

Formula of Vesuvian Meionite. By A. Kenngott (*Jahrb. f. Min.*, 1892, i, Mem. 49—53).—With a view to find a formula for meionite which would be in accord with Tschermak's theory, that the scapolite series consists of mixtures of a lime-alumina silicate and a soda-alumina silicate, the author has recalculated the published analyses of meionite from Vesuvius, and arrives at the formula $Ca_7Al_{10}O_{22},Si_{11}O_{22}$ as the most probable. It is that of a basic silicate in which the ratio of the oxygen in the lime and alumina to that in the silica is as 1 is to 1, and the ratio of the calcium, aluminium, and silicon atoms to the oxygen atoms is as 7 is to 11. B. H. B.

Rumpfite, a New Mineral. By G. Firtsch (*Jahrb. f. Min.*, 1892, i, Ref. 31—32; from *Sitzungsber. Wien. Akad.*, **99**, 1—5).—In fissures in the pinolite in the recently-discovered dolomite mass near St. Michael, in Upper Styria, there is found, with talc, a greenish-white mineral, with a perfect basal cleavage, a white streak, a hardness of 1·5, and a sp. gr. of 2·675. The mineral is optically uniaxial, and probably belongs to the hexagonal system, unless it is monoclinic, with a very small axial angle. Analysis yielded the following results:—

SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.	H_2O.	Total.
30·75	41·66	1·61	0·89	12·09	13·12	100·12

The formula is, consequently, $H_{28}Mg_7Al_{16}Si_{10}O_{65}$. The new mineral resembles most closely the chlorites, from which, however, it differs in chemical composition. B. H. B.

Meteorites of Turgaisk. By E. D. Kislakowsky (*Jahrb. f. Min.*, 1892, i, Ref. 51—52; from *Bull. soc. imp. des naturalistes de Moscou*, **4**, 187—199).—Two pieces have been found, weighing $32\frac{1}{2}$ and 16 kilograms respectively. Their sp. gr. was 6·6. Analysis showed them to consist of a portion amounting to 78·51 per cent. soluble in nitric acid, and containing:—

Fe.	Ni.	Co.	P.	Cu.	Total.
73·00	3·85	1·63	0·02	trace	78·50

whilst the residue contained:—

Fe.	Ni.	P.	Al_2O_3.	CaO.	MgO.	SiO_2.	Total.
2·99	1·15	0·30	2·86	1·56	4·77	7·67	21·30

The meteorite was calculated to consist of 3·85 per cent. of schreibersite, 9·88 of olivine, 8·06 of anorthite, and 78·25 of meteoric iron. The meteoric iron contained 93·10 per cent. of iron, 4·82 of nickel, and 2·08 of cobalt. The proportion of cobalt is unusually high, whilst that of the nickel and cobalt together is remarkably low for an octahedral iron. B. H. B.

Mineral Springs of Edepsos. By A. K. Dambergis (*Ber.*, **25** 99—107).—The springs of Edepsos are scattered over an area measuring 600 metres from east to west and 500 metres from north to south. Their number is about 60, but if all the small cracks from which water flows are counted, then they number above 100. They lie at an altitude varying from 48·78 to 5·60 metres above the sea level. The temperature of the water varies from 28° to 78°, and the highest springs have usually the lowest temperature. The volume of water from all the springs amounts to 8640 cubic metres per 24 hours. The water bubbles out clear, but on exposure to air soon deposits a precipitate; it tastes very salt and somewhat bitter. The steam which comes out with the water smells slightly of hydrogen sulphide, but the water itself is odourless. The specific gravity varies from 1·0168 to 1·0194, compared with distilled water at 25°. Nearly all the springs evolve a large volume of gas, which consists almost entirely of carbonic anhydride mixed with small quantities of oxygen and nitrogen, and sometimes a very small quantity of hydrogen sulphide. The deposit from the water varies in colour from white to reddish-brown; the white deposit consists of calcium carbonate with small quantities of magnesium carbonate, calcium sulphate and phosphate, alumina, and ferric oxide. Some of the springs give a red deposit, which consists of almost pure ferric oxide. In the neighbourhood of the springs are several cracks from which hot gas is

evolved. This gas varies in temperature from 46° to 62°, and consists of air, carbonic anhydride, and steam. The amount of solid in the water per 100 c.c. varies from 22·9582 grams to 33·5840 grams. A table is given containing a complete analysis of several of the waters.

E. C. R.

Waters of the North Sea on the Coasts of Holland. By H. W. B. Roozeboom (*Rec. Trav. Chim.*, **10**, 91—99).—In 1889, a series of samples of water, taken at 50—60 m. from the coast near Scheveningen, were examined by Koppeschaar. When the lock of the "Ververschingskanaal" was closed, the minimum amount of sodium chloride found was 17·96 grams per litre, and the maximum, 29·64 grams. These numbers correspond with the specific gravities of 1·0146 and 1·0241 at 15°.

A commission, continuing these researches, in 1890 examined 268 surface samples. The specific gravity varied from 1·0103 to 1·0241. The variations were due to fresh water from the "Nieuwe Waterweg." They were generally gradual, but instances are given of sudden variations. With increasing depth, these variations became less considerable and not so well defined. In 20 samples, at a depth of 1 to 2·5 m., the density varied from 1·0131 to 1·0233; 105 samples from the bottom, at 2·5—5 m., showed a variation from 1·0162 to 1·0239; 18 samples taken from the bottom, at 7·2—9·4 m., gave 1·0211—1·0245. With 88 samples collected when the lock gates were closed, the proportion of ammonia varied from 0 to 0·4 milligram per litre. In the greater number of cases, the quantitity of ammonia did not reach 0·1 milligram per litre.

82 analyses gave the maximum and minimum amounts of permanganate required for oxidation of the organic matter in boiling alkaline solution as 7·2 and 2·0 milligrams per litre. There is a distinct relation between the specific gravities and the amounts of potassium permanganate required; the smaller densities correspond with the higher values for permanganate.

The amounts of suspended matter varied between wide limits. Among 139 samples not contaminated with the waters of the canal, 63 per cent. gave below 30 milligrams per litre of sediment, which consisted, in great part, of organic matter. When the sediment exceeded 60 milligrams per litre, the loss by calcination became very constant at about 20 per cent.

An analysis by Van Bemmelen of the whole of the residues collected and air-dried gave:—4·25 per cent. of water, ±11 per cent. of organic matter, 19·6 per cent. of calcium carbonate, 8 per cent. of coarse sand, 23 per cent. of fine sand and clay deposited from the water, and 33·5 per cent. of true clay, remaining suspended in pure water for 24 hours. The composition of the North Sea sediment is thus similar to that of the Ij, Zuider Zee, and Dollard.

The organic matters are chiefly composed of fragments of marine animals and plants.

W. T.

Organic Chemistry.

Ammonio-Copper Ammonium Cyanide. By E. Fleurent (*Compt. rend.*, **113**, 1045—1047).—When copper hydroxide is dissolved in a freshly made boiling solution of ammonium cyanide, two distinct substances, which crystallise in large, violet or brown needles, separate on cooling. The author has not succeeded in determining the nature or conditions of formation of these compounds.

A stable ammonio-copper ammonium cyanide,

$$Cu_2(CN)_2,NH_4CN,3NH_3,$$

however, may be prepared by treating a solution of cupric chloride (15 grams) with excess of ammonia, adding ammonium chloride (3 grams) and potassium cyanide (22 grams), and heating the resulting solution (200 c.c.) in sealed tubes at 125—130° for three hours. The colourless liquid thus obtained, which loses ammonia and deposits colourless crystals on exposure to the air, is treated with acetic acid until a precipitate begins to form, after the removal of which the double cyanide separates in colourless, hexagonal plates. It is insoluble in cold water, and only sparingly soluble in hot water, but freely in ammonia, in which it forms a colourless solution which turns blue on exposure to the air. When heated above 200°, it loses ammonia and ammonium cyanide, and is converted into cuprous cyanide. When treated with dilute nitric or sulphuric acid, it is converted into cupric and hydrogen cyanides.

The author has obtained other compounds by varying the conditions, and has also prepared analogous bromides and iodides, which he is at present studying. Jn. W.

Dibromopropylene. By R. Lespieau (*Bull. Soc. Chim.* [3], **6**, 420—421).—The dibromopropylene, $CHBr{:}CH{\cdot}CH_2Br$ (termed by the author epidibromhydrin) has been prepared by the method employed by Friedel for the corresponding chlorine compound. Symmetrical dibromhydrin is treated with phosphorus pentoxide and distilled under reduced pressure. The product separates into two main portions: one of these is tribromhydrin boiling at 219°; the other boils with decomposition at 155°. The latter passes over at about 91° under 105 mm. pressure. It is colourless, but becomes yellowish-red in the light. Its formula is $C_3H_4Br_2$; the cryoscopic method with benzene gives its molecular weight as 198·27 as against the calculated value 200. Its density at 0° is 2·12. It takes up two atoms of bromine less energetically than its isomeride,

$$CH_2{:}CBr{\cdot}CH_2Br.$$

The product obtained does not solidify in a mixture of ice and salt, whereas its isomeride solidifies at about 0°.

Sodium ethoxide reacts on this compound at 0°, giving the ether $CHBr{:}CH{\cdot}CH_2{\cdot}OEt$. It is an oil insoluble in water, boiling at 145—146°, and of sp. gr. 1·47. Its molecular weight is found by

the cryoscopic method to be 160·58. Traces of propargyl methyl ether are formed at the same time, and this substance is the product when the oil is treated with sodium. W. T.

Formation of Acetylene from Bromoform. By P. Cazeneuve (*Compt. rend.*, **113**, 1054—1055).—Acetylene has been synthesised in various ways from chloroform and iodoform, but not hitherto from bromoform. When bromoform (10 grams) is warmed with dry powdered silver (50 grams), a reaction occurs which is so violent as to raise the mass to incandescence, and acetylene is evolved in nearly theoretical quantity. Powdered zinc may be substituted for the silver, but the action must then be started by allowing a few drops of ammoniacal cuprous chloride to trickle down the sides of the containing vessel. If a steady stream of the gas is required, it is best to use the copper-zinc couple, for which purpose the bromoform (20 grams) is treated with powdered zinc (80 grams), and 2 per cent. aqueous cupric chloride. Chloroform does not yield acetylene under these methods of treatment, except, perhaps, a trace with the copper-zinc couple. Jn. W.

Preparation of Cuprous Acetylide. By M. Kuntzmann (*Bull. Soc. Chim.* [3], **6**, 422).—The author prepares this compound by the action of acetylene on copper in presence of ammonia, whereby (1) the intermediate formation of ammoniacal cuprous chloride is obviated, and (2) it is not necessary to wash with ammonia as in the ordinary method of preparation. The gases containing acetylene are aspirated through a Woulffe's bottle containing ammonia solution, and thence through a cylinder containing copper turnings and ammonia. The red compound forms on the turnings and remains in suspension in the liquid, which itself becomes blue. In connection with a Jungfleisch apparatus for burning gas, 20—25 grams of the red compound have been obtained per hour, using 125 grams of commercial ammonia. W. T.

Action of Potassium and Sodium Sulphides on Chloroform. By L. Delmont (*J. Pharm.* [5], **24**, 425—429).—The action of alkaline sulphides on chloroform leads first to the formation of *thioformic acid*, CH_2S_2, now first obtained, next, to the production of intermediate chlorine compounds from which the thioxanthates can be regularly obtained, and, lastly, to the formation of alcoholates of the alkaline bisulphate. J. T.

Disodium Glycol. By De Forcrand (*Compt. rend.*, **113**, 1048—1051).—Disodium glycol cannot be obtained by the direct action of sodium on monosodium glycol, as this substance is solid, and cannot be heated in contact with sodium without decomposition. It may, however, be prepared by treating glycol with saturated aqueous soda (2 or 3 mols.), and evaporating the solution over phosphoric anhydride in the cold, when, after several days, brilliant plates of the hydrated compound, $C_2H_4Na_2O_2 + 10H_2O$, crystallise out. The anhydrous compound may be obtained as a white, amorphous,

porous mass by heating the hydrated compound in a current of hydrogen at 130°. The yield is only 8 to 10 per cent. Another method, which is better adapted for calorimetric study, and which gives practically the theoretical yield, consists in treating glycol with sodium ethoxide (2 mols.) in alcoholic solution. The glycol dissolves with evolution of heat, and the solution is boiled in a reflux apparatus for two or three hours, after which the alcohol is distilled off in a current of hydrogen, and the residue heated at 135° until it ceases to lose weight. The product thus obtained appears, however, to contain a little unchanged glycol.

The heat of solution of disodium glycol in water (1 gram mol. in 6 litres at 10°) is +21·49 Cal.; the heat of combination of glycol (1 gram mol. in 2 litres of water) with 1 eq. of sodium hydroxide (1 gram. mol. in 2 litres of water) is +0·28 Cal.; and that of monosodium glycol with sodium hydroxide under the same conditions is +0·08 Cal. From these data, and the assumption that the heat of fusion of glycol is the same as that of glycerol, −3·9 Cal., it is calculated that the first equivalent of sodium in displacing the hydrogen from glycol liberates +35·10 Cal., whilst the second liberates +27·68 Cal. There is thus a difference of +7·42 Cal. in favour of the first equivalent, which is also the case with glycerol and erythritol, for which the corresponding differences are +9·57 Cal. and +7·00 Cal. It is to be remarked also that the heat disengaged by the first equivalent of sodium in each of these three cases (+35·10, +39·99, +37·14 Cal.) is greater than that disengaged by the action of sodium on water (+31·87 Cal.; the water calculated as solid), while that disengaged by the action of the second equivalent (+27·68, +30·42, +31·16 Cal.) is distinctly less. Jn. W.

Compounds of Sorbitol and Perseïtol with Molybdic Acid. By D. Gernez (*Compt. rend.*, **113**, 1031—1033).—The rotatory power of sorbitol, like that of mannitol (Abstr., 1891, 1443), is affected by the presence of certain acid molybdates. When, for instance, sodium hydrogen or ammonium hydrogen molybdate (1/168 mol.) is added to an aqueous solution of sorbitol (1 mol.), the (negative) rotatory power is halved; it is destroyed, moreover, by the addition of double this amount, and, by still further additions, is reversed. The positive increase does not, however, continue indefinitely, as with either of the above salts a maximum is reached when 0·28 mol. has been added, the rotatory power at this point being numerically 20 times that of the original solution. This proportion would seem to indicate the presence of a compound of 1 mol. of sorbitol with 2 mols. of molybdic acid, but since the neutral molybdates are entirely inert towards polarised light, and the action of the acid salts may, therefore, be supposed to be due to the excess of acid, it is more likely that the compound present in the solution consists of 8 mols. of sorbitol with 9 mols. of the acid. Similar results are stated to have been obtained with perseïtol. Jn. W.

Preparation of Raffinose from Molasses. By J. W. Gunning (*Chem. Centr.*, 1891, ii, 798; from *Bull. assoc. belg. des chimistes*, 1891,

326).—The author uses the following method for the separation of raffinose from molasses :—The amount of a saturated solution of alum which is necessary to neutralise the molasses is determined in about 10 grams. A quantity of 1—5 kilos. of molasses is employed, water is added, together with the requisite quantity of alum solution, and then sufficient methyl alcohol to make it 60 per cent. The liquid is now filtered, and lead acetate added until no further precipitate forms. The precipitate is filtered off, and the solution neutralised with barium hydroxide and again filtered. In 50 c.c. of this solution, the amounts of raffinose and saccharose are estimated. From the remainder of the solution, the methyl alcohol is distilled, and the solution concentrated to a syrup. Whilst still warm, it is poured into a hot solution (1 : 1) of barium hydroxide in the proportion of 1 part of barium to 1 of sugar; the last portions are transferred by means of 50—100 c.c. of hot water. The mixture is boiled until a thick precipitate forms, when the latter is pressed from the solution. The solution is now concentrated to half the volume, and barium hydroxide solution added in the proportion of 2 mols. to 1 mol. of raffinose. Sufficient methyl alcohol is added to represent 75 per cent., and the liquid shaken thoroughly, when the barium raffinosate separates in agglomerations, which may easily be collected. It is washed with cold 75 per cent. methyl alcohol, dissolved in water, the barium precipitated by carbonic anhydride, the solution boiled, filtered, concentrated under diminished pressure to a syrup, and allowed to crystallise for two or three days. The crystalline mass is now washed with 60 per cent. methyl alcohol until all the saccharose is separated and then pressed. The raffinose is again dissolved in about seven times its weight of methyl alcohol, a little blood charcoal added, if necessary, and again allowed to crystallise. By this means, from 20—30 per. cent. of the raffinose present in the molasses is obtained. J. W. L.

Formaldehyde. By G. Lösekann (*Chem. Zeit.*, **14**, 1408—1409).—If paraformaldehyde be dissolved in hot water and the solution allowed to cool, or if it be rubbed with a little alcohol twice or thrice, the alcohol pressed out, and the residue treated similarly with ether, and then dried in a current of dry air, a white powder is obtained, which dissolves readily in hot water, and which is almost completely deposited again on cooling the solution. This substance was found to contain 88·2 per cent. of formaldehyde, as determined by Legler's method. After passing dry air over it for 40 minutes, 91·5 per cent. of formaldehyde was found. It was completely soluble in ammonia. After keeping in a stoppered tube for some time, 92·7 per cent. of formaldehyde was found. Trioxymethylene did not react like the paraldehyde, and the author concludes that trioxymethylene is, in reality, hexaoxymethylene, whilst paraldehyde is hexaoxymethylene hydrate. By passing hydrogen chloride into aqueous formaldehyde, a series of hydrochlorides were obtained, the first formed being $2CH_2O,HCl$, whilst $3CH_2O,2HCl$, $6CH_2O,5HCl$, and CH_2O,HCl were also obtained. J. W. L.

Action of Sulphurous Anhydride on Crotonaldehyde. By G. HAUBNER (*Monatsh.*, **12**, 541—555).—The author has extended the work of Ludwig (Abstr., 1889, 121) and Haymann (*ibid.*, 487) to crotonaldehyde, and finds that it also combines readily with sulphurous anhydride when that gas is led into its aqueous solution, kept cold with ice. The product is *hydroxybutanedisulphonic acid*, of which the barium salt, $C_4H_8S_2O_7Ba + 3H_2O$, forms an amorphous, white mass. The aqueous solution of this acid, on concentration, loses sulphurous acid and is converted into *butaldehydesulphonic acid*, which gives a gummy barium salt, $(C_4H_7SO_4)_2Ba + H_2O$. On oxidation with chlorine, hydroxybutanedisulphonic acid is converted into *β-sulphobutyric acid*, $SO_3H{\cdot}CHMe{\cdot}CH_2{\cdot}COOH$, the barium salt of which is very soluble in water, but almost insoluble in alcohol. The last-named acid gives acetic acid on fusion with potash, and consequently the sulpho-group is in the β-position, the compound having the constitution indicated above.

Barium butaldoximesulphonate is formed when hydroxylamine and baryta are heated with butaldehydesulphonic acid for four hours. On the addition of alcohol to its aqueous solution, it forms an amorphous precipitate; it has the constitution

$$(NOH{:}CH{\cdot}CH_2{\cdot}CHMe{\cdot}SO_3)_2Ba,$$

and, on reduction with sodium amalgam and subsequent distillation with lime in an atmosphere of hydrogen, gives a mixture of crotylamine, $CHMe{:}CH{\cdot}CH_2{\cdot}NH_2$, and butylamine.

On reduction of butaldehydesulphonic acid with sodium amalgam, the *sodium salt* of hydroxybutane-β-sulphonic acid, $C_4H_9SO_4Na$, is obtained. It is a hygroscopic, pale yellow salt, which, on distillation with lime, gives a mixture of crotyl alcohol and butyl alcohol.

G. T. M.

Action of Chlorine on some Ketones of the Fatty Series. By DÉMÈTRE-VLADESCO (*Bull. Soc. Chim.*, **6**, 395—415).—The action of chlorine on the four ketones—methyl ethyl ketone, methyl propyl ketone, propione, and butyrone—has been studied by the author, and a part of his results appear in this paper.

Methyl ethyl ketone and methyl propyl ketone are found among the products of distillation of wood, and have been prepared from light oils obtained in the rectification of methyl alcohol. In order to extract them, the portion distilling between 85° and 140° is washed with distilled water. The residue, insoluble in water, is treated with sodium hydrogen sulphite, and the solid compound formed freed from a liquid not combining with the sulphite and distilled with sodium carbonate. The product is fractionated. That portion passing over from 99° to 100° has the formula $C_5H_{10}O$, and was proved to be methyl propyl ketone. The portion distilling between 70° and 143° is treated with distilled water. The part of the light oil dissolved is then separated with potassium carbonate; the product is treated with sodium hydrogen sulphite, and the ketone combining therewith is recovered and fractionated. The fraction passing over between 79° and 82° is methyl ethyl ketone. It has been identified by the preparation of its oxime, the corresponding secondary alcohol, and methyl ethyl chloracetole.

12 kilos. of light oils, obtained during the rectification of 20,000 litres of methyl alcohol, yielded 600 grams of pure methyl ethyl ketone.

A slow current of chlorine, dry and free from hydrochloric acid, was passed through 500 grams of methyl ethyl ketone, contained in a reflux apparatus and cooled by immersion in a freezing mixture. The hydrogen chloride formed during the operation was absorbed in distilled water in a tared flask. By weighing this flask at intervals, the progress of the reaction was ascertained. The experiment was stopped when the weight of hydrogen chloride disengaged equalled half the weight of the ketone used. The chlorination occupied three days. Fractional distillation yielded two main products. The one, passing over at 114—116°, when redistilled under a pressure of 365 mm., allowed the isolation of a liquid boiling at 115° at 755 mm., and having the composition C_4H_7ClO. Its vapour density, by V. Meyer's method in aniline, was found to be 3·8 as compared with 3·7, the theoretical value. The other, passing over at 164—166°, when similarly treated, gave the pure compound, boiling at 165° at 753 mm., and of the composition $C_4H_6Cl_2O$, this formula being confirmed by its density of 4·8. Both substances are liquids insoluble in water.

The chlorinated ketone, $CH_3{\cdot}CO{\cdot}CHCl{\cdot}CH_3$, was prepared by Conrad's method, and its properties were found to agree with those of the monochlorinated derivative of methyl ethyl ketone. The chloroketone, $CH_3{\cdot}CO{\cdot}CHCl{\cdot}CH_3$, was obtained as follows:—The sodium derivative of ethyl methylacetoacetate, dissolved in absolute alcohol, was acted on by the calculated quantity of dry chlorine, the sodium chloride filtered off and the chlorine derivative remaining freed from alcohol by evaporation on the water-bath. This substance,

$$COMe{\cdot}CMeCl{\cdot}COOEt,$$

was then heated for 6 hours with dilute hydrochloric acid at 170—180° in sealed tubes. The chloro-ketone thus obtained was then distilled off. Chlorethyl methyl ketone, $COMe{\cdot}CHClMe$, yields with zinc methyl a substance which readily combines with sodium hydrogen sulphite and distils between 85° and 100°. It is inferred that the substance synthesised is methyl isopropyl ketone, which boils at 95°, and from this it follows that the formula given above represents the constitution of the monochlorinated derivative of ethyl methyl ketone.

Constitution of the Compound $C_4H_6Cl_2O$.—There are six possible isomerides of this formula; among these, the two most probable are $COMe{\cdot}CCl_2Me$ and $CH_2Cl{\cdot}CO{\cdot}CHClMe$. By treatment with hydroxylamine, in presence of sodium acetate, the two chlorine atoms are replaced by the group NOH, this acting in the same manner as the oxygen atom. Hence the formula $CH_3{\cdot}CO{\cdot}CCl_2{\cdot}CH_3$ probably represents the constitution of the dichlorinated derivative obtained from methyl ethyl ketone. W. T.

Preparation of Fatty 1 : 2-Diketones. By H. v. Pechmann (*Ber.*, **24**, 3954—3956).—The following method of preparing diacetyl has been found to give the best results:—100 grams of ethyl methylacetoacetate is mixed in a narrow-mouthed bottle of 5 litres capacity

with 1·75 litres of water and 280 grams of 25 per cent. soda solution, and allowed to remain over night; 50 grams of 98 per cent. sodium nitrite are then added, the whole cooled in ice-water, and treated in small portions with 20 per cent. sulphuric acid, a rapid current of air being drawn through the liquid during the process to ensure the thorough admixture of the substances. As soon as tropæolin paper is coloured violet by the solution, the addition of sulphuric acid is stopped, the whole made alkaline with soda, and again slightly acidified with sulphuric acid. The product is divided into two portions, each of which is treated with soda until yellow, mixed with 150 grams of sodium carbonate crystals, and boiled until one half of the liquid has distilled over; the residue is neutralised with dilute sulphuric acid, diluted to 1·75 litres, mixed with 250 grams of concentrated sulphuric acid without cooling, and quickly distilled. The diacetyl passes over with the steam, the distillation being complete when the liquid gives no yellow coloration with soda. The first distillate also contains a certain amount of nitroso-ketone, which may be recovered by adding soda until it is yellow, then 50 grams of sodium carbonate crystals, distilling off the alcohol, adding sulphuric acid to the residue, and again distilling until no more diacetyl passes over.

All the distillates, which contain in addition to diacetyl some unaltered nitroso-ketone, are united and distilled with one-seventh their weight of concentrated sulphuric acid until no more diketone passes over, and the new distillates again distilled with addition of common salt; the process being repeated until the diacetyl separates from the aqueous solution as a light yellow oil, which is dried by fused calcium chloride, and distilled. The pure compound boils at 87—88°.

Acetylpropionyl can be obtained from ethyl ethylacetoacetate in an exactly similar manner; it boils, when pure, at 108°. H. G. C.

Configuration of Fatty Ketoximes. By A. Hantzsch (*Ber.*, **24**, 4018—4024).—Previous investigations have shown that aldoximes, and the oximes of symmetrical ketones, exist only in one form, which may be represented by the configuration $C_nH_{2n+1}\cdot\overset{\overset{\displaystyle N\cdot OH}{\|}}{C}\cdot R$; as the oximes of the lower asymmetrical ketones of the fatty series are liquids, the question whether they exist in two stereoisomeric modifications can only be settled indirectly by studying their chemical behaviour. This the author has attempted to do by treating the ketoximes with phosphorus pentachloride in ethereal solution, and then boiling the product with potash; in every case, the oxime behaved as if it were a mixture of two stereoisomeric forms, and yielded two amines and two fatty acids. The oxime of methyl ethyl ketone, for example, gives ethylamine and smaller quantities of methylamine, acetic acid, and a still smaller quantity of propionic acid; it may, therefore, be concluded that it is converted by phosphorus pentachloride and water successively into ethylacetamide and smaller quantities of methylpropionamide, that is to say (assuming an explanation of the reaction, given by the author with the aid of graphic formulæ, to be correct), that it consists of the stereoisomerides of the configurations

$Me\cdot\overset{\|}{C}\cdot Et$ and $Me\cdot\overset{\|}{C}\cdot Et$ respectively, the former being present in the larger proportion.
$N\cdot OH$ $OH\cdot N$

The oxime of methyl propyl ketone, when treated in like manner, gives propylamine and a small quantity of methylamine, acetic acid, and a still smaller quantity of butyric acid.

The *oxime* of methyl hexyl ketone, $NOH{:}CMe\cdot[CH_2]_5\cdot CH_3$, is an oil, boiling at 213—217° under a pressure of 713 mm. with slight decomposition; when treated in the manner described above, it yields hexylamine, and a very much smaller quantity of methylamine, acetic acid, and a very little heptylic acid; it may, therefrom, be concluded that the principal constituent of this oxime is the stereoisomeride of the configuration $Me\cdot\overset{\|}{C}\cdot C_6H_{13}$.
$N\cdot OH$

The oxime of methyl isopropyl ketone yields propylamine and acetic acid as the principal products, only small quantities of methylamine and isobutyric acid being formed.

It is, of course, at present impossible to say whether the two stereoisomeric forms are actually present in the original oxime, or whether a single modification is partially converted into its stereoisomeride under the conditions employed in these experiments. The results show, however, that the nature of the alcohol radicles has a certain influence on the relative stability of the two theoretically possible configurations, a methyl group having a greater repellent action on the hydroxyl group than the other fatty alcohol radicles; for this reason, in the case of oximes of the general formula

$$NOH{:}CMe\cdot C_nH_{2n+1},$$

the configuration $Me\cdot\overset{\|}{C}\cdot C_nH_{2n+1}$ is more readily assumed than the con-
$N\cdot OH$

figuration $Me\cdot\overset{\|}{C}\cdot C_nH_{2n+1}$. (See Smith, this vol., p. 487). F. S. K.
$OH\cdot N$

α-Bromisovaleric Acid, Pimelic Acid, and Synthesis of Teraconic Acid. By B. Schleicher (*Annalen*, **267**, 114—133).—α-Bromisovaleric acid, prepared by treating isovaleric acid with bromine and amorphous phosphorus, and decomposing the product with boiling water, crystallises from ether and chloroform in lustrous prisms, melts at 44°, and boils at 230° under the ordinary pressure with slight decomposition (at 150° under a pressure of 40 mm. without decomposition). The potassium, ammonium, and sodium salts are readily soluble, do not crystallise, and are unstable in boiling aqueous solution; the barium, strontium, cadmium, and zinc salts are gum-like compounds. The *copper* salt, $(C_5H_8BrO_2)_2Cu$, crystallises in green plates; the *lead* salt, with 1 mol. H_2O, and the *calcium* salt, with 2 mols. H_2O, are crystalline. The *methyl* salt, $C_5H_8BrO_2Me$, prepared by treating the bromide of the acid with methyl alcohol, is a colourless liquid of sp. gr. 1·353 at 13°/13°, boiling at 174°. The ethyl salt boils at 186°, and its sp. gr. is 1·2776 at 12°/12°.

Ethyl α-carboxyethylpimelate, $CHMe_2\cdot CH(COOEt)\cdot CH(COOEt)_2$, prepared as described by Roser (Abstr., 1884, 423), is a heavy oil,

boiling at 276—278)°. α-Carboxypimelic acid, obtained by hydrolysing the ethyl salt with concentrated potash, melts at 160° with evolution of carbonic anhydride, and is readily soluble in water, alcohol, and ether, but more sparingly in chloroform and light petroleum. The *barium* salt, $(C_8H_9O_6)_2Ba_3$, and the *silver* salt, $C_8H_9O_6Ag_3$, are amorphous.

Pimelic acid, prepared by heating the α-carboxy-derivative, melts at 114°; its *strontium* salt, $C_7H_{10}O_4Sr$, is readily soluble in cold, but almost insoluble in boiling water. *Bromopimelic acid* was obtained as a syrup by treating pimelic acid with bromine and amorphous phosphorus; its *ethyl* salt, $C_{11}H_{19}BrO_4$, boils at 248—252° with slight decomposition, but distils unchanged at 165—167° under a pressure of 40 mm.; its *lead* salt, $C_7H_9BrO_4Pb$, and its *calcium* salt, $C_7H_9BrO_4Ca$, are sparingly soluble in water. When ethyl bromopimelate is heated with anhydrous sodium acetate at 180°, and the product hydrolysed with potash, teraconic acid is obtained.

Hydroxypimelic acid (*isopropylmalic acid*),

$$COOH{\cdot}CHPr^{\beta}{\cdot}CH(OH){\cdot}COOH,$$

can be obtained by heating ethyl bromopimelate with potash; it crystallises from ether in lustrous plates melting at 154°. The *calcium* salt, $C_7H_{10}O_5Ca$, is crystalline, but the *lead* salt, $C_7H_{10}O_5Pb$, is amorphous. F. S. K.

The Specific Gravity of Japan Wax. By O. Kleinstück (*Chem. Zeit.*, **14**, 1303—1304).—Determinations of the temperature at which Japan wax, as well as common wax, has the same sp. gr. as water showed that its expansion coefficient was greater than that of water, and that consequently, pieces of the wax sank in water at low temperatures, whilst, at temperatures above a certain point, they floated on the surface. By cutting small blocks of different specimens and allowing the temperature of the water to rise or fall very gradually, in order to give the wax time to assume the temperature of the water, the exact temperature could be determined at which the wax had the same sp. gr. as the water.

The author has also observed that after being recently melted (and after again solidifying), wax has the same density as water at a lower temperature than when some little time has elapsed since being melted. Three specimens were experimented with in 1888. Before being melted, this particular temperature was 17°, 17°, and 18° for the three specimens respectively, whilst, after being melted, the temperature of equal density was 11° for all three specimens.

In 1889, the temperature of equal density for three specimens was, before being melted, 15·9°, 15·3°, and 16·9°, whilst, after melting, the particular temperature was 10·8°, 13·4°, and 14·3° respectively. Determinations were made with three other specimens in 1889—1890. On August 1st, 1889, Specimen 1 had the same density as water at 16·2°; August 2nd, directly after melting and again solidifying, the temperature was 8°; August 17th, 12·3°; September 18th, 14·1°; March 2nd, 1890, 16·0°. The temperature of equal density for Specimen 2 was, for the same dates, 16·2°, 10·5°, 14·3°, 15·5, and

16·0°, whilst the corresponding readings for Specimen 3 were 17·5°, 12·7°, 15·7°, 17·4°, and 17·8°. On March 3rd, 1890, all three specimens were again melted, and after solidifying, the temperatures were 8·4°, 10·3°, and 11·3° for the three specimens respectively, whilst, on July 7th, 1890, the temperatures were 19·0°, 19·3°, and 20·2° respectively. Wax would appear to assume its normal density only very slowly after being melted. J. W. L.

Stereometric Relations of Erucic Acid and Brassidic Acid. By A. Holt (*Ber.*, **24**, 4120—4129).—Erucic acid and brassidic acid are not affected by heating under pressure with sodium amalgam or sodium in alcoholic solution, nor are they changed by heating with alcoholic potash at 150°.

Erucic acid dichloride, $C_{22}H_{42}Cl_2O_2$, is prepared by the action of chlorine on erucic acid, dissolved in chloroform; it crystallises from chloroform in small, lustrous plates melting at 46°. The *methyl salt*, $C_{21}H_{41}Cl_2{\cdot}COOMe$, melts at 30·5°.

Brassidic acid dichloride, $C_{22}H_{42}Cl_2O_2$, resembles the corresponding erucic acid derivative, and melts at 65°. The *methyl salt* melts at 42·5°.

On heating the dichloro-acids with sodium or sodium amalgam in alcoholic solution, the original acids are regenerated, whilst by the action of alcoholic potash in excess for 8—10 hours at 120—130°, monochlorinated substitution products are formed.

Chlorerucic acid, $C_{22}H_{41}ClO_2$, is prepared from brassidic acid dichloride, and melts at 37·5°. *Chlorobrassidic acid*, $C_{22}H_{41}ClO_2$, obtained from erucic acid dichloride, melts at 42°.

Bromerucic acid crystallises in colourless, lustrous needles which melt at 41·5°. The *methyl salt* melts at 18—19°.

Bromobrassidic acid, $C_{22}H_{41}BrO_2$, melts at 34°.

The above mono-haloïd acids are converted into erucic and brassidic acids respectively by the action of sodium in alcoholic solution.

The isomerism of erucic and brassidic acids is thus shown to have been correctly explained by J. Wislicenus; they are represented by the formulæ $\begin{matrix} X{\cdot}C{\cdot}H \\ \| \\ H{\cdot}C{\cdot}COOH \end{matrix}$ and $\begin{matrix} X{\cdot}C{\cdot}H \\ \| \\ COOH{\cdot}C{\cdot}H \end{matrix}$ respectively, since behenolic acid is much more readily formed from the di-haloïd compounds of erucic acid than from those of brassidic acid. J. B. T.

γ-Trichloro-β-Hydroxybutyric Acid. A New Synthesis of Malic Acid. By K. Garzarolli-Thurnlackh (*Monatsh.*, **12**, 556—565).—Chloral and malonic acid in molecular proportion were placed with an excess of acetic acid in a reflux apparatus, and heated in a water-bath for 25—40 hours, until carbonic anhydride was no longer evolved. The product was distilled until the temperature registered 124°, whereby acetic acid and chloral passed over. The residue was dissolved in water, and the yellow solution thus obtained treated with animal charcoal and concentrated until a crystalline mass of the sole product, *γ-trichloro-β-hydroxybutyric acid*, $CCl_3{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$, formed. It is readily soluble in hot water and in methyl and ethyl alcohols; dissolves sparingly in chloroform and ether; melts at

118·5°; does not reduce Fehling's solution; is optically active, and may be distilled unchanged in a vacuum. The *calcium salt*, $2(C_4H_4Cl_3O_3)_2Ca + 9H_2O$, is soluble in alcohol, and crystallises from water in slender, white needles; the *silver salt*, $C_4H_4Cl_3O_3Ag$, crystallises from water in long needles, and is decomposed with formation of silver chloride on long-continued boiling of its aqueous solution; the *methyl salt*, $C_4H_4Cl_3O_3Me$, crystallises from methyl alcohol in large, glistening plates, and melts at 61·2—61·6°; and the *acetyl derivative*, $C_4H_4Cl_3O_3Ac$, crystallises from chloroform in small, silky needles, has a characteristic odour, dissolves readily in alcohol and ether, and melts at 86—87°.

When γ-trichloro-β-hydroxybutyric acid is treated with concentrated solutions of potash or baryta, it is converted into malic acid. The calcium salt of the acid thus obtained appears to be identical with that of the malic acid prepared by Loydl (*Annalen*, **192**, 80) from fumaric acid. G. T. M.

Stereoisomeric Dimethyladipic Acids and Dimethylpimelic Acids. By N. Zelinsky (*Ber.*, **24**, 3997—4005).—*Ethyl dimethyldicyanoadipate*, $COOEt\cdot CMe(CN)\cdot CH_2\cdot CH_2\cdot CMe(CN)\cdot COOEt$, is formed by the action of ethylene bromide on ethyl sodio-α-cyanopropionate; it boils at 300—310° with slight decomposition.

Two isomeric dimethyladipic acids of the constitution

$$COOH\cdot CHMe\cdot CH_2\cdot CH_2\cdot CHMe\cdot COOH,$$

are obtained when the preceding compound is boiled with moderately concentrated sulphuric acid until the evolution of carbonic anhydride ceases; the two compounds are separated by fractional crystallisation from water. The more sparingly soluble acid forms monoclinic crystals, melts at 140—141°, and boils at 320—322°, yielding a distillate which has the same melting point as the original acid, but which has an odour of menthol; 100 parts of water at 22° dissolve only 0·5664 gram of the acid, and it is only sparingly soluble in chloroform and ether. The *silver* salt, $C_8H_{12}O_4Ag_2$, is a crystalline, unstable compound.

The more readily soluble dimethyladipic acid forms rhombic crystals, melts at 74—76°, and boils at 320—322°, the distillate having an odour of menthol; it is readily soluble in alcohol, ether, and chloroform, and 100 parts of water at 15° dissolve 6·7 grams of the acid. When heated with hydrochloric acid at 220°, it is converted into the isomeride. The *silver* salt, $C_8H_{12}O_4Ag_2$, is crystalline. Molecular weight determinations in glacial acetic acid solution showed that both acids have the molecular formula $C_8H_{14}O_4$; they have the same electrical conductivity, namely, $k = 0·0042$.

Ethyl dimethyldicyanopimelate, $CH_2[CH_2\cdot CMe(CN)\cdot COOEt]_2$, can be obtained by treating ethyl sodio-α-cyanopropionate with trimethylene bromide; it boils at 220—240° under a pressure of 40—50 mm., and on hydrolysis with concentrated potash it is converted into a liquid acid. When this acid is boiled with concentrated sulphuric acid for some time, it is converted into an oil, from which crystals of dimethylpimelic acid, $C_9H_{16}O_4$, are gradually deposited on

long keeping; after recrystallisation from hot water, this acid melts at 71—73°. The oily mother liquors from the crystalline acid possibly consist of a liquid isomeride. F. S. K.

Note by Abstractor.—The author has evidently overlooked the fact that dimethylpimelic acid has been previously described by Kipping and Mackenzie (Trans., 1891, 569), and also by Perkin and Prentice (*ibid.*, 818).

Condensation of Cyanides with Ethereal Salts. By H. Fleischhauer (*J. pr. Chem.* [2], **44**, 571—572).—*Ethyl cyanopyruvate oxime*, $CN{\cdot}CH_2{\cdot}C(NOH){\cdot}COOEt$, obtained from ethyl oxalate, methyl cyanide, and hydroxylamine, crystallises from hot water in colourless prisms, melts at 104°, and dissolves easily in alcohol and hot water, but not in ether; when heated with strong hydrochloric acid at 125° in a sealed tube, carbonic anhydride and ammonia, but no hydroxylamine, are formed; the *silver* compound was obtained.

The corresponding *hydrazone*, $CN{\cdot}CH_2{\cdot}C(N_2HPh)COOEt$, crystallises from absolute alcohol both in small, white prisms, and in large crystals, and from light petroleum in slender needles; it melts above 100°, and is easily soluble in alcohol and ether, but not in water. A. G. B.

Diiodoacetylenedicarboxylic Acid and Diiodoacrylic Acid. By P. Bruck (*Ber.*, **24**, 4118—4120, and **25**, 503).—Diiodoacetylenedicarboxylic acid, $COOH{\cdot}CI{:}CI{\cdot}COOH$, is prepared by heating acetylenedicarboxylic acid and iodine in molecular proportion with alcohol in a sealed tube for 5—6 hours at 100°, the product is freed from iodine, washed with benzene, and crystallised from a mixture of ether and benzene; it is deposited in small, needle-shaped crystals, melting at 192° with decomposition. The *sodium* and *potassium salts* are hygroscopic; the *silver salt* is amorphous; the *barium salt*, $C_4O_4I_2Ba + 3H_2O$, is crystalline.

Diiodoacrylic acid (propargylic acid diiodide), $CHI{:}CI{\cdot}COOH$, is obtained by heating propargylic acid and iodine in molecular proportion in chloroform solution in a sealed tube for 5—6 hours at 100°; it crystallises from chloroform in colourless prisms, and melts at 104°. The *silver salt* forms small, lustrous plates, and on heating at 100°, yields acetylene iodide. In the later communication (*Ber.*, **25**, 503), the author states that he had overlooked the preparation of this acid by Homolka and Stolz (Abstr., 1885, 1198). J. B. T.

Ethyl Acetonedicarboxylate. By H. v. Pechmann (*Ber.*, **24**, 4095—4104).—The existence of a dipotassium derivative (Abstr., 1890, 673), and the formation of ethyl methylacetonedicarboxylate (*loc. cit.*) from the silver derivative of ethyl acetonedicarboxylate (see below), leads the author to the view that ethyl acetonedicarboxylate has a ketone formula; its behaviour towards acetic chloride is also not in harmony with the alternative hydroxy-formula. Acetic chloride has no action on ethyl acetonedicarboxylate, but the

corresponding acid reacts with 2 mols. of acetic chloride or acetic anhydride, forming a compound which may be regarded as carboxydehydracetic acid; further experiments are, however, in progress on this reaction. The author does not consider that the fact cited by Nef, that ethyl acetoacetate combines with bromine, is a proof that it contains a doubly-linked carbon atom, and he draws attention to Linnemann's observation (*Annalen*, **125**, 307) that acetone forms an additive compound with bromine.

When ethyl potassioacetonedicarboxylate is dissolved in water (15 parts) and a slight excess of silver nitrate dissolved in water (20 parts) added, a crystalline pulp of the *silver derivative* is obtained; after remaining for 20 minutes in the dark, it is collected and washed successively with water, alcohol, and ether; it has the composition $C_9H_{13}AgO_5$, and is very sensitive towards light. When the last-mentioned compound is heated in a reflux apparatus for a quarter of an hour with methyl iodide, ethyl methylacetonedicarboxylate (Abstr., 1890, 673) is obtained, and this condenses with resorcinol in the presence of sulphuric acid with the formation of ethyl *αβ-dimethylumbelliferonecarboxylate*, $COOEt\cdot CH_2\cdot C\lessgtr^{C_6H_3(OH)}_{CMe—CO}\gtrO$, which crystallises from dilute alcohol in colourless, lustrous needles, and melts at 140°; it yields the corresponding *carboxylic acid* on boiling with 15 per cent. sodium hydroxide solution; this crystallises from dilute alcohol in colourless, felted needles, melts at 186—188°, and gives *β*-dimethylumbelliferone (Abstr., 1884, 67) when heated in an oil-bath at 200°. A. R. L.

Hydrochelidonic Acid or Acetonediacetic Acid. By J. Volhard (*Annalen*, **267**, 48—106; compare Abstr., 1890, 30).—Further experiments have proved that hydrochelidonic acid (acetonediacetic acid) has the constitution previously assigned to it; the constitution of the dilactone (termed in this paper the ketodilactone), from which the acid was obtained, is, however, still, to a certain extent, doubtful, since it behaves, in almost all respects, like the anhydride of an acid.

The ketodilactone (m. p. 69°, not 75°) dissolves in concentrated hydrobromic acid and in concentrated hydrochloric acid, yielding solutions from which, after a short time, hydrochelidonic acid is deposited in crystals. Lactones, as is well known, are not decomposed by concentrated acids, but anhydrides, such as those of succinic, glutaric, isopropylsuccinic, and phthalic acids, are readily converted into the corresponding acids on treatment with concentrated hydrochloric acid. When the ketodilactone is treated with a concentrated aqueous solution of potassium cyanide, it is quickly converted into the hydrogen potassium salt of hydrochelidonic acid, in which respect also it behaves like an anhydride; under like conditions, the anhydrides of succinic, phthalic, and maleïc acids are converted into the hydrogen potassium salts of the corresponding acids.

Hydrochelidonamic acid, $C_7H_{11}NO_4$, is formed when the ketodilactone is triturated with the theoretical quantity of ammonia, or, better, with well-cooled alcoholic ammonia; in the latter case, the precipi-

tated ammonium salt is washed with chloroform and then decomposed with the theoretical quantity of 50 per cent. acetic acid. It crystallises from alcohol in colourless plates, melts at 127°, and is readily soluble in water and hot alcohol, but only sparingly in acetone, chloroform, and cold alcohol, and almost insoluble in ether, benzene, and light petroleum; it has a strongly acid reaction, decomposes carbonates, and is not decomposed by cold alkalis. The *zinc* salt, $(C_7H_{10}NO_4)_2Zn + 2H_2O$, is crystalline, but most of the other metallic salts could not be obtained in crystals.

Hydrochelidonimide, $C_7H_9NO_3$, is formed when the preceding compound is heated at 145—150° for a long time under the ordinary atmospheric pressure, or, better, for about 30 minutes at 125—130° under reduced pressure (15 mm.). It separates from boiling alcohol in transparent, well-defined, prismatic crystals, melts at 117°, and is readily soluble in chloroform, but only sparingly in ether and benzene, and insoluble in light petroleum and carbon bisulphide; it dissolves freely in water, yielding a strongly acid solution, from which, after warming with zinc carbonate, the zinc salt of hydrochelidonamic acid is obtained on evaporation.

When the dry ammonium salt of hydrochelidonamic acid is gradually heated to about 160°, it is converted into the diimide, $C_7H_{10}N_2O_2$; this substance separates from hot water in colourless, rhombic crystals, $a : b : c = 0{\cdot}8146 : 1 : 0{\cdot}9358$, and is identical with the imidopimelinimide obtained by Marckwald (Abstr., 1888, 677) by the action of alcoholic ammonia on ethyl hydrochelidonate. It is insoluble in benzene, acetone, and light petroleum, and only very sparingly soluble in chloroform, but readily in water, glacial acetic acid, and concentrated hydrochloric acid; when warmed with concentrated potash, it is converted into ammonia and hydrochelidonic acid, but it is not acted on by acid chlorides, acetic anhydride, nitrous acid, hydroxylamine, or reducing agents. The *silver* derivative, $C_7H_8N_2O_2Ag_2$, is a colourless, amorphous substance.

Hydrochelidon-bismethylimide, $C_9H_{14}N_2O_2$, is obtained when the ketodilactone (1 mol.) is treated with an alcoholic solution of methylamine (2 mols.), the solution evaporated over sulphuric acid, and the residue gradually heated to 160°. It crystallises from boiling alcohol in thin, lustrous plates, sinters together at 135°, and melts completely at 140—141°; it is very readily soluble in water, ether, chloroform, and ethyl acetate, and is not decomposed by boiling alkalis, but when fused with potash it yields methylamine.

Hydrochelidonanilic acid, $NHPh{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, is formed, together with the dianilide, when the ketodilactone is heated with aniline at 120—130°; after treating the crystalline product with chloroform to free it from aniline and unchanged ketodilactone, the anilic acid is extracted with cold ammonia and reprecipitated with hydrochloric acid. It crystallises from hot water in transparent, lustrous prisms, melts at 138—139° with decomposition, and dissolves freely in alkalis; the *silver* salt, $C_{13}H_{14}NO_4Ag$, is a colourless, seemingly amorphous compound.

The *dianilide*, $CO(CH_2{\cdot}CH_2{\cdot}CO{\cdot}NHPh)_2$, is also produced when methyl hydrochelidonate is boiled with aniline for a long time; it

crystallises from hot alcohol in small needles, melts at 186—187°, and is almost insoluble in cold water.

Lach has shown that when phthalic anhydride is treated with an alcoholic solution of hydroxylamine, it is converted into phthalylhydroxylamine (Abstr., 1883, 1104); benzoic anhydride, under the same conditions, is converted into dibenzhydroxamic acid.

Hydrochelidonic acid dioxime, $C_7H_{10}N_2O_4$, is formed when the ketodilactone is treated with a well-cooled alcoholic solution of hydroxylamine; it crystallises from water in monosymmetric plates, $a : b : c = 1{\cdot}9672 : 1 : 1{\cdot}3614$; $\beta = 88° 52'$, containing 2 mols. H_2O, both of which are expelled at 100°. It crystallises from alcohol in anhydrous needles, which begin to darken at 230° and decompose on further heating, but without melting; it dissolves freely in hot water, soda, and hydrochloric acid, but is only sparingly soluble in warm alcohol, and insoluble in chloroform, acetone, light petroleum, carbon bisulphide, and benzene. Its aqueous solution has a feebly acid reaction, but has no action on carbonates; when the dioxime is boiled with concentrated hydrochloric acid, it is decomposed into hydroxylamine and hydrochelidonic acid. The *diacetyl* derivative, $C_7H_{10}N_2O_5Ac_2$, prepared by warming the dioxime with acetic anhydride, crystallises from hot alcohol in lustrous prisms, melts at 195—196°, and is soluble in acetone, chloroform, glacial acetic acid, and methyl alcohol, but insoluble in ether, benzene, and toluene; it dissolves freely in hot water, but seems at the same time to undergo decomposition, the solution having an acid reaction; its constitution is probably represented by the formula $CO[CH_2{\cdot}CH_2{\cdot}C(OAc){:}NOH]_2$, and that of the dioxime by the formula $\begin{matrix}CH_2-CH_2\\ |\\ C(NOH)\cdot O\end{matrix}>C<\begin{matrix}CH_2-CH_2\\ |\\ O\cdot C(NOH)\end{matrix}>$.

These experiments having left the constitution of the ketodilactone still undecided, the author examined the behaviour of pimelic acid with acetic chloride, acetic anhydride, and phosphorus pentachloride; as, under various conditions, the pimelic acid remained unchanged, and as, moreover, its constitution is very similar to that of hydrochelidonic acid, it follows that the reason why hydrochelidonic acid readily loses the elements of water must be sought for in the presence of the carbonyl group, or, in other words, that the ketodilactone is not an anhydride, but a dilactone of the constitution

$$\begin{matrix}CH_2{\cdot}CH_2\\ |\\ CO-O\end{matrix}>C<\begin{matrix}CH_2{\cdot}CH_2\\ |\\ O-CO\end{matrix}\cdot$$

The true analogues of such a compound would be, not the ordinary dilactones, but the oxetones; it is necessary, therefore, to obtain some evidence that the oxetones have the constitution assigned to them by Fittig (Abstr., 1890, 866) before any conclusions regarding the constitution of the ketodilactone can be drawn from analogy; this evidence is afforded by the synthesis of dimethyloxetone in the following manner:—

Ethyl diallylacetonedicarboxylate, $C_{15}H_{22}O_5$, can be obtained by treating ethyl acetonedicarboxylate with sodium ethoxide and allyl bromide; it boils at 185—186° under a pressure of 10 mm. with slight

decomposition, and on treatment with bromine in carbon bisulphide solution, it yields a brown oil with evolution of hydrogen bromide.

Diallylacetonedicarboxylic acid, prepared by hydrolysing the ethyl salt with alcoholic potash in the cold, crystallises in slender needles melting at 96° with evolution of carbonic anhydride.

Diallylacetone, $C_9H_{14}O$, is obtained when the dicarboxylic acid is heated for some time at 100°, and also when ethyl diallylacetonedicarboxylate is hydrolysed with warm alcoholic potash; it is a colourless oil, boils at 185—186° (at 116° under a pressure of 70 mm.), and combines with hydroxylamine and with phenylhydrazine, yielding oily products. When treated with hydrobromic acid at 0°, it is converted into a dibromide of the composition $C_9H_{16}OBr_2$, identical with the compound obtained by Fittig and Rasch (Abstr., 1890, 867) by the action of hydrobromic acid on dimethyloxetone; this dibromide is decomposed by hot water, yielding Rasch's dimethyloxetone.

The constitution of dimethyloxetone having been determined by the experiments just described, its peculiar behaviour with acids can be easily explained, and is clearly analogous to that of the ketodilactone. The analogy between the two compounds is, however, even more evident when their methods of formation are studied, the reactions by which the oxetone is produced from 2 mols. of valerolactone being quite similar to those by which the ketodilactone is formed from 2 mols. of succinic anhydride.

The compound of the composition $C_{19}H_{20}N_4O_2$, obtained by Bredt (Abstr., 1890, 864) by treating the ketodilactone with phenylhydrazine, has probably the constitution represented by the formula $CO<\begin{matrix}N(NHPh)\\CH_2—CH_2\end{matrix}>C<\begin{matrix}N(NHPh)\\CH_2—CH_2\end{matrix}>CO$, and may therefore be named *dihydrazidopimelic anhydride;* it is readily soluble in boiling glacial acetic acid, but only sparingly in carbon bisulphide, and almost insoluble in ether, benzene, and light petroleum; it is not acted on by alkalis or dilute acids, and it dissolves in concentrated sulphuric acid with a rose-red coloration. The *diacetyl* derivative, $C_{23}H_{24}N_4O_4$, prepared by treating the dihydrazido-compound with acetic chloride at 100°, crystallises from alcohol in lustrous, seemingly quadratic octahedra, and is readily soluble in warm glacial acetic acid and warm chloroform, but only sparingly in most of the other ordinary solvents; it dissolves in concentrated sulphuric acid, yielding a solution which turns red on shaking or on adding a drop of ferric chloride. The *dibenzoyl* derivative, $C_{33}H_{28}N_4O_4$, sinters together at 100°, but without melting completely, and begins to decompose at 110°. A compound of the composition $C_{23}H_{28}N_4O_2$ is formed when the ketodilactone is heated with asymmetrical ethylphenylhydrazine at 100°; it crystallises from hot methyl alcohol in microscopic octahedra, melts at 220—222°, and dissolves freely in chloroform, but is only moderately easily soluble in hot acetone, and insoluble in ether and light petroleum; its behaviour with concentrated sulphuric acid and ferric chloride, and with acids and alkalis, is the same as that of dihydrazidopimelic anhydride.

That hydrochelidonic acid has a symmetrical constitution is rendered highly probable by the above experiments on the constitution of the

ketodilactone; this view is proved to be correct by the synthesis of the acid from acetonedicarboxylic acid in the following manner:—Ethyl acetonedicarboxylate is treated with sodium ethoxide and ethyl chloracetate, and the product boiled with concentrated hydrochloric acid until the evolution of carbonic anhydride ceases; from the solution obtained in this way, hydrochelidonic acid can be easily isolated.

F. S. K.

The Phenylhydrazonehydrazide of Levulinic Acid. By J. Volhard (*Annalen*, **267**, 106—113).—Bredt's assumption that the hydrazine derivatives of hydrochelidonic acid (compare preceding abstract) and levulinic acid resemble one another in constitution and in their manner of formation (Abstr., 1890, 863) is without foundation, and consequently his conclusion that the two acids are analogously constituted is incorrect.

The hydrazone of levulinicphenylhydrazide described by Bredt can be prepared by warming levulinic acid with phenylhydrazine; it is a colourless, microcrystalline powder, melts at 180·5—181·5°, and is readily decomposed by warm, dilute hydrochloric acid; its constitution is most probably expressed by the formula

$$N_2HPh{:}CMe{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}N_2H_2Ph.$$

Levulinicphenylhydrazoneazobenzene, $C_{17}H_{18}N_4O$, is obtained when an alcoholic solution of the hydrazone of levulinicphenylhydrazide is warmed with yellow mercuric oxide; it crystallises in flat, transparent prisms, melts at 142—142·5°, and is readily soluble in benzene, chloroform, and glacial acetic acid, but only sparingly in light petroleum, and insoluble in water, alkalis, and dilute acids. It is not acted on by boiling alkalis, but it is decomposed by warm cencentrated hydrochloric acid with formation of methylindoleacetic acid, benzene, chlorobenzene, ammonia, aniline, and nitrogen; it has in all probability the constitution represented by the formula

$$N_2HPh{:}CMe{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}N_2Ph.$$

F. S. K.

Stereoisomerism of the Dimethyldihydroxyglutaric Acids. By N. Zelinsky (*Ber.*, **24**, 4006—4017).—A *nitrile* of the constitution $CH_2[CMe(CN){\cdot}OH]_2$ is gradually deposited when hydrochloric acid of sp. gr. 1·19 is added drop by drop to a well-cooled mixture of acetylacetone, potassium cyanide, and water; it separates from hot alcohol and benzene in crystals, melts at 134—136° with decomposition, and is only sparingly soluble in ether.

A *lactone* of *dimethyldihydroxyglutaric acid* (*dimethylhydroxybutyrolactonecarboxylic acid*, $COOH{\cdot}CMe<\begin{matrix}O{\cdot}CO\\CH_2-\end{matrix}>CMe{\cdot}OH$, is obtained when the preceding compound is treated with hydrochloric acid of sp. gr. 1·19, first at the ordinary temperature and then at 100°, the solution evaporated to dryness, and the residue extracted with ether; it crystallises from water in large, rhombic plates, melts at 189—190°, is optically inactive, and is only sparingly soluble in water and alcohol, but readily in ether. The *barium* salt, $(C_7H_9O_5)_2Ba + 2H_2O$, prepared by treating the lactonic acid with barium carbonate, crystal-

lises in silky needles. When the lactonic acid is boiled with barium hydroxide, the *barium* salt of dimethyldihydroxyglutaric acid, $C_7H_{10}O_6Ba + 2\frac{1}{2}H_2O$, is obtained; this compound is decomposed by acids, the lactonic acid being regenerated; the potassium salt shows a like behaviour.

The *dilactone*, $CMe\begin{matrix}CO\cdot O\\ \diagup\\ \diagdown\\ O\cdot CO\end{matrix}CH_2\begin{matrix}\diagup\\ \diagdown\end{matrix}CMe$, is produced when the lactonic acid is distilled; it forms small, colourless crystals, melts at 104—105°, and is readily soluble in ether, alcohol, and benzene, but only moderately easily in hot, and almost insoluble in cold, water. It is not acted on by boiling water, and it dissolves unchanged in concentrated sulphuric acid.

Dimethyldihydroxyglutaric acid, $C_7H_{12}O_6$, can be obtained by boiling the dilactone for a short time with excess of dilute potash, and then acidifying with sulphuric acid; it separates from ether and water in colourless crystals, melts at 103—104°, and is readily soluble in alcohol and hot water, but only moderately easily in ether and cold water. It is probably identical with the acid (m. p. 95—96°) obtained by Auwers and Jackson (Abstr., 1890, 1098) from dibromodimethylglutaric acid. When titrated with very dilute barium hydroxide or potash in the cold, it behaves like a monocarboxylic acid, but at higher temperatures it shows the behaviour of a dicarboxylic acid. The fact that this acid is stable, whilst the dicarboxylic acid which is formed on treating the lactonic acid with alkalis is unstable, leads to the conclusion that dimethyldihydroxyglutaric acid exists in two structurally identical modifications, the configurations of which may be represented by the formulæ

$$\begin{matrix}CH_3\\ OH\cdot C\cdot COOH\\ CH_2\\ OH\cdot C\cdot COOH\\ CH_3\end{matrix}$$

Unstable acid.

and

$$\begin{matrix}COOH\\ CH_3\cdot C\cdot OH\\ CH_2\\ OH\cdot C\cdot COOH\\ CH_3\end{matrix}$$

Stable acid.

The stable acid (m. p. 103—104°) is optically inactive, but seems to consist of two optically active modifications; it separates from ether in well-defined crystals, some of which were found to be enantiomorphous. F. S. K.

A New Pentonic Acid and the Second Inactive Trihydroxyglutaric Acid. By E. Fischer and O. Piloty (*Ber.*, **24**, 4214—4225). —It has been shown that when certain monocarboxylic acids of the sugar group are heated with quinoline or pyridine, they are converted into stereoisomeric acids, differing only from the original compounds in the relative position of the carboxyl to the adjacent carbon atom.

When arabonic acid, $OH\cdot CH_2\cdot\begin{matrix}OH\\ C\\ H\end{matrix}-\begin{matrix}OH\\ C\\ H\end{matrix}-\begin{matrix}H\\ C\\ OH\end{matrix}\cdot COOH$, is treated by this method, in the manner to be described, it yields a new acid,

$OH\cdot CH_2\cdot\overset{OH}{\overset{|}{C}}-\overset{OH}{\overset{|}{C}}-\overset{OH}{\overset{|}{C}}\cdot COOH$, which the authors name *ribonic acid*.
H H H

For this purpose, a 10 per cent. aqueous solution of arabonic acid (600 grams) is heated with pyridine at a maximum temperature of 130°, in a copper autoclave, for three hours, a concentrated solution of barium hydroxide (650 grams) added, and after boiling off the pyridine, and precipitating the barium with a small excess of sulphuric acid, it is treated with lead carbonate (60 grams) mixed with water to a paste, in order to precipitate the excess of sulphuric acid. The solution is then filtered while hot, the filtrate treated with hydrogen sulphide, and the lead sulphide removed by filtration. It is then boiled with an excess of calcium carbonate for half an hour, treated with animal charcoal, and the filtrate evaporated to a thin syrup. This is allowed to remain for 12 hours, when calcium arabonate (400 grams) separates and is removed, whilst the mother liquor is exactly precipitated with oxalic acid, and the filtrate boiled with an excess of cadmium hydroxide for half an hour, treated with animal charcoal, filtered hot, and evaporated to a syrup, from which crude cadmium ribonate (115 grams) separates after a time in cauliflower-like masses, and is crystallised from a small quantity of hot water. When an aqueous solution of the pure salt is treated with hydrogen sulphide, and the filtrate evaporated to a syrup, a crystalline cake of the *lactone*, $C_5H_8O_5$, is obtained; this is dissolved in ethyl acetate (30 parts) by boiling, and the filtrate evaporated to one-third, whereby the lactone separates in long, colourless prisms; it melts at 72—76°, has a neutral reaction, does not reduce Fehling's solution, and is very easily soluble in water, alcohol, and acetone, somewhat sparingly in ethyl acetate, and very sparingly in ether. It has a specific rotatory power $[\alpha]_{D20} = -18$, which remains the same if the solution is examined 12 hours after preparation. The *calcium*, *barium*, and *lead* salts are very readily soluble in water, and leave gummy residues when their solutions are evaporated; the *mercury* salt, obtained by boiling the lactone with water and mercuric oxide, separates from its solution as a jelly, which changes after a time into delicate needles; when basic lead acetate is added to an aqueous solution, the ribonic acid is precipitated. The above-mentioned *cadmium* salt dissolves readily in hot water, and separates quickly on cooling in mammelated groups of delicate needles; its aqueous solutions have a specific rotation $[\alpha]_{D20°} = 0{\cdot}6$. The *phenylhydrazide*, $C_5H_9O_5\cdot N_2H_2Ph$, obtained by heating the lactone, phenylhydrazine, and water (1 gram of each) for an hour on the water-bath, treating the crystalline product with alcohol, and crystallising it from boiling absolute alcohol, forms colourless needles, melts at 162—164°, and decomposes at 180°.

Ribonic acid is distinguished from arabonic acid by the fact that the calcium salt of the latter crystallises well, as also by the difference in the melting points and solubilities of their respective phenylhydrazides (see Abstr., 1890, 1398). Furthermore, the lactone of arabonic acid melts at 98°, and has a specific rotation $[\alpha]_{D20} = -73{\cdot}9$, remaining unaltered after 14 hours; the values given by Bauer

(Abstr., 1886, 869) are too low, as is also the determination of the rotatory power by Allen and Tollens (Abstr., 1891, 669), the latter chemists having evidently dealt with a mixture of the acid and the lactone.

Ribonic acid is converted into arabonic acid when the lactone of the former (2 grams) is heated with water (10 grams) and pyridine (1·5 grams) in a sealed tube at 130—135° for three hours; it is then converted first into the barium and subsequently into the calcium salt, the yield being 1 gram of the salt.

Ribose.—When to a 10 per cent. aqueous solution of ribonic lactone, cooled to its freezing point, $2\frac{1}{2}$ per cent. sodium amalgam is added by degrees with vigorous shaking, the solution being kept acid by the addition of dilute sulphuric acid, the reduction proceeds quickly, and after adding a quantity of the amalgam corresponding with 10 times the weight of the lactone, the operation is stopped, and the solution decanted from the mercury. It is then made alkaline, the filtrate exactly neutralised with sulphuric acid in the cold, and absolute alcohol (6 parts) added, whereby the whole of the sodium sulphate and a portion of the unattacked sodium arabonate are precipitated. To the filtrate, 20 per cent. basic lead acetate solution is added as long as a precipitate is formed, and an excess of basic lead acetate to this filtrate, and then concentrated baryta solution until precipitation is complete. The precipitate, which contains the chief portion of the ribose, is carefully washed with water, and decomposed with very dilute sulphuric acid, filtered, and exactly precipitated with baryta; the filtrate from this, on evaporation, yields the sugar as a colourless syrup, containing only a small quantity of inorganic matter; a considerable quantity of furfuraldehyde is also formed.

When equal quantities of the last-mentioned syrup and phenylhydrazine are mixed with a very small quantity of absolute alcohol and allowed to remain for 12 hours, the *phenylhydrazide* separates on adding ether as a brownish syrup which solidifies after a time, and crystallises from alcohol in colourless crystals, sinters at 150°, melts at 154—155°, with gradual decomposition, and is very readily soluble in water. The *parabromophenylhydrazide*, $C_{11}H_{15}O_4BrN_2$, separates when the sugar is boiled with absolute alcohol and parabromophenylhydrazine for 12 hours. The product, after washing with ether, crystallises from alcohol as a colourless crystalline powder, melts at 164—165° with gradual decomposition, and is readily soluble in water. The *osazone* was also prepared, and appears to be identical with that obtained from arabinose, a result which was to be anticipated.

Ribonic acid is converted into trihydroxyglutaric acid as follows:—The lactone (10 grams) is heated in a platinum dish with nitric acid, sp. gr. 1·2 (25 c.c.), for 20—25 minutes on the water-bath with constant stirring; the product is added to water (160 c.c.), neutralised with calcium carbonate, treated with animal charcoal, and filtered while hot, whereby a portion of the calcium trihydroxyglutarate separates on cooling as a yellow, crystalline powder, and a further yield is obtained on evaporating the filtrate to one-third in a partial vacuum; whilst another portion separates on allowing the mother liquor to remain in the cold for several days, the entire yield

being 4·5 grams. When the calcium salt is digested with a hot solution containing the calculated quantity of oxalic acid, and the filtrate evaporated under diminished pressure at 60°, the *lactone*, $C_5H_6O_6$, is obtained; it separates from a concentrated solution in ethyl acetate in nodules consisting of aggregates of small needles, melts when quickly heated at 170—171°; it is very readily soluble in water and alcohol, fairly in acetone, somewhat sparingly in ethyl acetate, but almost insoluble in ether; it is optically inactive. When boiled with hydriodic acid and amorphous phosphorus for four hours, it is converted into glutaric acid. The acid corresponding with the last-described lactone may be represented by the configuration

$$\begin{array}{l} \quad OH\ OH\ OH \\ COOH\cdot\dot{C}-\dot{C}-\dot{C}\cdot COOH. \\ \quad H\ \ H\ \ H \end{array}$$

The isomeric trihydroxyglutaric acid, $\begin{array}{l} \quad OH\ H\ \ OH \\ COOH\cdot\dot{C}-\dot{C}-\dot{C}\cdot COOH \\ \quad H\ \ OH\ H \end{array}$, from xylose exhibits no tendency to form a lactone, even when its aqueous solution is evaporated under diminished pressure or at the ordinary pressure; when crystallised from ethyl acetate, it melts at 152°, instead of 145·5° as previously stated (Abstr., 1891, 1177), and yields a potassium salt, $C_5H_6O_7K_2 + 2H_2O$, which crystallises well; whereas a crystalline potassium salt could only be obtained from the isomeric acid from ribose with difficulty. The difference of the two trihydroxyglutaric acids appears therefore to be beyond doubt.

A. R. L.

Action of β-Iodopropionic Acid on Ethyl Thiocarbamate. By N. A. Langlet (*Ber.*, **24**, 3848—3853).—*Carbamine-β-thiolactic acid*, $NH_2\cdot CO\cdot S\cdot CH_2\cdot CH_2\cdot COOH$, is obtained by heating ethyl thiocarbamate (10·5 grams) with β-iodopropionic acid (20 grams) until gas begins to be evolved; the reaction then takes place without further heating, and ethyl iodide distils over. The product is poured into a dish and allowed to cool, and the solid compound thus obtained crystallised from hot water and washed with ether. It crystallises from water in white, lustrous leaflets, melts at 147·5°, and tastes and reacts acid. When oxidised in hydrochloric acid solution with potassium chlorate, it yields β-sulphonepropionic acid. The *alkali* salts are very hygroscopic, and were not obtained pure; by excess of alkali, it is very easily decomposed into thiolactic acid, carbonic acid, and ammonia. The *calcium* salt, $(NH_2\cdot CO\cdot S\cdot C_2H_4\cdot COO)_2Ca,3H_2O$, is obtained by neutralising a solution of the acid with calcium carbonate; it crystallises in pure white needles, is very soluble in water, insoluble in alcohol, loses its water of crystallisation at 100°, and easily decomposes above that temperature. The *barium* salt crystallises with 2 mols. of water, has similar properties to the calcium salt, but is not stable in solution. The *silver* salt,

$$NHAg\cdot CO\cdot S\cdot C_2H_4\cdot COOAg,$$

is obtained as a yellowish-white precipitate on adding silver nitrate to a solution of the acid.

Sinapanpropionic acid, $NH<^{CO-S}_{CO\cdot CH_2}>CH_2$, is obtained by heating ethyl thiocarbamate (10·5 grams), β-iodopropionic acid (20 grams), and acetic anhydride (10 grams) until reaction sets in. The acetic acid is evaporated off on the water-bath; the mixture allowed to cool, the semi-solid mass mixed with ether, and the crystals separated and crystallised from hot water. It forms short, colourless needles or rhombic plates, melts at 159°, sublimes unchanged, and is easily soluble in hot water, but only sparingly so in cold. The solution has a neutral reaction; the acid properties of the compound are shown by the ease with which it dissolves in cold potash. When heated with excess of potassium hydroxide, it does not yield thiolactic acid. When boiled with mercuric oxide, the sulphur is not eliminated, but the chain is broken with formation of the mercaptide of β-thiolactic acid.

Carbaminethiolactic acid is also obtained in small quantity on boiling an alcoholic solution of β-iodopropionic acid with potassium thiocyanate, and hydrolysing the product by boiling with hydrochloric acid. In an experiment in which the boiling with hydrochloric acid was continued for some time, a small quantity of sinapanpropionic acid was also formed.

Although it is not possible to obtain a closed-chain compound from carbamide and β-iodopropionic acid, the author has obtained a compound which he believes to have the formula $CH_2<^{S\cdot C(NH_2)}_{CH=CH}>N$ or $CH_2<^{S\cdot C(NH)}_{CH=CH}>NH$, by employing the aldehyde in place of the acid. The substance, which is difficult to purify, is sparingly soluble in water, easily so in acids, and gives insoluble precipitates with platinic and mercuric chlorides. The further description of this compound is reserved for a later date. E. C. R.

Silver Compound of Thiocarbamide. By N. Kurnakow (*Ber.*, **24**, 3956—3962; compare Reynolds, Trans., 1892, 249).—The author finds that the compound described by Reynolds (*Annalen*, **150**, 235) as the silver compound of thiocarbamide, $Ag_2O,2CSN_2H_4 + 4H_2O$, consists of a mixture of double compounds of the general formula $AgNO_3,nCSN_2H_4$, n being 1, 2, or 3. The compound $AgNO_3,CSN_2H_4$ may be obtained pure by pouring a solution of thiocarbamide into one containing an excess of silver nitrate, and recrystallising the precipitate from water containing silver nitrate and nitric acid. It dissolves readily in a solution of thiocarbamide on warming, and on slow cooling the compound $AgNO_3,3CSN_2H_4$ separates out in white crystals. On adding an excess of hydrochloric acid to the solution of the last compound, a white, crystalline precipitate is formed, which separates from aqueous thiocarbamide in prismatic crystals, and is identical with the double compound of silver chloride and thiocarbamide, $AgCl,2CSN_2H_4$, described by Volhard (this Journ., 1874, 574) and Baumann (this Journ., 1875, 632).

The author has found that the supposed compounds of thiocarbamides with mercuric oxide likewise contain nitric acid, and believes

that these have a constitution similar to the silver compounds. He regards the existence of any compounds of thiocarbamides with oxides as extremely doubtful. H. G. C.

Alloxanhydrazone. By O. Kühling (*Ber.*, **24**, 4140—4145).—*Alloxanhydrazone*, $CO<^{NH\cdot CO}_{NH\cdot CO}>C{:}N\cdot NHPh$, is prepared by the addition of phenylhydrazine hydrochloride to alloxan or alloxantin in hot aqueous solution; a considerable evolution of nitrogen occurs, and the hydrazone separates in the form of a voluminous, yellow precipitate; the purification of the compound is a matter of some difficulty, and is best accomplished by repeatedly boiling with water, dissolving the residue in glacial acetic acid, adding hydrochloric acid, and heating the solution for several hours in a reflux apparatus; the crystals which separate on cooling this solution are then extracted several times with boiling water. The compound melts at 298—300°, and readily dissolves in alkalis and alkali carbonate solutions; it is not hydrolysed by heating with acids.

Dimethylalloxanhydrazone, $CO<^{NMe\cdot CO}_{NMe\cdot CO}>C{:}N\cdot NHPh$, is obtained in a similar manner to the preceding compound, by the action of phenylhydrazine hydrochloride on tetramethylalloxantin; it is deposited from glacial acetic acid in slender, yellow crystals melting at 261°, and is insoluble in alkalis.

On heating alloxanphenylhydrazone with sodium carbonate solution until the red colour disappears and then acidifying with hydrochloric acid, *glyoxalylamidoformic acid phenylhydrazone*,

$$NHPh\cdot N{:}CH\cdot CO\cdot NH\cdot COOH,$$

is obtained; it crystallises from dilute alcohol, is soluble in alkalis, melts at 169°, and rapidly oxidises on exposure to air.

Dimethylalloxanphenylhydrazone yields a compound of the formula $NHPh\cdot N{:}CH\cdot CO\cdot NMe\cdot CO\cdot NHMe$ by the action of sodium carbonate; it crystallises from dilute alcohol containing a little hydrochloric acid in pale-yellow needles, melts at 123—124°, and is insoluble in alkalis. J. B. T.

Condensation of Levulinic Acid with Furfuraldehyde. By E. A. Kehrer (*Ber.*, **24**, 4104—4105).—The statement recently put forward by Erdmann that the author and Ludwig do not wish to reserve this subject for themselves is incorrect. A. R. L.

β-Isopropylthiophen. By A. Thiele (*Annalen*, **267**, 133—138).—*β-Isopropylthiophen*, $C_7H_{10}S$, prepared from sodium isopropylsuccinate by Volhard and Erdmann's method, is a colourless, mobile, highly refractive liquid, having an odour like that of benzene. It boils at 157—158° under a pressure of 754 mm., and is insoluble in water, but miscible with the ordinary organic solvents; it gives the indophenine reaction.

β-Isopropylacetothienone, C_7H_9AcS, is obtained when aluminium chloride is added in small portions at a time to a solution of isopro-

pylthiophene and acetic chloride in light petroleum, and the mixture warmed on the water-bath until the evolution of hydrogen chloride ceases; it is a yellow oil, boils at 237°, and is readily volatile with steam. The *oxime* crystallises in slender needles. The *hydrazone* crystallises from ether in yellow plates, and darkens on exposure to the air.

β-Isopropylpropiothienone, $C_{10}H_{14}OS$, prepared in like manner, is a yellow oil, boils at 251°, and is readily volatile with steam; on oxidation with potassium permanganate in dilute alkaline solution, it yields a yellow, oily acid, which, from analyses of its salts, is probably β-propylthienylglyoxylic acid, $CS_4H_2Pr{\cdot}CO{\cdot}COOH$. F. S. K.

Action of Dilute Nitric Acid on Nononaphthene. By Konovaloff (*Compt. rend.*, **113**, 1052—1053).—The nononaphthene, C_9H_{18}, which the author found some years ago to be identical with hexahydropseudocumene, is easily nitrated by heating with dilute nitric acid (sp. gr. 1·16 to 1·03) in sealed tubes, at temperatures varying from 110° to 150°, according to the strength of the acid. The chief product is *nitrononononaphthene*, $C_9H_{17}{\cdot}NO_2$, which boils at 131—133° under a pressure of 40 mm., and at 224—227° with partial decomposition under atmospheric pressure. Its specific gravity is 1·0062 at 0°/0° and 0·9908 at 20°/0°. It dissolves very sparingly in concentrated potash, and is reprecipitated from this solution by water. It gives a pale-green colour with nitrous acid, owing, perhaps, to the formation of the pseudonitrole. When heated with a mixture of nitric and sulphuric acids, it is decomposed with the formation of a base. A base is also formed when it is distilled at atmospheric pressure. It is reduced by zinc and acetic acid to the amidonaphthene and a compound, $C_8H_{16}CO$, which is stated to be a ketone.

Amidononononaphthene, $C_9H_{17}{\cdot}NH_2$, boils at 173—175°. It is a powerful base, as it forms a salt with carbonic anhydride. The *hydrochloride*, $C_9H_{17}{\cdot}NH_2{,}HCl$, crystallises from light petroleum, in which it is sparingly soluble, in cubes, but these, when exposed to the air, are transformed into crystals which act on polarised light and belong to another system. It is soluble also in water, alcohol, ether, and benzene. The *platinochloride*, $(C_9H_{17}{\cdot}NH_2)_2{,}H_2PtCl_6$, is easily soluble in alcohol and warm water, and crystallises from the latter in brilliant, yellow scales. Amidononononaphthene forms a compound with nitrous anhydride which may be converted into an alcohol.

The *ketonic compound*, $C_8H_{16}CO$, which is, perhaps, a homologue of menthone, $C_{10}H_{18}O$ boils at 180—182°, and has a specific gravity of 0·8903 at 0°/0° and 0·8747 at 20°/0°. It is insoluble in water, and has a faint odour, which resembles those of menthol and suberone. It can be reduced to an alcohol, and forms a compound with hydroxylamine, but it does not combine with sodium hydrogen sulphite or phenylhydrazine, or reduce Fehling's or ammoniacal silver solution. The *oxime*, $C_9H_{16}{:}NOH$, is a liquid which boils with partial decomposition at 220—225°; it is soluble in alcohol and acids, and is reconverted into the amine by reduction with sodium in alcoholic solution, and into the ketonic substance by boiling with acids. Jn. W.

Derivatives of Paranitrorthochlorobenzyl Bromide. By O. Witt (*Ber.*, **25**, 77—89).—*Paradinitrorthodichlorostilbene*, $C_2H_2(C_6H_3Cl\cdot NO_2)_2$, is obtained as a yellow, flocculent precipitate by heating a mixture of paranitrorthochlorobenzyl bromide and potassium or sodium hydroxide in molecular proportion, dissolved in alcohol. Parahydrazorthodichlorodibenzyl alcohol is formed at the same time, and remains in solution. It is also obtained by gradually adding alcoholic potash to an alcoholic solution of the bromide until the yellow precipitate begins to turn red; the yield is not so good as that obtained by the first method; and, if the alkali be added too rapidly, parazoxyorthodichlorostilbene is also formed. The yellow precipitate is insoluble in ether, alcohol, light petroleum, benzene, chloroform, carbon bisulphide, and acetone, somewhat soluble in acetic acid, and very easily soluble in hot nitrobenzene. It crystallises in small, yellow needles, and melts at 294°. It does not yield nitroamidodichlorostilbene when treated with tin and hydrochloric acid, or with zinc-dust and acetic acid, and gives resinous products when treated with alcoholic ammonium sulphide. Dinitrodichlorostilbene can also be obtained from paranitrorthochlorotoluene.

Parazoxyorthodichlorostilbene, $O<\begin{matrix}N\cdot C_6H_3Cl\cdot CH\\ \|\\ N\cdot C_6H_3Cl\cdot CH\end{matrix}>$, is prepared by the following methods:—(1) By gradually adding excess of alkali or sodium ethoxide to an alcoholic solution of paranitrorthochlorobenzyl bromide or paranitrorthochlorotoluene and heating the mixture for 8—10 hours in a reflux apparatus; (2) by heating paranitrorthochlorobenzyl ethyl ether or methyl ether with alkali for some time in alcoholic solution; (3) by heating paradinitrorthodichlorostilbene, suspended in alcohol, with excess of alkali, for 8—10 hours in a reflux apparatus. The last two methods give theoretical yields. It is a reddish-brown compound, is only sparingly soluble in alkaline alcohol, insoluble in all other solvents, decomposes above 300°, and partially sublimes. It is purified by extraction with hydrochloric acid, water, nitrobenzene, alcohol, and ether.

Parahydrazorthodichlorodibenzyl alcohol, $N_2H_2(C_6H_3Cl\cdot CH_2\cdot OH)_2$, is contained, as mentioned above, in the mother liquors from the preparation of paradinitrorthodichlorostilbene, and is obtained from them, by steam distillation, as an oil which soon solidifies. It crystallises from alcohol and ether, melts at 35°, is soluble in acetic acid and chloroform, and turns green on exposure to light. It does not show basic properties, does not yield alcohol when treated with concentrated hydrochloric acid, and when heated in a sealed tube with concentrated hydrochloric acid it does not yield a benzidine; neither does it yield a hydrazoïn with benzaldehyde. On reduction, it yields paramidorthochlorobenzyl alcohol.

Paranitrorthochlorobenzyl methyl ether, $NO_2\cdot C_6H_3Cl\cdot CH_2\cdot OMe$, is obtained by dissolving paranitrorthochlorobenzyl bromide and alkali hydroxide or sodium in methyl alcohol in molecular proportion, heating the mixture in a reflux apparatus for one hour, and then distilling the ether with steam. It crystallises in white plates, melts at 54°, is soluble in alcohol, ether, and acetic acid, insoluble in water, and turns pale green on exposure to light.

Paranitrorthochlorobenzyl ethyl ether, $NO_2 \cdot C_6H_3Cl \cdot CH_2 \cdot OEt$, is obtained by heating paranitrorthochlorobenzyl bromide and potassium cyanide, in molecular proportion, with ethyl alcohol, in a sealed tube, for four hours at 100°, and distilling the ether with steam. It crystallises in well-formed needles, melts at 33°, and is soluble in alcohol, ether, chloroform, and acetic acid, insoluble in water. When heated in a sealed tube with concentrated hydrochloric acid, it yields alcohol and paranitrorthochlorobenzyl alcohol.

Paramidorthochlorobenzyl ethyl ether, $NH_2 \cdot C_6H_3Cl \cdot CH_2 \cdot OEt$, is obtained by reducing the preceding compound with tin and hydrochloric acid. It is an oil which does not solidify in a freezing mixture. The *hydrochloride* forms long, white needles, and sublimes at 240° with partial decomposition.

Paranitrorthochlorobenzyl alcohol, $NO_2 \cdot C_6H_3Cl \cdot CH_2 \cdot OH$, is obtained by heating its ethyl ether in a sealed tube with fuming hydrochloric acid for some time at 100°, and is an oil which could not be obtained crystalline.

Paramidorthochlorobenzyl alcohol is obtained by reducing the preceding compound with tin and hydrochloric acid, and is also an oil, but yields crystalline salts. It is also obtained by reducing parahydrazorthodichlorodibenzyl alcohol with tin and hydrochloric acid. The *hydrochloride* crystallises in broad, white needles, turns green on exposure to air, decomposes at 254°, and partially sublimes, and is soluble in water, hydrochloric acid, and alcohol, insoluble in ether.

Paramidorthochlorotoluene, $C_6H_3MeCl \cdot NH_2$, is obtained by reducing paranitrorthochlorobenzyl bromide with tin and hydrochloric acid. It is an oil at ordinary temperatures, crystallises when cooled, and then melts at 26°. The hydrochloride crystallises in white needles, and is soluble in water and alcohol, insoluble in ether.

Paranitrorthochlorobenzylaniline, $NHPh \cdot CH_2 \cdot C_6H_3Cl \cdot NO_2$, is obtained, together with dinitrodichlorodibenzylaniline, by heating paranitrorthochlorobenzyl bromide (1 mol.) with aniline (2 mols.) in alcoholic solution for four hours in a reflux apparatus. On adding water to the mixture, a yellow powder is obtained, from which the nitrochlorobenzylaniline is extracted with hot hydrochloric acid, and, on cooling, the *hydrochloride* crystallises in transparent, white plates, which soon turn red. The free base which may be obtained by treating the hydrochloride with water, crystallises from alcohol in yellow plates, melts at 73°, and is soluble in ether and acetic acid.

Paradinitrorthodichlorodibenzylaniline, $NPh(CH_2 \cdot C_6H_3Cl \cdot NO_2)_2$, is obtained by heating nitrochlorobenzyl bromide and aniline in molecular proportion, dissolved in alcohol, for eight hours in a reflux apparatus. It is purified by extraction with hot hydrochloric acid and crystallisation from acetic acid, forms small, yellow crystals, melts at 172°, and is somewhat soluble in alcohol, ether, and chloroform. It does not give salts with acids.

Paradinitrorthodichlorodibenzylamine, $NH(CH_2 \cdot C_6H_3Cl \cdot NO_2)_2$, is obtained as a white precipitate, together with trinitrotrichlorotribenzylamine by passing ammonia into a boiling alcoholic solution of nitrochlorobenzyl bromide. The precipitate is dissolved in hydrochloric acid, reprecipitated with dilute alkali, and then fractionally

crystallised from alcohol, in which the dibenzylamine is less soluble. It crystallises in white, microscopic needles, melts at 120°, is soluble in alcohol, chloroform, and concentrated acids, with which it forms easily decomposable salts, is sparingly soluble in ether, and insoluble in water. The tribenzylamine was not obtained in a pure condition.

E. C. R.

Condensation of Isoamylene and Cinnamene with Phenols. By W. Koenigs and R. W. Carl (*Ber.*, **24**, 3889—3900).—The condensation was effected by allowing the hydrocarbon and the phenol to remain for four days with a mixture of 1 part of concentrated sulphuric acid with 9 of glacial acetic acid, diluting with water, neutralising with ammonia and ammonium carbonate, decomposing the acetyl compound formed by boiling with aqueous soda, filtering the alkaline solution, acidifying it, distilling over, first, unacted-on phenol with steam at 100°, and, finally, the condensation product with superheated steam at 160—170°. The hydrocarbon adds itself on, if possible, in the para-position to the hydroxyl; probably, also, to some extent in the ortho-position, as paracresol also yields a condensation product.

Isoamylthymol, $OH\cdot C_6H_2MePr^{\beta}\cdot CMe_2Et$ [Me : OH : Pr^{β} : C_5H_{11} = 1 : 3 : 4 : (?)6], obtained by the addition of isoamylene to thymol, melts at 76·5°, and boils at 275° (uncorr.) under 716 mm. pressure. When boiled with water, it has a musk-like odour; it dissolves in dilute alkalis and in the usual organic solvents, and crystallises from light petroleum in magnificent, colourless, transparent, monoclinic prisms ($a : b : c$ = 2·5136 : 1 : 2·4997 ; β = 68° 16′).

The phenylhydroxyphenylethane, $OH\cdot C_6H_4\cdot CHMePh$, obtained by the addition of cinnamene to phenol (Koenigs, Abstr., 1891, 208), was shown to be a para-compound, because its methyl derivative, obtained by boiling the phenol with potash and methyl iodide in methyl alcohol, yields paramethoxybenzophenone when oxidised with potassium dichromate and sulphuric acid.

Phenylorthohydroxytolylethane, $OH\cdot C_6H_3Me\cdot CHMePh$ [Me : OH = 1 : 2], obtained by the addition of cinnamene to orthocresol, forms a yellowish syrup, which decomposes partially when distilled, and dissolves in most solvents, water excepted. The *methyl derivative* forms a yellow oil boiling at 300—310°, dissolves readily in acetone, ether, light petroleum, and chloroform, sparingly in methyl alcohol, very sparingly in water. When oxidised with dilute sulphuric acid and manganese dioxide, it yields *phenyl orthomethoxytolyl ketone*. $OMe\cdot C_6H_3Me\cdot COPh$, identical with the substance obtained by treating the *methyl derivative of orthocresol* (a colourless oil boiling at 165°, uncorr., and smelling like aniseed) with benzoic chloride in the presence of aluminium chloride. It melts at 80°, and crystallises from ether in rhombs or in fine twins, resembling those of staurolite.

Phenylmetahydroxytolylethane, $OH\cdot C_6H_3Me\cdot CHMePh$ [Me : OH = 1 : 3], obtained by the addition of cinnamene to metacresol, crystallises with difficulty; it melts at 124°, decomposes partially when distilled, dissolves readily in most solvents, water excepted, and sparingly in light petroleum. Its *methyl derivative* melts at 63°.

Paracresol and α-naphthol unite with cinnamene, but no crystalline

products could be obtained. β-Naphthol forms a compound with phenylethylene which does not crystallise, but its *benzyl derivative*, $OBz{\cdot}C_{10}H_6{\cdot}CHMePh$, crystallises from dilute alcohol in plates with a pearly lustre, and melts at 138°.

The *benzoyl derivative of β-naphthol* crystallises from hot alcohol in colourless prisms with a silky lustre, from hot light petroleum in spherical aggregates; it melts at 106°. C. F. B.

Synthesis of the Sixth Dihydroxytoluene. By L. Limpach (*Ber.*, **24**, 4136—4140).—*Methoxycresol* [Me : OH : OMe = 1 : 2 : 3] is prepared from the corresponding amidomethoxycresol by means of the diazo-reaction as a viscid liquid which solidifies in a freezing mixture, melts at 39°, and boils at 209° (uncorr.); it is almost insoluble in water, but readily dissolves in alcohol, benzene, ether, and chloroform. The corresponding *ethoxycresol* is obtained in a similar manner to the methoxy-derivative, which it closely resembles, and is an oily liquid boiling at 214° (uncorr.).

Dihydroxytoluene, $C_6H_3Me(OH)_2$ [Me : OH : OH = 1 : 2 : 3], is formed by heating either of the preceding compounds with six parts of fuming hydrochloric acid in a sealed tube for eight hours at 160°; it solidifies at low temperatures, melts at 47°, and boils at 238—240° (uncorr.), undergoing slight decomposition; it is somewhat sparingly soluble in ether, but readily dissolves in water, alcohol, benzene, or chloroform. With ferric chloride, a green coloration is produced which soon disappears; the addition of ammonia changes the green colour to violet. The constitution of the compound is proved by the method of its formation; it differs, however, in properties from isorcinol, but as the latter compound is prepared by the fusion of toluenedisulphonic acid with potassium hydroxide, it is probably identical with one of the other isomerides.

Nitromethoxycresol [Me : NO_2 : OMe = 1 : 2 : 4] solidifies at low temperatures, forming yellow prismatic crystals which melt at 17°. J. B. T.

Action of Nitrous Acid on some Unsaturated Aromatic Compounds. By A. Angeli (*Ber.*, **24**, 3994—3996).—Compounds, such as apiole, safrole, eugenol, and methyleugenol, which contain an allyl group are not acted on by nitrous acid; the corresponding isomerides, isoapiole, isosafrole, and isomethyleugenole and asaron, and anethoïl, compounds which contain the propenyl group, react readily with nitrous acid, yielding in every case two products, namely, the true nitrosite, and a compound differing therefrom in composition by 1 mol. H_2O.

Isosafrole nitrosite, $C_{10}H_{10}N_2O_5$, crystallises in colourless needles, and melts at 132°; the second product crystallises in yellow needles, melts at 124°, and has the composition $C_{10}H_8N_2O_4$.

The isapiole derivative, $C_{12}H_{12}N_2O_6$, melts at 170°; the methyliso-eugenol derivative melts at 117°. F. S. K.

Hexachloroparadiketohexene. By T. Zincke and O. Fuchs (*Annalen*, **267**, 1—47; compare Zincke, Abstr., 1890, 964).—Hexachloroparadiketohexene, $\begin{matrix}CCl{\cdot}CO{\cdot}CCl_2\\ \|\quad\quad\ |\\ CCl{\cdot}CO{\cdot}CCl_2\end{matrix}$, is best prepared by heating

chloranil (5 grams) with manganese dioxide (5 grams) and hydrochloric acid of sp. gr. 1·19 (15 grams) at 180° for 10 hours. It melts at 89°, and boils at 275—285°, with partial decomposition into chlorine and chloranil; it is readily volatile with steam, and has a peculiar, irritating odour. On prolonged boiling with acetic acid, it is converted into chloranil, the same change taking place when it is heated with acetic acid and potassium iodide; when heated with dilute acetic acid at 140—150° for some hours, or when treated with stannous chloride, it is reduced to tetrachloroquinol. When shaken with 10 per cent. potash in the cold, it is decomposed into dichloromaleïc acid (m. p. 119—120°), trichlorethylene, and hydrogen chloride; well-cooled alcoholic potash converts it into an oily acid, which has probably the constitution $CCl_2{:}CCl{\cdot}CO{\cdot}CCl{:}CCl{\cdot}COOH$, since it is decomposed into trichlorethylene and dichloromaleïc acid by aqueous alkalis.

Pentachloranilidoparadiketohexene (m. p. 144°) is moderately easily soluble in most of the ordinary solvents, except water, and is very stable towards concentrated hydrochloric acid. When its warm alcoholic solution is treated with stannous chloride until it becomes pale yellow, and the product is then oxidised with ferric chloride, trichloranilidoquinone is deposited in blue needles, together with some other substance, probably the corresponding dichloro-derivative.

αββ-Trichlorophenyl-γ-pyridonecarboxylic acid (m. p. 245°) crystallises in small, colourless needles, and is only sparingly soluble in ether, chloroform, and benzene, and almost insoluble in warm water. The *barium* salt, $(C_{12}H_5Cl_3NO_3)_2Ba$, is a crystalline compound readily soluble in warm water. The *silver* salt, $C_{12}H_5Cl_3NO_3Ag$, crystallises in colourless needles, is very sparingly soluble in cold water, and quickly turns violet on exposure to light. The *methyl* salt crystallises from hot alcohol in plates, and melts at 205° with decomposition.

αββ-Trichloro-γ-phenylpyridone, $\begin{matrix} CCl{\cdot}NPh{\cdot}CH \\ \| \qquad\quad \| \\ CCl{\cdot}CO{\cdot}CCl \end{matrix}$, is produced when the preceding compound is boiled with alcohol or acetic acid, or heated alone at its melting point. It crystallises from dilute alcohol in colourless needles, melts at 245°, and is readily soluble in hot glacial acetic acid, but more sparingly in hot alcohol, and almost insoluble in benzene, ether, and chloroform; it is not acted on by phenylhydrazine, aniline, hydroxylamine, or methyl iodide.

ββ-Dichloro-α-hydroxyphenylpyridonecarboxylic acid (m. p. 206°) crystallises in colourless needles, and is almost insoluble in benzene, chloroform, and light petroleum, but moderately easily in warm water, and readily in ether, alcohol, and glacial acetic acid; it is not acted on by phenylhydrazine, hydroxylamine, or aniline in alcoholic solution, but it is readily oxidised and destroyed by hot, dilute nitric acid. The *silver* salt, $C_{12}H_5Cl_2NO_4Ag_2$, is a colourless, crystalline compound, moderately stable in the light; it explodes when heated in a dry state. The *barium* salt is readily soluble. The *methyl* salt, $C_{14}H_{11}Cl_2NO_4$, prepared from the silver salt, crystallises from dilute alcohol in rhombic plates, melts at 140°, and dissolves freely in chloroform, benzene, alcohol, and glacial acetic acid, but is almost insoluble in ether and light petroleum, and insoluble in water.

Acetoxydichloropyridone, $C_{13}H_9Cl_2O_3N$, is obtained when dichlorohydroxypyridonecarboxylic acid is heated with acetic anhydride and sodium acetate until the evolution of carbonic anhydride ceases; it crystallises from acetic acid in colourless, nacreous plates, melts at 143°, and is readily soluble in warm alcohol, glacial acetic acid, benzene, and chloroform, and moderately easily in ether, but insoluble in water and light petroleum.

ββ-Dichloro-α-hydroxyphenylpyridone, $C_{11}H_7Cl_2NO_2$, can be obtained by heating the carboxy-derivative, described above, or by warming trichlorophenylpyridone with 10 per cent. alcoholic potash; it is, however, best prepared by hydrolysing acetoxydichlorophenylpyridone with 10 per cent. alcoholic soda. It crystallises from hot alcohol in colourless needles, melts at 192°, and is moderately easily soluble in alcohol, ether, chloroform, and hot water, but almost insoluble in benzene and light petroleum. The *sodium* derivative crystallises in colourless needles, and is readily soluble in water. The *barium* derivative crystallises in colourless, seemingly rhombic plates. The *silver* derivative crystallises in colourless needles, and is moderately stable in the light. The *methyl* derivative crystallises from dilute alcohol in yellowish needles melting at 136°.

Pentachloro-α-ketophenyl-γ-piperidone, $\begin{matrix}CO\cdot NPh\cdot CHCl\\ |\quad\quad\quad |\\ CCl_2\cdot CO\cdot CCl_2\end{matrix}$, is deposited in crystals when chlorine is passed into a concentrated glacial acetic acid solution of dichlorohydroxyphenylpyridone; it crystallises in thin plates, melts at 147°, and is moderately easily soluble in benzene, light petroleum, chloroform, ether, hot glacial acetic acid, and hot alcohol, but insoluble in water. It liberates iodine from potassium iodide, and is readily decomposed by soda with formation of dichloracetanilide (m. p. 119°), aniline, and other products, the nature of which could not be determined. On reduction with stannous chloride in warm glacial acetic acid solution, it seems to yield a mixture of dichlorhydroxy- and tetrachlorhydroxy-phenylpyridone. When warmed with potassium acetate in acetic acid solution, 1 atom of chlorine is displaced by an acetyl group, a compound of the composition $C_{13}H_9Cl_4NO_4$ being formed; this substance crystallises from dilute acetic acid in slender needles, and melts at 150°.

An *acid* of the composition $C_{12}NH_{13}Cl_4O_5$ is formed when pentachloroketophenylpiperidone is gradually treated with 10 per cent. soda in cold methyl alcoholic solution; it separates from a mixture of ether and light petroleum in compact, transparent, seemingly rhombic crystals, melting at 114° with decomposition. It dissolves unchanged in soda, but on keeping the solution for a long time an odour of carbylamine is observed, and the solution then contains aniline and an oily acid which, from an analysis of its calcium salt, is probably dichloracetic acid. The constitution of the acid is probably represented by the formula

$$CHCl_2\cdot C(OH)_2\cdot NPh\cdot CH(OMe)\cdot CCl_2\cdot COOH.$$

Pentachloromethylamidoparadiketohexene, $\begin{matrix}CCl_2\cdot CO\cdot C\cdot NHMe\\ ||\quad\quad\quad ||\\ CCl_2\cdot CO\cdot CCl\end{matrix}$, is

formed when an aqueous solution of methylamine is gradually added to an ethereal solution of hexachlorodiketohexene; it forms yellow needles, melts at 134°, and is readily soluble in alcohol, ether, and glacial acetic acid, but rather more sparingly in light petroleum and benzene, and insoluble in water.

αββ-Trichloromethyl-γ-pyridonecarboxylic acid, $\begin{matrix}\mathrm{CCl{\cdot}NMe{\cdot}C{\cdot}COOH}\\ \|\qquad\quad\|\\ \mathrm{CCl{\cdot}CO{\cdot}CCl}\end{matrix}$, prepared by treating the preceding compound with 10 per cent. soda, crystallises from hydrochloric acid in slender, colourless needles, melts at 220°, with evolution of carbonic anhydride, and is decomposed on boiling with alcohol, glacial acetic acid, or water, yielding trichloromethylpyridone.

αββ-Trichloromethyl-γ-pyridone, $\begin{matrix}\mathrm{CCl{\cdot}NMe{\cdot}CH}\\ \|\qquad\quad\|\\ \mathrm{CCl{\cdot}CO{\cdot}CCl}\end{matrix}$, crystallises in slender, colourless needles, melts at 222°, and is readily soluble in water and ether.

A compound of the constitution $\mathrm{CCl_2{:}CCl{\cdot}CO{\cdot}CCl{:}CCl{\cdot}CO{\cdot}NHMe}$ is formed when an aqueous solution of methylamine is gradually added to a well-cooled alcoholic solution of the hexachlorodiketone; it crystallises from boiling light petroleum in transparent plates, melts at 126°, and is readily soluble in most ordinary solvents except water. It dissolves unchanged in cold soda, but on heating the solution, complete decomposition ensues; when warmed with barium hydroxide, it is decomposed into dichloromaleïc acid, methylamine, and trichlorethylene.

Pentachloramidoparadiketohexene, $\begin{matrix}\mathrm{CCl_2{\cdot}CO{\cdot}C{\cdot}NH_2}\\ \|\qquad\quad\|\\ \mathrm{CCl_2{\cdot}CO{\cdot}CCl}\end{matrix}$, can be prepared by treating the hexachlorodiketone with anhydrous ammonia in well-cooled ethereal solution; it crystallises from water in yellow needles, melts at 141—142°, and dissolves freely in potash without evolution of ammonia. F. S. K.

Metachloroparacetotoluidide. By E. Lellmann (*Ber.*, **24**, 4111—4112).—The author criticises a recent paper of Erdmann's on this subject (Abstr., 1891, 1466). Metachloroparacetotoluidide is most conveniently prepared by dissolving paracetotoluidide (50 grams) in glacial acetic acid (400 grams), and treating the solution with chlorine diluted with 2 vols. of anhydrous carbonic anhydride; the product is separated from the acid, dried over quicklime, and recrystallised twice from dilute alcohol; it melts at 118°, and is quite pure. The yield is 40—42 per cent. of the theory, but it could probably be increased by the use of a larger proportion of acetic acid.

J. B. T.

Dimolecular Nitriles. By P. S. Burns (*J. pr. Chem.* [2], **44**, 568—570).—When benzoylimidopropionylethyl cyanide (Abstr., 1891, 888) is treated with phosphoric chloride, it yields a *chloro-derivative*, $\mathrm{N{\leqslant}\begin{matrix}\mathrm{CPhCl}\\ \mathrm{CEt}\end{matrix}{>}CMe{\cdot}CN}$, which melts at 97°; this points to the constitution $\mathrm{N{\leqslant}\begin{matrix}\mathrm{CPh(OH)}\\ \mathrm{CEt}\end{matrix}{>}CMe{\cdot}CN}$ for the benzoyl derivative. When

the chlorinated derivative is heated with hydrochloric acid at 150°, it is reconverted into the benzoyl derivative; whilst heating with alcoholic potassium hydroxide gives rise to the corresponding *ethoxy-derivative*, melting at 55°.

The reaction between imidopropionylmethyl cyanide and benzoic chloride (2 mol. proportions) yields a *compound*, NBz:CMe·CHBz·CN, which forms beautiful crystals melting at 158°. Alcoholic potassium hydroxide converts this into *acetylbenzoylmethyl cyanide* (*α-cyanobenzoylacetone*), COMe·CHBz·CN, which crystallises in prisms, melts at 74°, and is decomposed by water at 150° into benzoylacetone, carbonic anhydride, and ammonia. Acetylbenzoylmethyl cyanide has the properties of a *β*-diketone; with ammonia, it yields an *imido-derivative*, which crystallises in needles melting at 148°, and with phenylhydrazine, a *compound*, $C_{17}H_{13}N_3$, which melts at 189°, and is probably cyanodiphenylmethylpyrazolone. A. G. B.

Substitution of the Azo-Group for Ketonic Oxygen. By T. Curtius and H. Lang (*J. pr. Chem.* [2], **44**, 544—568; compare Abstr., 1889, 1157; 1891, 39).—Benzoylphenylazomethylene (Abstr., 1891, 1357) explodes when sharply heated above its melting point; it dissolves easily in alcohol, less so in ether and benzene, and not at all in water. When it is treated with iodine (1 mol. proportion) in alcoholic solution, nitrogen is evolved, and *benzoylphenyldiiodo-methane* (diiododeoxybenzoïn) separates as a colourless, crystalline powder, which was not analysed; it is decomposed by air into benzile and hydrogen iodide. By the action of bromine on a chloroform solution of benzoylphenylazomethylene, benzoylphenyldibromo-methane (dibromodeoxybenzoïn), melting at 112°, is formed; the same compound obtained by the action of bromine on deoxybenzoïn melts at 110—112° (*Annalen*, **155**, 68); when heated with water, it is decomposed into benzile and hydrogen bromide; silver nitrate removes all its bromine in the cold.

By the action of hydrogen chloride on an ethereal solution of benzoylphenylazomethylene, chlorodeoxybenzoïn and nitrogen are formed. *Chlorodeoxybenzoïn* crystallises in long, colourless needles, and melts at 65°; the chlorodeoxybenzoïn prepared from dichlorodeoxybenzoïn is described in *Ber.*, **17**, 1163, as a thick, yellow oil crystallising below 0°. With zinc-dust and glacial acetic acid in ether, benzoylphenylazomethylene is reduced to deoxybenzoïn (m. p. 55°; b. p. 310°) with formation of ammonia. With hot water, benzoylphenylazomethylene yields, among other substances, a colourless compound which melts at 151°; with hot, dilute sulphuric acid or potassium hydroxide, it explodes; with hot alcohol, a sparingly soluble substance separates in greenish needles, melting at 192°. When benzoylphenylazomethylene decomposes spontaneously, it becomes converted into an opaque, white substance, which is free from nitrogen, but has not been otherwise analysed.

Azoisatin, $N\lessdot^{C(OH)}_{C_6H_4-}\!\!>C{:}N_2$, is obtained as its mercury compound when hydrazisatin (10 grams. Abstr., 1891, 1360) is heated with mercuric oxide (20 grams) and benzene (500 grams) for several days

in a reflux apparatus; the liquid is filtered while hot, and the residue washed with benzene, and extracted with hot alcohol; the alcoholic solution is then evaporated, and the residual mercury compound suspended in water through which hydrogen sulphide is passed; when all the mercury is separated, the azoisatin is extracted with ether. Azoisatin crystallises from benzene or glacial acetic acid in small, dark-red prisms; it melts with evolution of gas at 161°, and explodes when sharply heated, with the production of brown fumes; it is easily soluble in benzene, chloroform, and glacial acetic acid, but less so in ether, and still less so in cold absolute alcohol; it is not changed by hot water, and only with difficulty attacked by alcoholic solution of iodine; mineral acids decompose it in the cold. Determinations of the molecular weight of azoisatin by the cryoscopic method indicate that the above formula should be doubled; the constitution of the substance is thus a little uncertain. The *mercury compound*, $(C_8H_4N_3O)_2Hg$, crystallises in microscopic, dark-brown needles, which are stable in air, and explode when heated.

Diammonium methylhydrazimethylenecarboxylate,

$$N_2H_2{:}CMe{\cdot}COOH,N_2H_4$$

(compare Abstr., 1891, 39), is obtained when pyruvic acid is neutralised with hydrazine hydrate in alcoholic solution, another molecular proportion of hydrazine hydrate added, the mixture warmed for a short time on the water-bath, and slowly evaporated; it forms a colourless, crystalline powder, melts at 115—117°, and is moderately soluble in water. With benzaldehyde, it yields benzalazine. When barium pyruvate and hydrazine sulphate, in molecular proportion, are ground together with water, the mixture becomes warm, and neither barium nor sulphuric acid can be detected in the filtrate; but when it is evaporated to a syrup and mixed with absolute alcohol, an oil separates and gradually solidifies to a white, crystalline, hygroscopic mass, $C_5H_{10}N_2O_3$, which melts at 121°.

Methyl hydrazopropionate has been already described (Abstr., 1891, 39).

Ethyl hydrazopropionate, $N_2H_2{:}CMe{\cdot}COOEt$, is left in solution when the product of the action of ethyl pyroracemate on hydrazine hydrate (in molecular proportion) is crystallised from alcohol, and is obtained in colourless needles by evaporating this mother liquor. The laminæ, which are less soluble in alcohol, are *hydrazopropionylhydrazine*, $N_2H_2{:}CMe{\cdot}CO{\cdot}NH{\cdot}NH_2$, which forms a white, crystalline compound when shaken with benzaldehyde in aqueous solution; no such condensation product is obtained from ethyl hydrazopropionate—an indication that the latter contains the group NHNH, and not NNH_2.

Methyl azomethylenecarboxylate (methyl α-diazopropionate),

$$N_2{:}CMe{\cdot}COOMe,$$

is obtained by the action of mercuric oxide on methyl hydrazopropionate in benzene; it cannot be separated from the benzene by fractional distillation, as it does not distil without decomposition. When the benzene solution is acted on by iodine and ammonia, *α-diiodopropionamide*, $Me{\cdot}CI_2{\cdot}CONH_2$, is formed; it crystallises in small, yellow needles, and melts at 127°, but has not been analysed.

Methyl α-amidopropionate hydrochloride, $NH_2{\cdot}CHMe{\cdot}COOMe,HCl$, obtained by the action of methyl alcohol and hydrogen chloride on α-alanine, crystallises in colourless, slender prisms, and melts at 157°; it deliquesces with water, and is soluble in hot alcohol, but not in ether and benzene. By diazotising 50 grams of this compound, and distilling under reduced pressure, 4 grams of methyl azomethylenecarboxylic acid were obtained.

From the above experiments, it may be generally stated that by the successive action of hydrazine and mercuric oxide on α-ketonic acids, the ketonic oxygen can be displaced by the azo-group, the same compounds being produced as are obtained by the action of nitrous acid on the ethereal salts of amido-aliphatic acids.

Diethyl aspartate (Abstr., 1885, 885; *J. pr. Chem.* [2], **38**, 474), explodes when heated to 150° under 12 mm. pressure; it yields *asymmetrical diiodosuccinamide* when treated with iodine and concentrated ammonia; this crystallises in nearly colourless, lustrous tables.

Methyl diazoacetate boils at 73° under 80 mm. pressure; ethyl diazoacetate boils at 84° under 61 mm. pressure; amyl diazoacetate boils at 89° under 13 mm. pressure.

Ethyl azimethylenedicarboxylate, $COOEt{\cdot}CH{:}N_2{:}CH{\cdot}COOEt$, is the residue (4 per cent.) left on fractionating ethyl diazoacetate; it is a yellow liquid which smells of cyanogen and hydrocyanic acid; it boils at 42° (12 mm.), and is insoluble in water; when evaporated with acid silver nitrate, it yields silver cyanide, and when hydrolysed by acids or alkalis, it yields acetic acid and hydrazine. This salt is a powerful reducing agent, and yields benzalazine with alkaline benzaldehyde.

Diammonium phenylhydrazimethylenecarboxylate,

$$N_2H_2{:}CPh{\cdot}COOH,N_2H_4,$$

is obtained by acting on well-cooled ethyl benzoylformate with hydrazine hydrate (1 mol. proportion) in alcohol; it forms colourless, spherical crystals, and melts at 118—120°; it is a strong reducing agent, dissolves sparingly in cold, and freely in hot, water, and yields benzalazine with benzaldehyde. When less than one molecular proportion of hydrazine hydrate was used, a substance which was probably *diethyl diphenylazimethylenedicarboxylate*,

$$COOEt{\cdot}CPh{:}N{\cdot}N{:}CPh{\cdot}COOEt,$$

was obtained; this crystallises in yellow needles, melts at 135°, and is freely soluble in hot alcohol and ether; it is very stable towards cold acids and alkalis; when it is warmed with concentrated sulphuric acid and water added, an aromatic oil and hydrazine sulphate are produced; when gradually heated, it sublimes unchanged, but is decomposed by rapid heating. A. G. B.

Derivatives of Phenylhydrazine. By C. Willgerodt and E. G. Mühe (*J. pr. Chem.* [2], **44**, 451—466).—*Metachlorophenylhydrazine*, $C_6H_4Cl{\cdot}NH{\cdot}NH_2$ [$Cl : NH{\cdot}NH_2 = 3 : 1$], obtained by the reduction of metachlorodiazobenzene with stannous chloride, is a brownish-red

oil, insoluble in water, but soluble in alcohol, toluene, ether, and chloroform. The *hydrochloride* crystallises in white laminæ, melts at 235—236°, and dissolves in hot water, hot alcohol, slightly in ether and hot chloroform, not at all in benzene.

Picrylmetachlorophenylhydrazine, $C_6H_2(NO_2)_3 \cdot NH \cdot NH \cdot C_6H_4Cl$, prepared from metachlorophenylhydrazine and picryl chloride, crystallises in small, red prisms, decomposes at 177—178°, and dissolves in glacial acetic acid, benzene, hot ether, chloroform, but only sparingly in alcohol, and not at all in water.

Picrylmetachlorazobenzene, $C_6H_2(NO_2)_3 \cdot N_2 \cdot C_6H_4Cl$, obtained by oxidising picrylmetachlorophenylhydrazine, crystallises in red laminæ, melts at 138—139°, and dissolves in glacial acetic acid, alcohol, benzene, and chloroform, but not in water.

Dinitronitrosophenylmetachlorazobenzene, $NO \cdot C_6H_2(NO_2)_2 \cdot N_2 \cdot C_6H_4Cl$, prepared by heating picrylmetachlorophenylhydrazine with glacial acetic acid in a reflux apparatus, crystallises in yellow prisms or laminæ, melts at 204—205°, and dissolves easily in glacial acetic acid, benzene, and chloroform, sparingly in alcohol, and not at all in water.

Dinitrosonitrophenylmetachlorazobenzene, $NO_2 \cdot C_6H_2(NO)_2 \cdot N_2 \cdot C_6H_4Cl$, prepared by heating picrylmetachlorophenylhydrazine with alcohol at 120°, crystallises in yellow laminæ, melts at 184° (uncorr.), and dissolves in glacial acetic acid, benzene, and chloroform, but not in water.

Dinitronitrosophenylnitrometachlorazobenzene,

$$NO \cdot C_6H_2(NO_2)_2 \cdot N_2 \cdot C_6H_3Cl \cdot NO_2,$$

obtained in the nitration of dinitronitrosometachlorazobenzene, is a yellow, amorphous powder, decomposes at 194°, and dissolves easily in glacial acetic acid and chloroform, but only sparingly in hot alcohol and ether.

Picrylnitrometachlorazobenzene, $C_6H_2(NO_2)_3 \cdot N_2 \cdot C_6H_3Cl \cdot NO_2$, from the nitration of picrylmetachlorazobenzene, crystallises in yellow laminæ, decomposes at 124—125°, and is freely soluble in glacial acetic acid, benzene, and toluene, but only sparingly in alcohol, ether, and chloroform.

Orthoparadinitrophenylmetachlorophenylhydrazine,

$$C_6H_3(NO_2)_2 \cdot N_2H_2 \cdot C_6H_4Cl,$$

is obtained by heating alcoholic solutions of α-dinitrochlorobenzene (1 mol.) and metachlorophenylhydrazine (2 mols.) together in a reflux apparatus; it crystallises in beautiful, yellow, rhombic prisms, melts at 151—152°, and dissolves in glacial acetic acid, alcohol, benzene, and chloroform.

α-Dinitrophenylmetachlorazobenzene, $C_6H_3(NO_2)_2 \cdot N_2 \cdot C_6H_4Cl$, from the oxidation of the preceding compound, crystallises in slender, red needles, and melts at 122—123°; it dissolves in glacial acetic acid, chloroform, and alcohol.

Nitronitrosophenylmetachlorazobenzene, $NO_2 \cdot C_6H_3(NO) \cdot N_2 \cdot C_6H_4Cl$, obtained by the prolonged heating of the corresponding hydrazine with glacial acetic acid, crystallises in yellow, slender needles; it melts at 202°, and is sparingly soluble in alcohol, but freely in glacial acetic acid.

Orthoparadinitrosophenylmetachlorazobenzene, $C_6H_3(NO)_2{\cdot}N_2{\cdot}C_6H_4Cl$, is prepared from orthoparadinitrophenylmetachlorophenylhydrazine by heating it with alcohol in a sealed tube at 150° for six hours; it crystallises in soft, white needles, melts at 159°, and is only sparingly soluble in alcohol, but easily so in glacial acetic acid, benzene, and chloroform.

Orthoparadinitrophenylnitrometachlorazobenzene,

$$C_6H_3(NO_2)_2{\cdot}N_2{\cdot}C\,H_3Cl{\cdot}NO_2,$$

from the nitration of the dinitrometachlorazobenzene, crystallises in yellowish-red needles, decomposes at 165°, and is sparingly soluble in alcohol, although freely in glacial acetic acid, chloroform, and benzene.

Nitronitrosophenylmetachlorazoxybenzene,

$$NO{\cdot}C_6H_3(NO_2){\cdot}N_2O{\cdot}C_6H_4Cl,$$

obtained by oxidising the nitronitrosophenylmetachlorazobenzene with chromic acid in glacial acetic acid, crystallises in slender, yellow needles which melt at 166—167°; it dissolves in glacial acetic acid, benzene, and chloroform, but only sparingly in ether.

Trinitronitrosoazobenzenephenylhydrazine,

$$N_2H_2Ph{\cdot}C_6H_3(NO_2){\cdot}N_2{\cdot}C_6H_2(NO_2)_2{\cdot}NO,$$

prepared from trinitronitrosometachlorazobenzene and phenylhydrazine, is an amorphous, red powder, decomposes at 130°, and is soluble in alcohol, chloroform, and glacial acetic acid.

Dinitrodinitrosodisazobenzene, $NO{\cdot}C_6H_2(NO_2)_2{\cdot}N_2{\cdot}C_6H_3(NO){\cdot}N_2Ph$, obtained by heating the preceding compound with alcohol, is a yellowish-brown, amorphous substance; it decomposes at 158°, and is easily soluble in chloroform and glacial acetic acid.

Nitrotrinitrosodisazobenzene, $NO_2{\cdot}C_6H_2(NO)_2{\cdot}N_2{\cdot}C_6H_3(NO){\cdot}N_2Ph$, obtained by heating trinitronitrosoazobenzenephenylhydrazine with alcohol in a sealed tube for three hours at 160°, is an amorphous, brown substance, melts at 175—176° with decomposition, and dissolves sparingly in alcohol, but more freely in glacial acetic acid and chloroform.

Trinitronitrosoazobenzenemetachlorophenylhydrazine,

$$NO{\cdot}C_6H_2(NO_2)_2{\cdot}N_2{\cdot}C_6H_3(NO_2){\cdot}N_2H_2{\cdot}C_6H_4Cl,$$

prepared from trinitronitrosometachlorazobenzene and metachlorophenylhydrazine, is a yellow-brown, amorphous substance, decomposes at 169—170°, and dissolves sparingly in alcohol, but more easily in chloroform, benzene, and glacial acetic acid.

Tetranitrazobenzenephenylhydrazine,

$$C_6H_2(NO_2)_3{\cdot}N_2{\cdot}C_6H_3(NO_2){\cdot}N_2H_2Ph,$$

obtained from tetranitrometachlorazobenzene and phenylhydrazine, is a reddish-brown, amorphous substance, decomposes at 193°, and is sparingly soluble in alcohol, but more freely in benzene and glacial acetic acid.

Tetranitrazobenzenemetachlorophenylhydrazine,

$$C_6H_2(NO_2)_3{\cdot}N_2{\cdot}C_6H_3(NO_2){\cdot}N_2H_2{\cdot}C_6H_4Cl,$$

is dark-brown and amorphous; it blackens at 160—170°, and decomposes at 205—206°; it dissolves in benzene, toluene, chloroform, and glacial acetic acid.

Tetranitrometachlorodisazobenzene,

$$C_6H_2(NO_2)_3\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_4Cl,$$

obtained as described for the analogous compounds, crystallises in dark-red prisms, melts at 91°, and dissolves easily in organic solvents.

Dinitrodinitrosometachlorodisazobenzene,

$$NO\cdot C_6H_2(NO_2)_2\cdot N_2\cdot C_6H_3(NO)\cdot N_2\cdot C_6H_4Cl,$$

is a greenish-yellow, amorphous powder, decomposes at 225—226°, and is sparingly soluble in alcohol, but more freely in chloroform and benzene.

Pentanitrometachlorodisazobenzene,

$$C_6H_2(NO_2)_3\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_3Cl\cdot NO_2,$$

from the nitration of the corresponding tetranitro-compound, forms ill-defined, yellow crystals which decompose at 157°; it is moderately soluble in glacial acetic acid, benzene, and chloroform, but only sparingly in alcohol.

Trinitrazobenzenemetachlorophenylhydrazine,

$$C_6H_3(NO_2)_2\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2H_2\cdot C_6H_4Cl,$$

prepared from trinitrometachlorazobenzene and metachlorophenylhydrazine, is a yellowish-brown, amorphous substance, decomposes at 127—128°, and dissolves in benzene and chloroform, but hardly at all in alcohol.

Pentanitrodisazobenzenephenylhydrazine,

$$C_6H_2(NO_2)_3\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2H_2Ph,$$

is a dark, red-brown, amorphous substance; it decomposes at 144°, and dissolves sparingly in alcohol, but better in benzene, chloroform, and glacial acetic acid. A. G. B.

Secondary Asymmetrical Hydrazines obtained by the Action of Aldehydes or Ketones on Hydrazine Hydrate. By T. Curtius and L. Pflug (*J. pr. Chem.* [2], **44**, 535—544; compare Abstr., 1889, 393; 1891, 1355—1360).—As already pointed out (Abstr., 1891, 1355), when hydrazine hydrate (1 mol. proportion) acts on an aldehyde or ketone (2 mol. proportions), di- and tetra-substitution products of azimethylene are respectively produced. When, however, an aldehyde or ketone is added to an excess of hydrazine hydrate, asymmetrical secondary hydrazines are produced. These are, with few exceptions, unstable bases, readily decomposing into hydrazine and azimethylene derivatives.

Benzalhydrazine (phenylmethylenehydrazine), $CHPh:N\cdot NH_2$, was described as cinnamalbenzalazine by Curtius and Thun (Abstr., 1891, 1357). It can be obtained pure as follows:—10 grams of hydrazine hydrate is placed in a flask with some barium oxide, and 19 grams of benzaldehyde is gradually added with constant shaking. After several hours' digestion on the water-bath, 2 volumes of dry

ether are added to the cooled flask, and the mixture filtered; the ethereal solution is dried for several days over potassium hydroxide, filtered, and distilled under a pressure of 14 mm., when benzalhydrazine distils over in almost the calculated quantity at 140°. Benzalhydrazine is a clear, colourless liquid, boils at 140° (14 mm.), and solidifies at 12° to a white mass of tabular crystals which melt at 16°; it has an intense odour of hot soap-lye, reduces alcoholic ammoniacal silver solution, and must be preserved in a sealed tube, as it decomposes very rapidly in moist air with formation of benzalazine and hydrazine hydrate.

Benzaldehyde reacts with benzalhydrazine to form benzalazine and water; iodine reacts with it to form benzalazine, nitrogen, and hydrogen iodide, which reacts with more benzalhydrazine, forming benzalazine and diammonium iodide (hydrazine monohydriodide, m. p. 125°; compare Abstr., 1891, 264). When reduced by sodium amalgam in ether, benzalhydrazine yields benzalazine, and, on addition of hydrochloric acid to the ethereal liquid, diammonium dichloride (m. p. 197°; compare Abstr., 1889, 340) crystallises out; hydrogen chloride passed into a dry ethereal solution of benzalhydrazine brings about the same change.

When a solution of benzalhydrazine in benzene is treated with mercuric oxide in the cold, it becomes of a deep, carmine colour. This indicates the formation of a benzaltetrazone, analogous to diphenylmethylenetetrazone (Abstr., 1891, 1359), but the colour of the solution rapidly fades, with evolution of nitrogen and formation of benzalazine.

Phenylmethylmethylenehydrazine, $CMePh{:}N{\cdot}NH_2$, is prepared by digesting a mixture of acetophenone (10 grams) with hydrazine hydrate (8 grams) and some sticks of barium oxide for three days on the water-bath, then adding more barium oxide and 5 volumes of absolute ether; the filtrate is fractionated, most of it distilling between 240° and 260°; this portion is the new hydrazine, the residue in the retort being bimethylphenylazimethylene (Abstr., 1891, 1355). Phenylmethylmethylenehydrazine is a pale-yellow liquid, boils at 255°, and is extremely unstable in moist air; even in absence of air it gradually loses nitrogen and ammonia, yielding dimethylphenylazimethylene. With mercuric oxide, it becomes deep-red, but the tetrazone is very unstable.

Phenylmethylphenylazimethylene, $CMePh{:}N{\cdot}N{:}CHPh$, is obtained by shaking phenylmethylmethylenehydrazine with benzaldehyde and water rendered feebly alkaline and crystallising the product from alcohol; it forms yellow, spear-shaped prisms, melts at 59°, and dissolves easily in ether, benzene, and alcohol, but not in water.

When methyl propyl ketone (15 grams) and hydrazine hydrate (10 grams) are heated with barium oxide, the product of the action distils between 160° and 170°, and behaves as methylpropylmethylenehydrazine, but, on redistillation, it evolves gas and becomes dimethylpropylazimethylene (Abstr., 1891, 1355).

Dimethylmethylenehydrazine, $CMe_2{:}N{\cdot}NH_2$, is prepared by gradually adding acetone (15 grams) to a mixture of hydrazine hydrate (15 grams) with barium oxide; after seven days, the impure base (17·5 grams) may be poured off and distilled. This compound is a

clear, colourless, mobile liquid, boils at 124—125°, and decomposes, when kept, with evolution of nitrogen and ammonia; with benzaldehyde, it yields acetone and benzalazine. It is coloured intensely red by mercuric oxide. A. G. B.

Action of Phenylhydrazine on Ethyl Ethoxyoxalacetate. By W. Wislicenus and M. Scheidt (*Ber.*, **24**, 4210—4214; compare this vol., p. 49).—When phenylhydrazine is added to a cold aqueous solution of ethyl ethoxyoxalacetate, an *additive* compound separates as a yellow oil which subsequently solidifies; it crystallises from alcohol in small, white crystals, melts at 111°, has the composition $C_{16}H_{24}N_2O_6$, and is insoluble in cold ether, sparingly soluble in cold water and alcohol, readily so in the boiling liquids; phenylhydrazine separates on treating it with cold aqueous alkalis.

Ethyl ethoxyoxalacetate phenylhydrazone,

$$COOEt\cdot C(N_2HPh)\cdot CH(OEt)\cdot COOEt,$$

is obtained by heating the last-described compound with alcohol and adding water, when an oil separates which solidifies after a while, and is purified by dissolving in alcohol, adding water until turbidity is produced, and filtering from resin; it separates, on allowing the filtrate to remain, in long, yellow needles, melts at 52—54°, and is soluble in all solvents, except water.

Ethyl phenylhydrazoneketophenylpyrazolonecarboxylate,

$$NPh\begin{cases} N=C\cdot COOEt \\ CO\cdot C\cdot N_2HPh \end{cases},$$

is produced by boiling an acetic acid solution of ethyl ethoxyoxalacetate (1 mol.) and phenylhydrazine (3 mols.) in a reflux apparatus for an hour, pouring into water, extracting the precipitated oil with ether, washing the ethereal solution with alkali, and, after removing the solvent, crystallising from alcohol and light petroleum; it forms small, orange-yellow needles, melts at 152—154°, and is sparingly soluble in water, and not very readily so in ether. The corresponding acid, which is identical with that of Knorr (Abstr., 1888, 724), is obtained by treating the ethyl salt with aqueous potassium hydroxide. A. R. L.

Action of Acetic Anhydride on Diazoamido-compounds. By F. Heusler (*Ber.*, **24**, 4156—4161).—Diazoamidobenzene reacts with explosive violence when warmed with acetic anhydride, but the reaction proceeds with tranquillity if the reagents are heated together in the presence of dry toluene, nitrogen being evolved, and a small quantity of an oil, having the odour and boiling point of diphenyl ether, together with acetanilide, being obtained.

Benzenediazoacetanilide, $PhN_2\cdot NPhAc$, is produced when diazoamidobenzene (100 grams) is shaken with acetic anhydride (60 grams) and absolute ether (300 grams) and the mixture allowed to remain in a closed flask for five weeks at the temperature of the room. At the end of this time, needles separate and adhere to the sides of the flask; these are dissolved in chloroform, and the compound precipitated

by the addition of ether; it melts at 129—130° with decomposition, deflagrates when heated to a high temperature, and decomposes into phenol, acetic acid, aniline, and nitrogen, on boiling with dilute mineral acids; it also decomposes, when heated with ethyl alcohol, giving rise to benzene, aldehyde, acetanilide, and nitrogen, but attempts to separate diazobenzene ethyl ether, which is perhaps formed in the first stage of the decomposition, were unsuccessful. A similar decomposition is occasioned, although not so readily, by other alcohols, but the formation of aldehydes was not observed. Benzenediazoacetanilide dissolves in alcoholic soda with the formation of diazoamidobenzene.

Toluenediazoacetotoluide, $Me^{1}\cdot C_6H_4\cdot N_2^{4}\cdot N^{4}Ac\cdot C_6H_4^{1}Me$, is obtained from paradiazoamidotoluene and acetic anhydride in the same manner as the benzene derivative. The ethereal solution is shaken with dilute soda solution to free it from acid, and the compound isolated by evaporating the solvent; after repeated recrystallisation from ether, it forms colourless needles and melts at 104—105° with decomposition; it is very soluble in the usual organic solvents, and in its chemical behaviour resembles benzenediazoacetanilide.

Orthodiazoamidotoluene (see B. Fischer and Wimmer, Abstr., 1887, 819) is prepared by mixing orthotoluidine (2 mols.) dissolved in ether with amyl nitrite (1 mol.) in a dish at −20°, and, after allowing the mixture to remain for several hours, breaking up the crystalline cake, collecting, and washing the product first with 90 per cent. and then with more dilute alcohol; it melts at 51°. When orthodiazoamidotoluene is dissolved in benzene or ether and the mixture boiled in a reflux apparatus with acetic anhydride, and after distilling off the solvent, acidified with hydrochloric acid, boiled to hydrolyse the acetotoluide, steam distilled, then made alkaline and again steam distilled, a resinous mass remains, which, on purification, is found to be indazole. To avoid collision with the work of Witt, Nölting, and Grandmougin, who obtained nitroindazole from paranitrorthodiazotoluene (Abstr., 1891, 312), the author has relinquished the study of the action of acetic anhydride on compounds containing the diazo-group in the ortho-position relatively to the methyl radicle. He is at present engaged in studying the reaction between benzenediazopiperidide and acetic anhydride, and he states that no diphenyl ether is formed in this reaction. A. R. L.

Heat Developed in the Isomeric Change of the Oxime of Opianic Anhydride. By C. Liebermann (*Ber.*, **25**, 89—90).—The author, in conjunction with F. Stohmann, has determined the amount of heat developed in the change of the oxime of opianic anhydride to hemipinimide. The heat of combustion of the oxime of opianic anhydride was found to be 1152·3 Cal., that of hemipinimide 1099·7 Cal., giving a difference of 52·6 Cal. as the heat evolved by the molecular change. This amount of heat is 10 times that developed in the change of allocinnamic into cinnamic acid, and more than six times the amount due to the change of maleïc into fumaric acid.

E. C. R.

Action of Benzenesulphonic Chloride on Amidoximes. By F. TIEMANN (*Ber.*, **24**, 4162—4167).—The author makes general and introductory remarks on Pinnow's paper (next abstract).

A. R. L.

Action of Benzenesulphonic Chloride on Amidoximes. By J. PINNOW (*Ber.*, **24**, 4167—4176).—Paramethylbenzenylamidoxime is converted into the isomeric paratolylcarbamide as follows:—The amidoxime (15 parts), mixed with finely powdered anhydrous sodium carbonate (5·3 parts), is suspended in chloroform (80 parts), and a solution of benzenesulphonic chloride (17·65 parts) in chloroform (40 parts) gradually added; carbonic anhydride is evolved with the development of heat, and the reaction is completed by heating the mixture on the water-bath for an hour; on now distilling off the solvent, and extracting the oily residue with boiling water, a white substance is obtained, which, after recrystallisation from a mixture of benzene and alcohol, melts at 180°, and has all the properties of paratolylcarbamide. The reaction probably occurs in two stages, thus:— $C_6H_4Me{\cdot}C(NONa){\cdot}NH_2 + PhSO_2Cl = C_6H_4Me{\cdot}N(OSO_2Ph){\cdot}NH_2 + NaCl$; and $C_6H_4Me{\cdot}N(OSO_2Ph){\cdot}NH_2 + H_2O = C_6H_4Me{\cdot}NH{\cdot}CO{\cdot}NH_2 + PhSO_3H$.

Metabromoparatolylcarbamide, $C_6H_3MeBr{\cdot}NH{\cdot}CO{\cdot}NH_2$, is obtained, together with other bromo-derivatives, when paratolylcarbamide is dissolved in glacial acetic acid and treated with bromine; it is isolated by fractional crystallisation, melts at 184·5° (uncorr.), is insoluble in water, easily soluble in alcohol and benzene, and sparingly so in light petroleum; it yields metabromoparatoluidine (b. p. 240°), when heated with hydrochloric acid in a sealed tube at 160°, and gives benzonitrile and benzoylmetabromoparatoluidide (m. p. 148·5°) on heating it with benzoic chloride.

Benzenylamidoxime is coverted into phenylcarbamide by treating it with benzenesulphonic chloride in the above-described manner; the product of this reaction has been erroneously described as dehydrodibenzenylamidoxime by Goldberg (*Inaug. Diss., Berlin*, 1891); the triacetyldehydrodibenzenylamidoxime described by this author is acetylphenylcarbamide (Creath, this Journal, 1876, i, 400; Kühn, Abstr., 1885, 260); whilst the compound described as cyaphenine is diphenylcarbamide. Goldberg (*loc. cit.*) states that when the so-called dehydrodibenzenylamidoxime is brominated in glacial acetic acid solution, it yields a tribromo-derivative melting at 198°; in reality it is found that when phenylcarbamide is treated in this manner, a mixture of compounds results, from which *parabromophenylcarbamide*, $C_6H_4Br{\cdot}NH{\cdot}CO{\cdot}NH_2$, a compound crystallising from benzene in white needles of a silvery lustre, and melting at 260°, may be isolated; the latter decomposes into parabromaniline, ammonia, and carbonic anhydride when heated in a sealed tube at 160°, and yields carbonic anhydride, benzonitrile, and *benzoylparabromanilide*, melting at 201°, on treatment with benzoic chloride.

The oil which remains after extracting the product of the reaction between paramethylbenzenylamidoxime and benzenesulphonic chloride (see above) with water yields on subsequent extraction with alcohol a

compound, probably $C_6H_4Me{\cdot}C\lessdot^{N{\cdot}O}_{N:SPhO}$, which forms silky needles, melts at 89°, and is indifferent towards acids and alkalis; a similar derivative, melting at 157—158°, is obtained from benzenylamidoxime. When a solution of phenylethenylamidoxime in chloroform is heated with anhydrous sodium carbonate and benzenesulphonic chloride, benzylcarbamide (m. p. 148°), together with a large quantity of *phenylethenylamidoximebenzenesulphone*, $CH_2Ph{\cdot}C(NH_2){:}NO{\cdot}SO_2Ph$, a compound sparingly soluble in water and easily so in boiling alcohol, crystallising therefrom in compact, lustrous crystals; it is, doubtless, the primary product of the reaction. A. R. L.

New Method of Preparing Benzenylhydrazoximamidobenzylidene. By F. Tiemann (*Ber.*, **24**, 4176—4177; compare Stieglitz, Abstr., 1890, 254).—When bromine is dropped into a solution of benzenylamidoxime in absolute alcohol, it is absorbed with the evolution of hydrogen bromide; after a while, however, the colour of the bromine no longer disappears, and later, a white, crystalline compound, and subsequently a red one separate; the former may be converted into the latter by treating it with bromine. These derivatives are so unstable that their composition could not be determined. When either is treated with aqueous ammonia, and the resulting white crystalline mass dissolved in alcohol, benzenylhydrazoximidobenzylidene separates on adding water; whilst dibenzenylazoxime is produced if the compounds are boiled with alcohol. A. R. L.

Constitution of the Hydroxamic Acids. By W. Lossen (*Ber.*, **24**, 4059—4062).—A reply to Tiemann (this vol., p. 300), in which the author upholds the general formula $R{\cdot}C(OH){:}NOH$ against that proposed by Tiemann (*loc. cit.*). A. R. L.

Constitution of the Hydroxamic Acids. By F. Tiemann (*Ber.*, **24**, 4062—4064).—A rejoinder to Lossen (preceding abstract).

Stereoisomeric Derivatives of Benzhydroxamic Acid. By A. Werner (*Ber.*, **25**, 27—48).—The nature of the hydroxamic acids has been frequently investigated and discussed; according to Lossen (Abstr., 1889, 1064), they have a constitution represented by the formula $R{\cdot}C(OH){:}N{\cdot}OH$, whilst Tiemann (this vol., p. 300) regards the tautomeric formula $R{\cdot}CO{\cdot}NH{\cdot}OH$ as more probable. There are also a number of derivatives of benzhydroxamic acid possessing, undoubtedly, the same structure, which, nevertheless, exist in two or more isomeric forms; for this fact no explanation has hitherto been given, although Lossen suggests that they may possibly be stereoisomerides. The author has, therefore, investigated the matter afresh, and finds that these compounds are, in reality, stereometric nitrogen isomerides.

The nomenclature of the hydroxamic acid derivatives is, at present, very confusing, and to simplify it the author makes the following alterations: the term *hydroxamic acid* is reserved for true hydroxy-derivatives of acid amides $R{\cdot}CO{\cdot}NH{\cdot}OH$ [or the tautomeric form $R{\cdot}C(OH){:}N{\cdot}OH$]. The compounds obtained from these by substitu-

tion of an alkyl or acidyl group for the labile hydrogen atom, and which can only exist in the "oxime" form R·C(OR′):N·OH, are termed *hydroximic acids*. The hydroxamic acids and their derivatives may be represented by the four following formulæ:—

(1.) R·CO·NH·OH. (3.) R·CO·NR″·OH.
(2.) R·CO·NH·OR′. (4.) R·CO·NH·OR″.

The compounds represented in formula (1) are the simple hydroxamic acids, and can also react in the tautomeric form R·C(OH):N·OH; their names are derived from that of the acidyl group they contain, C_6H_5·CO·NH·OH being benzhydroxamic acid, as hitherto. The compounds of formula (2), that is, those in which the "acid" hydrogen atom is replaced by an alkyl or acidyl group, can also react in the tautomeric form, and are named in the usual manner according to the name of the substituent radicle. The compounds whose structure is represented by formulæ (3) and (4) do not show tautomerism, and are likewise named in the usual manner from the names of the radicles they contain. The hydroximic acids are represented by the general formulæ

(1.) R·C(OR′):N·OH, (2.) R·C(OR′):N·OR″.

The first represents the simple hydroximic acids, and the second their ethers or ethereal salts, according as R″ is an alkyl or acidyl group. A table of the more important benzhydroxamic acid derivatives with both their old and new names may be found in the original.

Ethylbenzhydroximic acid, OEt·CPh:N·OH, has been found by Lossen and his pupils to exist in two modifications (α- and β-). To ascertain that these have a distinct chemical individuality both were converted into the acetyl and paranitrobenzyl derivatives, which were found to be quite distinct compounds in both cases; the identity of their structure was shown by the molecular weight (ascertained by Raoult's method) and by the fact that both are converted almost quantitatively by hydrochloric acid into benzoic acid and hydroxylamine hydrochloride. It is, therefore, most probable that they form stereoisomerides of the formulæ

$$\begin{matrix} Ph\cdot C\cdot OEt \\ \| \\ HO\cdot N \end{matrix}, \qquad \begin{matrix} Ph\cdot C\cdot OEt \\ \| \\ N\cdot OH \end{matrix}.$$

To ascertain which of the compounds has the "syn" and which the "anti" configuration (compare Hantzsch, this vol., p. 312), both were treated with phosphorus pentachloride and subsequently with water at a low temperature (Abstr., 1891, 441). The α-compound was thus converted into ethyl phenylcarbamate, which could only be obtained from a compound having the "syn" configuration, by the following series of changes:—

$$\begin{matrix} Ph\cdot C\cdot OEt \\ \| \\ HO\cdot N \end{matrix}, \quad \begin{matrix} Ph\cdot C\cdot OEt \\ \| \\ Cl\cdot N \end{matrix}, \quad \begin{matrix} Cl\cdot C\cdot OEt \\ \| \\ Ph\cdot N \end{matrix}, \quad \begin{matrix} HO\cdot C\cdot OEt \\ \| \\ Ph\cdot N \end{matrix},$$

the last formula representing the tautomeric form of ethyl phenylcarbamate. The β-compound, on the other hand, yields a phosphate $PO(O\cdot N{:}CPh\cdot OEt)_3 + H_2O$, and not a substance of the configuration

$Ph\cdot\underset{\underset{N\cdot Cl}{||}}{C}\cdot OEt$, as would be expected from a compound having the "anti" configuration; in such a substance, however, the relative positions of Cl and OEt would be similar to that found in Sandmeyer's chlorimidoformates $\underset{\underset{N\cdot Cl}{||}}{R'\cdot C\cdot OR''}$, which show no tendency to intramolecular change. A further reason for the formation of a phosphate is found in the fact that, as already observed by Lossen, the β-compound behaves much more as an alcohol than an acid. Hence it appears that α-ethylbenzhydroximic acid is *ethylsynbenzhydroximic acid*, and the β-compound, *ethylantibenzhydroximic acid*.

The author next investigated the conditions under which stereoisomeric derivatives of benzhydroxamic acid are formed, and found that stereoisomerism occurs with compounds of the general formulæ $OR'\cdot CPh{:}N\cdot OH$ (an example of this being seen in the above ethylbenzhydroximic acids), $OR'\cdot CPh{:}N\cdot OR''$, but not with those having the general formula $OH\cdot CPh{:}N\cdot OR$. For this last fact the author accounts as follows: in the preparation of alkyl derivatives of the benzhydroxamic acids, and indeed of almost all oximes, there is formed in addition to the normal "oxygen ether" $OH\cdot CPh{:}N\cdot OR$, a certain quantity of the "nitrogen ether" $CPh\cdot O\cdot NR(OH)$, whence the benzhydroxamic acids must exist in the tautomeric forms

$$Ph\cdot\underset{\underset{OH}{|}}{\overset{\overset{N}{||}}{C}}\cdot OH \quad , \qquad Ph\cdot\underset{\underset{OH\quad N}{\diagup\quad\diagdown}}{\overset{\overset{N}{|}}{C}}{:}O \quad .$$

The labile hydrogen atom, now in combination with the oxygen, now with the nitrogen, is the cause of the non-existence of both stereoisomerides of the benzhydroxamic acids, for if the derivative with the less favourable configuration were to be formed, it might at once yield the tautomeric form, which in passing back to the oxime form would naturally give the more favourable configuration. This series of reactions is represented by the following formulæ:—

$$\begin{array}{ccccc} Ph\cdot\underset{\underset{N\cdot OH(R)}{||}}{C}\cdot OH & \rightarrow & Ph\cdot\underset{\underset{(R)HO}{\diagup}}{\overset{\overset{N}{|}}{C}}{:}O & \leftarrow & Ph\cdot\underset{\underset{H}{\diagdown}}{\overset{\overset{N}{||}}{C}}\cdot OH \\ & \leftarrow & & \leftarrow & (R)\cdot HO\cdot N \end{array} \quad .$$

In favour of this view is the fact that in the ethylation of the pure benzoyl derivative of benzhydroximic acid by the action of ethyl iodide on its silver salt, a certain quantity of the stereoisomeride is always obtained, showing that in some phase of the process the benzoyl derivative must have passed into the more favourable configuration.

The author has further investigated the compounds obtained by substituting chlorine for hydroxyl in the benzhydroxamic acids, that is, the derivatives of *benzenylchloroxime*, $CPhCl{:}N\cdot OH$, in order to ascertain whether these can exist in two stereoisomeric forms. The

results obtained with benzenylchloroxime paranitrobenzyl ether, $CPhCl{:}N{\cdot}OCH_2{\cdot}C_6H_4{\cdot}NO_2$, led to distinct conclusions, but benzenylchloroximeglycollic acid was found to exist in two well-marked stereoisomerides, probably corresponding with the configurations

$$\begin{matrix} Ph{\cdot}C{\cdot}Cl \\ \| \\ COOH{\cdot}CH_2{\cdot}O{\cdot}N \end{matrix}, \qquad \begin{matrix} Ph{\cdot}C{\cdot}Cl \\ \| \\ N{\cdot}O{\cdot}CH_2{\cdot}COOH \end{matrix}.$$

Of the detailed results given in the experimental portion of the paper, the following may be mentioned:—Ethylsynbenzhydroximic acid, when treated with hydrogen chloride in dry ethereal solution, yields the *hydrochloride*, which forms a white, crystalline meal melting at 90—91°; the *sodium* salt crystallises in nacreous plates, but a silver salt could not be prepared. The acid is, as already stated, converted by the action of phosphorus pentachloride and subsequent treatment with water into ethyl phenylcarbamate, melting at 49—50°; a small quantity of diphenylcarbamide is also obtained in the reaction. The *acetyl* derivative, $OEt{\cdot}CPh{:}N{\cdot}OAc$, is obtained by the action of acetic anhydride at the ordinary temperature, and forms large plates melting at 38—39°. The corresponding *paranitrobenzyl ether*, $OEt{\cdot}CPh{:}N{\cdot}O{\cdot}CH_2{\cdot}C_6H_4{\cdot}NO_2$, is prepared by the action of paranitrobenzyl chloride on the salts of ethylbenzhydroximic acid, and by treating the silver salt of the paranitrobenzyl ether of benzhydroximic acid with ethyl iodide; it crystallises in flat needles, and melts at 55—56°.

Ethylantibenzhydroximic acid yields a parallel series of derivatives: the *hydrochloride* melts at 95° with evolution of hydrogen chloride; the *acetyl* derivative crystallises in long needles melting at 57°; and the *paranitrobenzyl* derivative in yellow plates melting at 66—67°. The compound obtained by the action of phosphorus pentachloride, $PO(O{\cdot}N{:}CPh{\cdot}OEt)_3$, forms long prisms, and melts at 130—131°.

The following derivatives of benzhydroxamic acid have been prepared:—the *acetyl* derivative, $COPh{\cdot}NH{\cdot}OAc$ or $OH{\cdot}CPh{:}N{\cdot}OAc$, which crystallises in silky needles, and melts at 125°; the *benzoyl* derivative, $CPh{\cdot}O{\cdot}NH{\cdot}OBz$ or $OH{\cdot}CPh{:}N{\cdot}OBz$, already prepared by Lossen, and termed dibenzhydroxamic acid, which melts at 161°, and not as stated by the latter at 153°; the *paranitrobenzyl* derivative, crystallising in yellowish plates, and melting at 161°. In no case, as already mentioned in the theoretical portion of the paper, was any indication observed of the existence of stereometric isomerides of these compounds.

The investigation of the derivatives of benzenylchloroxime was commenced with the study of the action of phosphorus pentachloride on the benzoyl derivative of benzhydroxamic acid. The products obtained were, however, simply benzhydroxamic acid and benzoic chloride. The experiments were continued with the *paranitrobenzyl ether of benzenylchloroxime*, $CPhCl{:}N{\cdot}O{\cdot}CH_2{\cdot}C_5H_4{\cdot}NO_2$, which was prepared by the action of phosphorus pentachloride on the paranitrobenzyl ether of benzhydroxamic acid, and also from the *paranitrobenzyl ether of benzamidoxime* (which crystallises in sulphur-yellow plates, and melts at 105—106°), by diazotising in hydrochloric acid solution. The product crystallises in druses of white needles, and

melts at 92°; no formation of an isomeride was observed, although the mother liquors from the first preparation contain a very small quantity of a substance melting at 65°, the amount of which was insufficient for analysis. Better results were obtained with *benzenylchloroximeglycollic acid*, $CPhCl{:}N{\cdot}O{\cdot}CH_2{\cdot}COOH$, which is prepared by diazotising benzenylamidoxime in hydrochloric acid solution, and crystallises from alcohol in nacreous plates melting at 134—135°, readily soluble in alcohol, ether, and chloroform, sparingly in water, and insoluble in light petroleum. It dissolves in soda, the *sodium* salt soon separating out in silky crystals, which, on acidification, yield the original acid; if, however, these be allowed to remain in the acid solution, the crystals fall to a white powder. When the latter is treated with alcohol, a little of the original acid is extracted, but the residue is almost insoluble in all solvents, with the exception of acetic acid. It melts at 195°, has the same composition as the original acid, but stronger acid properties, and in all probability is the stereoisomeric benzenylchloroximeglycollic acid. Further experiments to test the truth of this view are in progress, and to determine, if this supposition prove correct, which possesses the "syn" and which the "anti" configuration. H. G. C.

Phenylthiocarbamide and Imidothiocarbamates. By A. Bertram (*Ber.*, **25**, 48—65).—The action of alkyl haloïds on disubstituted thiocarbamides has been frequently investigated (this Journ., 1875, 883; Abstr., 1879, 650; 1887, 43; 1888, 600, 944), but hitherto their action on mono-substituted carbamides has not been examined. The author therefore treated phenylthiocarbamide, obtained according to Clermont's method (*Ber.*, **9**, 446) with methyl iodide; the reaction takes place spontaneously when the two compounds are mixed, but it is preferable to add a little alcohol, and warm the mixture gently. On cooling, colourless crystals of the hydriodide of a new base separate; the base is isolated by the addition of sodium carbonate to the aqueous solution of the salt, extracting with ether, and allowing the ethereal solution to evaporate spontaneously. It is thus obtained in colourless, monosymmetric prisms ($a : b : c = 1{\cdot}3649 : 1 : 0{\cdot}8914$; $\beta = 64° 43'$), having the composition $C_8H_{10}N_2S$, and melting at 71°. On dry distillation, it yields chiefly aniline and methyl mercaptan, showing that the methyl group is united with the sulphur atom; on treatment with sulphuric acid, it yields methyl phenylthiocarbamate, $MeS{\cdot}CO{\cdot}NHPh$ (Will, Abstr., 1881, 905; 1882, 723), the elements NH being replaced by O. It therefore also contains the imido-group, and must be *methyl imidophenylthiocarbamate*, $SMe{\cdot}C(NH){\cdot}NHPh$. The *hydriodide* forms colourless needles melting at 147°, the *nitrate* a white, crystalline powder melting at 113°, the *picrate* deep-yellow, rectangular plates melting at 175°, the *platinochloride*, $(C_8H_{10}N_2S)_2,H_2PtCl_6$, an orange, crystalline precipitate. It yields two *sulphates*: $C_8H_{10}N_2S,H_2SO_4$ and $(C_8H_{10}N_2S)_2,H_2SO_4$, both of which melt at 171°, the former giving a brown, the latter a colourless liquid.

Methyl imidophenylthiocarbamate readily reacts with another molecule of methyl iodide, forming the hydriodide of *methyl imidomethyl-*

phenylthiocarbamate, SMe·C(NH)·CMePh, which is a pale-yellow oil, and does not crystallise at 0°. Its *hydriodide* melts at 184°; the *picrate* forms yellow prisms, which have a paler colour than the picrate of the preceding base, as is also the case with the *platino*-chloride, $(C_9H_{12}N_2S),H_2PtCl_6$. On treatment with sulphuric acid, the base is converted into *methyl methylphenylthiocarbamate*, SMe·CO·NMePh, which crystallises from dilute alcohol in slender plates melting at 54°; the formation of this compound shows that the second methyl radicle has entered the amido-, and not the imido-group. The latter group may, however, also be methylated by heating the base with anhydrous methyl iodide, the hydriodide thus formed being treated with sodium carbonate. *Methyl methylimido-methylphenylthiocarbamate*, SMe·C(NMe)·NMePh, may be distilled with but slight decomposition under the ordinary pressure, when it boils at 265°; its *hydriodide* melts at 184°, and is much more soluble than those of the foregoing bases; the *picrate* has a lemon-yellow colour, and melts at 126°, whilst the *platinochloride* melts at 174° with decomposition. When the base is heated with sulphuric acid, it yields the same product as the dimethylated compound, namely methyl methylphenylthiocarbamate, SMe·CO·NMePh, the group NMe being replaced by O.

The corresponding ethyl derivatives may be obtained in an exactly similar manner from phenylthiocarbamide and ethyl iodide. *Ethyl imidophenylthiocarbamate*, SEt·C(NH)·NHPh, is a colourless, odourless liquid, which readily gives off ethyl mercaptan; its hydriodide melts at 103°, and its picrate at 196°. With ethyl iodide, it yields the *hydriodide of ethyl imidoethylphenylthiocarbamate*,

SEt·C(NH)·NEtPh,HI,

which may be obtained in crystals from benzene; the *picrate* melts at 170°, and the *platinochloride* at 148° with decomposition. *Ethyl ethyl-imidoethylphenylthiocarbamate*, SEt·C(NEt)·NEtPh, is a yellowish, colourless oil, and boils at 273°; its *picrate* melts at 96°, and its *platinochloride* at 135°, decomposition commencing at a higher temperature.

The action of ethyl iodide on triethylthiocarbamide has been examined by Grodski, who believed at first that the product was tetrethylthiocarbamide, but afterwards stated that it was an imido-thiocarbamate (Abstr., 1882, 823). The author finds that methyl iodide reacts readily with methyl symmetrical diphenylthiocarbamide, forming the hydriodide of a base which has the composition $C_{15}H_{16}N_2S$. It is a yellowish oil, boiling above 300°, almost without decomposition, and on treatment with carbon bisulphide is converted into *methyl methylphenyldithiocarbamate*, SMe·CS·NMePh, which is also formed by the action of carbon bisulphide on methyl methyl-imidomethylphenylthiocarbamate, and crystallises in slender, colourless plates, melting at 88°. The base $C_{15}H_{16}N_2S$ must therefore be *methyl phenylimidomethylphenylthiocarbamate*, SMe·C(NPh)·NMePh.

Ethylene bromide acts on diphenylthiocarbamide with formation of a hydrothiohydantoïn (Will, Abstr., 1881, 906) and on thiocarbamide itself, with formation of the compound $C_2H_4[S·C(NH)·NH_2]_2$

(Andreasch, Abstr., 1883, 665). The monosubstituted thiocarbamides act in a manner similar to the unsubstituted compounds; thus phenylthiocarbamide forms a crystalline substance having the constitution $C_2H_4[S{\cdot}C(NH){\cdot}NHPh]_2$ or $C_2H_4[S{\cdot}C(NPh){\cdot}NH_2]_2$, which melts at 139°, is insoluble in water, but soluble in alcohol, ether, and benzene. Its *hydrochloride* and *hydrobromide* form slender needles, and melt at 218° and 214° respectively; the *platinochloride*, $C_{16}H_{18}N_4S_2,H_2PtCl_6$, has a pale reddish-brown colour, and melts at 150° with decomposition; the *picrate*, $C_{16}H_{18}N_4S_2 + 2C_6H_3N_3O_7$, is a crystalline precipitate, and melts at 196°.

Bromine-water acts on a solution of methyl imidophenylthiocarbamate in hydrobromic acid, yielding a mixture of symmetrical tribromaniline, dibromo- and tribromo-phenylcarbamide, which separates out as an insoluble precipitate, whilst the solution contains methylsulphonic acid, obtained by the oxidation of the mercaptan group. *Dibromophenylcarbamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_3Br_2$ [NH : Br : Br = 1 : 2 : 4], and *tribromophenylcarbamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_2Br_3$ [NH : Br : Br : Br = 1 : 2 : 4 : 6], may also be obtained directly from phenylcarbamide, and melt at 201° and 270° respectively; both distil at a high temperature almost unchanged.

When methyl mercaptan, obtained by the decomposition of some of the above compounds, was led into alcohol containing freshly precipitated mercuric oxide, a mixture of mercuric methylmercaptide with mercuric oxide was obtained. To estimate the amount of methylmercaptan, this must be dissolved in acetic acid, which yields a double salt of mercuric methylmercaptide and acetate,

$$Hg(MeS)_2,2Hg(OAc)_2;$$

on the addition of mercuric chloride, the compound MeSHgCl is precipitated, and may be separated and weighed. H. G. C.

Methylenedibenzamide and Analogous Compounds. By H. Thiesing (*J. pr. Chem.* [2], **44**, 570—571).—Methylenedibenzamide was prepared by adding concentrated sulphuric acid to a hot solution of solid paraformaldehyde (1 mol. proportion) and benzonitrile (2 mol. proportions) in glacial acetic acid, cooling, mixing with water, and recrystallising from hot alcohol; it melts at 218° (uncorr.).

Methylenedinitrodibenzamide is obtained when nitrobenzonitrile is used in the above prescription; it crystallises in slender needles, and melts at 214° (uncorr.). *Methylenediparatoluylamide*, obtained when paratolunitrile is used, crystallises in bundles of slender needles, melts at 217° (uncorr.), and dissolves in alcohol, ether, chloroform, and strong acids; it is decomposed by hot hydrochloric acid with formation of paratoluic acid. *Methylenediorthotoluylamide* is a gelatinous mass which melts at 199° (uncorr.). *Methylenedi-α-toluylamide* is obtained when benzyl cyanide is used; it crystallises from hot alcohol in slender, prismatic needles, and melts at 211° (uncorr.). A. G. B.

Derivatives of Phenylamidoacetic Acid. By A. Kossel (*Ber.*, **24**, 4145—4156).—*Methyl phenylamidoacetate hydrochloride*,

$$NH_3Cl{\cdot}CHPh{\cdot}COOMe,$$

is prepared by dissolving phenylamidoacetic acid in methyl alcohol, and saturating the solution with hydrogen chloride; it is purified by crystallisation from water, melts at 224°, and dissolves in alcohol or benzene, but is insoluble in ether. The *ethyl salt*, $NH_3Cl{\cdot}CHPh{\cdot}COOEt$, is prepared in a similar manner to the preceding compound, and crystallises in long, colourless needles melting at 197°. The *allyl salt*, $NH_3Cl{\cdot}CHPh{\cdot}COO{\cdot}C_3H_5$, crystallises from alcohol, on the addition of ether; it darkens at 220°, and melts at 226° with decomposition. The *amyl* derivative, $NH_3Cl{\cdot}CHPh{\cdot}COO{\cdot}C_5H_{11}$, crystallises in colourless needles which melt at 154°. The free ethereal salts are obtained from the hydrochlorides by dissolving these in water, covering the solution with a layer of ether, and cautiously adding potash, the solution being continually shaken; or the hydrochlorides may be suspended in ether, and decomposed by means of argentic oxide. The ethereal solution is then dried over barium oxide, the ether removed by distillation, and the residue purified by fractionation in a vacuum.

Methyl phenylamidoacetate, $NH_2{\cdot}CHPh{\cdot}COOMe$, crystallises from light petroleum in long, slender needles which melt at 32°. The *ethyl salt*, $NH_2{\cdot}CHPh{\cdot}COOEt$, is a pale yellow, oily liquid boiling at 257°. The *allyl* and *amyl* salts are colourless, viscid liquids, which are not decomposed by boiling with water.

Phenylamidoacetic anhydride, $CHPh<^{CO{\cdot}NH}_{NH{\cdot}CO}>CHPh$, is obtained by heating methyl phenylamidoacetate at 160°, and is a colourless crystalline powder, insoluble in ordinary media; it darkens at 250°, and melts at 274° with decomposition. The molecular weight of this compound could not be determined, as it undergoes decomposition at high temperatures.

Ethyl phenyluramidoacetate, $NH_2{\cdot}CO{\cdot}NH{\cdot}CHPh{\cdot}COOEt$, is prepared by the action of potassium cyanide in aqueous solution on ethyl phenylamidoacetate hydrochloride; it melts at 139°, and yields *α*-phenylhydantoïn, $CHPh<^{NH{\cdot}CO}_{CO{\cdot}NH}$, on hydrolysis in aqueous or alkaline solution.

With benzoic chloride and potash, ethyl phenylamidoacetate hydrochloride yields *ethyl phenylhippurate*, $NHBz{\cdot}CHPh{\cdot}COOEt$, which is soluble in alcohol or ether, and melts at 84°. The free *acid* melts at 174°. The *silver salt* crystallises in white needles.

Ethyl phenylthiouranilidacetate, $NHPh{\cdot}CS{\cdot}NH{\cdot}CHPh{\cdot}COOEt$, prepared from ethyl phenylamidoacetate and phenylthiocarbimide, melts at 162°; on hydrolysis in acid or alkaline solution, it yields *diphenylthiohydantoïn*, $CHPh<^{NH{\cdot}CS}_{CO{\cdot}NPh}$, which melts at 233°.

Ethyl phenyluranilidacetate, $NHPh{\cdot}CO{\cdot}NH{\cdot}CHPh{\cdot}COOEt$, is obtained as a colourless, crystalline powder by treating ethyl phenylamidoacetate with phenylcarbimide in ethereal solution; it melts at 165°, and on hydrolysis with dilute potash, yields the acid $NHPh{\cdot}CO{\cdot}NH{\cdot}CHPh{\cdot}COOH$, which melts at 154°, and is also formed by heating diphenylthiohydantoïn with potash.

Ethyl ethylurethanophenylacetate, COOEt·NH·CHPh·COOEt, is prepared by the mutual action of ethyl phenylamidoacetate (2 mols.) and ethyl chloroformate (1 mol.) in ethereal solution; it crystallises from dilute alcohol in long, white needles which melt at 54°. *Ethylurethanophenylacetic acid*, COOEt·NH·CHPh·COOH, is formed by the hydrolysis of the preceding compound with dilute potash, and melts at 155°.

By the action of nitrous acid on methyl phenylamidoacetate hydrochloride, methyl phenylhydroxyacetate is produced, whilst the corresponding ethyl salt is formed with nitrous acid and ethyl phenylamidoacetate.

Ethyl phenylamidoacetate nitrite, NO_2·NH_3·CHPh·COOEt, is formed from ethyl phenylamidoacetate hydrochloride and argentic nitrite in ethereal solution; it crystallises in small, white needles, which melt at 59° with evolution of nitrogen. Attempts to obtain ethyl phenyldiazoacetate from the preceding compound were unsuccessful.

J. B. T.

The Stereoisomeric and Polymeric Cinnamic Acids. By C. Liebermann (*Ber.*, **25**, 90—95).—F. Stohmann has furnished the author with the heats of combustion of allocinnamic acid, α- and β-truxillic acid, and polycinnamic acid, and compared them with the heat of combustion of cinnamic acid. Of these compounds, the most labile, namely, allocinnamic acid, gives the highest heat of combustion; cinnamic acid gives 5·2 cal. less. A similar difference is observed in the case of the labile and stable forms of other substances.

The polycinnamic acids give lower heats of combustion than cinnamic acid; the lowest number being obtained in the case of the most stable acid, also the one of highest molecular weight. The relations of the heats of combustion calculated for the formula $C_9H_8O_2$ are as follows:—

Allocinnamic acid ..	1047·6 cal.	β-Truxillic acid..	1040·1 cal.
Cinnamic acid	1042·3 „	α-Truxillic acid..	1035·3 „
	Polycinnamic acid.....	1021·0 cal.	

From the comparison of the heats of formation of cinnamic acid and allocinnamic acid taken in conjunction with the values obtained for other stereoisomeric unsaturated acids, it appears, at first sight, easy to determine which of the two configurations,

$$\text{I.}\ \begin{matrix}\text{Ph·C·H}\\ \|\\ \text{H·C·COOH}\end{matrix} \quad \text{and} \quad \text{II.}\ \begin{matrix}\text{Ph·C·H}\\ \|\\ \text{COOH·C·H}\end{matrix},$$

represents cinnamic, and which allocinnamic, acid. The author, after a searching inquiry into the matter, comes to the conclusion that neither the physical nor chemical properties of cinnamic acid provide means of determining its formula with certainty.

If the cinnamic acids be compared with stereoisomerides of the fatty acid series, then the physical and chemical properties seem to indicate that allocinnamic acid : cinnamic acid as erucic acid : brassidic acid, angelic acid : tiglic acid, and isocrotonic acid : crotonic acid. Then, according to Wislicenus' well-founded supposition, the experiments of Holt (*Ber.*, **24**, 4120) on erucic and brassidic acid

derivatives show that the fatty acids must be represented by the axial symmetrical formula I, the elaïdin acids by the plane symmetrical formula II—

$$\text{I.}\quad \begin{matrix} X\cdot C\cdot H \\ \| \\ H\cdot C\cdot COOH \end{matrix}, \qquad \text{II.}\quad \begin{matrix} X\cdot C\cdot H \\ \| \\ COOH\cdot C\cdot H \end{matrix},$$

from which we may conclude that allocinnamic acid is represented by formula I, and cinnamic acid by formula II.

If, however, the fundamental principle of Wislicenus' theory be considered, namely, that the revolution of the carbon atom system, to which the stereoisomerism is referred, is a consequence of the opposite chemical affinities of the radicles combined with it, so that a positive radicle of one carbon atom approaches a negative radicle of the other, and *vice versâ*, then the cinnamic acids differ from the fatty acids. For if, in the latter, the alkyl is considered positive, the phenyl in the former must be considered negative. From this point of view, the cinnamic acids must be compared with those unsaturated acids in which the two doubly-linked carbon atoms are each combined with a hydrogen atom and a negative group; then the analogues of the cinnamic acids are fumaric and maleïc acid. Now, from its physical and chemical properties, allocinnamic acid corresponds with maleïc acid, and cinnamic acid with fumaric acid, whence the former should be represented by formula II, the latter by formula I—the direct opposite to the conclusion previously arrived at.

The author concludes that other methods must be employed to settle the question. The determination of which two of the four monobromocinnamic acids, $C_2HPhBr\cdot COOH$, are derived from cinnamic acid, and the investigation of the dihalogen derivatives prepared from phenylpropiolic acid, are likely to throw some light on the matter. But the experiments are difficult, since the reduction (resubstitution) does not take place under all conditions; thus, in alkaline solution, the cinnamic derivatives yield hydrocinnamic acid, and in acid solution, allocinnamic acid easily undergoes isomeric change to cinnamic acid. E. C. R.

Diiodocinnamic Acid. By C. Liebermann and H. Sachse (*Ber.*, **24**, 4112—4118; compare Abstr., 1891, 1483).—Diiodocinnamic acid, $CPhI{:}CI\cdot COOH$, is readily prepared by mixing phenylpropiolic acid with 10 per cent. of anhydrous ferrous iodide, and adding iodine in carbon bisulphide solution; the reaction requires 10 days for completion; the acid crystallises in the monosymmetric system, $a : b : c = 0{\cdot}2093 : 1 : 0{\cdot}5008$; $\beta = 69°\ 38{\cdot}5'$. The sodium salt crystallises with $3H_2O$; the *calcium salt* is deposited from water in lustrous plates. On heating the silver salt at about 70°, phenyliodoacetylene, $CPh{:}CI$ is formed, the silver combining with a β-iodine atom. *Triiodocinnamene*, $CPhI{:}CI_2$ is formed by the addition of iodine to the preceding compound, and crystallises from alcohol, on the addition of water, in colourless needles melting at 108°. The same compound is also obtained by the action of iodine, in potassium iodide solution, on the silver salt of phenylacetylene.

Diiodostearolic acid, $C_{18}H_{32}O_2I_2$, is prepared in a similar manner to

diiodocinnamic acid, but the reaction proceeds more slowly, and the compound is difficult to purify; it crystallises from alcohol on the addition of water, and melts at 50—51°. The *ammonium salt* crystallises in small, lustrous plates; the *silver salt* decomposes at 100°, and yields an iodo-acid, which is being further investigated.

Diiodobehenolic acid, $C_{22}H_{40}O_2I_2$, is prepared like the preceding compound, and melts at 47°; in appearance, it closely resembles behenolic acid. The *silver salt* decomposes on heating with the formation of silver iodide.

The authors have shown with what difficulty unsaturated acids form iodine additive compounds; they point out the bearing of this fact on the interpretation of the "iodine values" obtained in the analysis of oils and fats by Hübl's method; they have treated a number of pure unsaturated acids with Hübl's reagent, but in no case succeeded in isolating any iodine additive compound; the reaction appears to be very complicated, and may consist in the addition of chlorine to the unsaturated acid. J. B. T.

An Isomeric Dichlorhydrin Metahydroxybenzoate. By C. Göttig (*Ber.*, **24**, 3845—3848; see also Abstr., 1891, 1482).—The author has examined the amorphous fatty compound obtained, together with β-dichlorhydrin metahydroxybenzoate, by the action of hydrogen chloride on a solution of metahydroxybenzoic acid in glycerol. He believes this compound to be a stereoisomeride of β-dichlorhydrin metahydroxybenzoate, and names it iso-β-dichlorhydrin metahydroxybenzoate.

Iso-β-dichlorhydrin metahydroxybenzoate is obtained when the above reaction is allowed to proceed at a temperature of 120—140°. It is purified by crystallisation from absolute alcohol, melts at 76—79°, is easily soluble in alcohol, ether, benzene, and carbon bisulphide, sparingly so in cold water, and forms nodular aggregates or needles. When boiled with water, it is converted into its crystalline isomeride. When warmed with alkalis, it is decomposed into epichlorhydrin and metahydroxybenzoic acid, the latter undergoing partial decomposition. E. C. R.

Phenyl-α-hydroxycrotonic Acid. By F. Tiemann (*Ber.*, **24**, 4065—4073).—In this paper, an account is given of the work already done by others on phenyl-α-hydroxycrotonic acid (Matsmoto, this Journal, 1876, i, 80; Peine, Abstr., 1884, 1344; Pinner and Lifschütz, *ibid.*, 1887, 1054), and the outline of an investigation carried out at the author's suggestion by Biedermann (see following abstract). A. R. L.

Derivatives of Phenyl-α-hydroxycrotonic Acid. By J. Biedermann (*Ber.*, **24**, 4074—4082; compare preceding abstract).—*γ-Phenyl-γ-bromo-α-hydroxybutyric acid*,

$$CHPhBr{\cdot}CH_2{\cdot}CH(OH){\cdot}COOH,$$

separates as a crystalline mass when phenyl-α-crotonic acid is dissolved in aqueous hydrogen bromide saturated at 0°; when crystallised from alcohol, it forms white needles, melts at 126°, and is readily soluble in

alcohol, ether, and chloroform, but insoluble in light petroleum. *γ-Phenyl-α-hydroxybutyro-γ-lactone*, $CHPh<\begin{matrix}CH_2\cdot CH\cdot OH\\ |\\ O-CO\end{matrix}$, is obtained:—(1) When the bromo-acid is boiled with water, the solution neutralised with sodium carbonate, and extracted with ether; (2) when the bromo-acid is heated with dilute sodium carbonate solution; (3) when the same compound is treated with sodium amalgam, and the solution acidified from time to time with sulphuric acid; (4) when phenyl-α-hydroxycrotonic acid is boiled with dilute sodium carbonate. It crystallises in broad needles, melts at 39°, and dissolves readily in most solvents, but is only sparingly soluble in water and light petroleum; its solutions have a neutral reaction. *γ-Phenyl-αγ-dihydroxybutyric acid* cannot be prepared, as it readily passes into the lactone, but its salts are obtained when the lactone is dissolved in solutions of the alkalis or alkaline earths. The *hydrazide*,

$$OH\cdot CHPh\cdot CH_2\cdot CH(OH)\cdot CO\cdot N_2H_2Ph,$$

is obtained by boiling an alcoholic solution of the lactone and phenylhydrazine (equal mols.) for 6—8 hours. It crystallises from benzene containing a little alcohol in white needles, melts at 133°, is decomposed by alkalis, and gives a reddish-violet colour with ferric chloride.

γ-Phenyl-α-acetoxycrotonic acid, $CHPh{:}CH\cdot CH(OAc)\cdot COOH$, is prepared by heating well dried phenyl-α-hydroxycrotonic acid with acetic chloride in molecular proportion until the evolution of hydrogen chloride ceases; the product, after cooling, is collected, and when repeatedly crystallised from glacial acetic acid forms bright, yellow needles, melts at 118°, and is readily soluble in alcohol and ether, but insoluble in cold water, benzene, light petroleum, and chloroform. Boiling alkalis hydrolyse it.

γ-Phenylcroton-α-lactone, $CHPh{:}CH\cdot CH<\begin{matrix}O\\ |\\ CO\end{matrix}$, is produced when dry phenyl-α-hydroxycrotonic acid is boiled with somewhat more than one molecular proportion of acetic anhydride in a reflux apparatus for five hours; it crystallises from glacial acetic acid in bright red leaflets, melts at 93°, and is sparingly soluble in boiling water, readily so in alcohol and ether. On adding ferric chloride to its hot aqueous solution, a red precipitate is produced, which redissolves to a green solution on the addition of sodium carbonate; it is reconverted into the acid by alkalis. The *phenylhydrazide*,

$$CHPh{:}CH\cdot CH(OH)\cdot CO\cdot N_2H_2Ph,$$

obtained by heating an alcoholic solution of the α-lactone and phenylhydrazine (equal mols.) on the water-bath for two hours, crystallises from alcohol in white needles, melts at 154°, and is insoluble in water, benzene, and light petroleum. It dissolves in alkalis undergoing hydrolysis, but in concentrated sulphuric acid without decomposition. The *anilide*, $CHPh{:}CH\cdot CH(OH)\cdot CO\cdot NHPh$, formed by heating an alcoholic solution of the α-lactone and aniline on the water-bath for an hour, crystallises from alcohol in lustrous needles, and melts at 150°. The *amide*, $CHPh{:}CH\cdot CH(OH)\cdot CONH_2$, prepared by adding an excess

of alcoholic ammonia to the finely-powdered α-lactone, allowing the mixture to remain for several days, and finally digesting it on the water-bath for 4—5 hours, crystallises from boiling water in white needles, melts at 125° to a blue liquid, is soluble in alcohol, but only sparingly so in benzene, and is hydrolysed by alkalis and ammonia.

When an alcoholic solution of phenyl-α-hydroxycrotonic acid and phenylhydrazine (equal mols.) is boiled in a reflux apparatus for six hours, a compound $C_{16}H_{14}N_2O$, melting at 98°, is formed, which yields a bromo-derivative $C_{16}H_{13}BrN_2O$, melting at 145°, and is, perhaps, a derivative of phenylpyridazone (Ach, Abstr., 1890, 70) of the formula $CHPh<^{CH=CH}_{NH\cdot NPh}>CO$.

A. R. L.

A New Method of Preparing the Amide, Anilide, and Phenylhyrazide of Mandelic Acid. By J. Biedermann (*Ber.*, **24**, 4083—4084).—When finely powdered mandelic acid (dried at 100°) is heated with an excess of acetic anhydride for six hours in a reflux apparatus, the product poured into water, and the resulting solution, after neutralising with sodium carbonate, extracted with ether, the corresponding α-lactone remains after distilling the ether from the extract, as a syrup which solidifies to an amorphous mass on being left over sulphuric acid. Mandelamide, agreeing with Tiemann and Friedländer's description (Abstr., 1882, 56), is obtained when the α-lactone is digested with an excess of ammonia in a closed flask at 100° for six hours; mandelanilide (Reissert and Kayser Abstr., 1891, 438), when the same compound is similarly digested with an alcoholic solution of aniline for 10 hours; and mandelic phenylhydrazide melting at 182° (Reissert and Kayser, Abstr., 1890, 155), when it is heated in a reflux apparatus with an alcoholic solution of phenylhydrazine in molecular proportion for five hours.

A. R. L.

Paraxylalphthalide. By A. Ruhemann (*Ber.*, **24**, 3964—3976).—Paratolylacetic acid, like phenylacetic and metatolylacetic acids (Abstr., 1891, 200), readily unites with phthalic anhydride on heating, with elimination of water and carbonic anhydride and formation of a phthalide. The two compounds are heated together with a little anhydrous sodium acetate, first at 230°, and after a time at 255°, the cooled product being powdered and recrystallised from boiling alcohol. *Paraxylalphthalide*, $CO<^{C_6H_4}_{O\ \ \ -}>C{:}CH\cdot C_6H_4Me$, is thus obtained in beautiful, yellow needles melting at 151°, sparingly soluble in alcohol and ether, more readily in boiling benzene, and easily in hot acetic acid. It combines directly with bromine, forming a *dibromide*, $C_{16}H_{12}Br_2O_2$, which crystallises from ether or chloroform in white, lustrous prisms, and melts at 150° with violent evolution of bromine and hydrogen bromide.

When fused with potash, paraxylalphthalide yields the potassium salt of *paramethyldeoxybenzoïnorthocarboxylic acid*,

$$C_6H_4Me\cdot CH_2\cdot CO\cdot C_6H_4\cdot COOH;$$

the free acid crystallises from alcohol in white, lustrous plates, and melts at 126°. By the action of hydroxylamine, it probably first yields the oxime, the latter then losing water, forming an *oximidolactone*, $C_6H_4 \cdot \underset{\underset{CO\cdot O\cdot N}{|\!|}}{C}\cdot CH_2\cdot C_7H_7$, which crystallises in slightly pink needles and melts at 126°. Alcoholic ammonia at 100° converts paraxylalphthalide into the *amide* of the above acid, $C_6H_4Me\cdot CH_2\cdot CO\cdot C_6H_4\cdot CONH_2$, which melts at 135—140°, and very readily loses water, forming *paraxylalphthalimidine*, $CO<\begin{matrix}C_6H_4\\NH-\end{matrix}>C{:}CH\cdot C_7H_7$; this substance crystallises in well developed, yellow, rhombic prisms, and melts at 203—204°. When subjected to the action of phosphorus and hydriodic acid, it takes up 2 atoms of hydrogen forming *paraxylylphthalimidine*,

$$CO<\begin{matrix}C_6H_4\\NH-\end{matrix}>CH\cdot CH_2\cdot C_7H_7,$$

which crystallises from hot water in long, lustrous needles and melts at 149°. Towards dehydrating agents it behaves in a manner similar to benzylphthalimidine (Abstr., 1888, 143), yielding a compound of unknown constitution. Paraxylalphthalimidine is acted on by nitrous acid in chloroform solution, with formation of *nitroparaxylalphthalimidine*, $CO<\begin{matrix}NH-\\C_6H_4\end{matrix}>C{:}C(NO_2)C_7H_7$, an intermediate dinitro-additive compound being probably formed. The nitro-compound forms lustrous, yellow needles, and melts at 227° with decomposition. Nitrous acid also gives with paraxylalphthalide, in the first place, an unstable *dinitro*-additive compound, $\begin{matrix}CO\cdot O\\|\\C_6H_4\end{matrix}>C(NO_2)\cdot CH(NO_2)\cdot C_7H_7$, which melts with vigorous decomposition at 240°, and on boiling with alcohol, yields *nitroparaxylalphthalide*, $\begin{matrix}CO\cdot O\\|\\C_6H_4\end{matrix}>C{:}C(NO_2)\cdot C_7H_7$. The latter melts at 205—207°, decomposing at the same time, like the nitro-derivatives of metaxylalphthalide and benzalphthalide, into phthalic anhydride and paratolyl isocyanate. With boiling aqueous potash, it yields phthalic anhydride, and a substance which is apparently paratolylnitromethane.

By the action of phosphorus and boiling hydriodic acid, nitroparaxylalphthalide is, like the corresponding metaxylal- and benzal-derivatives, converted into an isomeride of paraxylalphthalide, namely, *isoparaxylalphthalide*, $C_6H_4<\begin{matrix}CH{:}C\cdot C_7H_7\\|\\CO\cdot O\end{matrix}$; the latter forms white, prismatic crystals, melts at 116°, and is converted by alcoholic ammonia at 100° into *isoparaxylalphthalimidine*, $C_6H_4<\begin{matrix}CH{:}C\cdot C_7H_7\\|\\CO\cdot NH\end{matrix}$, which crystallises in long, pointed prisms, and melts at 226—228°. When this substance is treated with phosphorus oxychloride at 100°, it yields *α-chloro-β-paratolylisoquinoline*, $C_6H_4<\begin{matrix}CH{:}C\cdot C_7H_7\\|\\Cl{:}N\end{matrix}$, which

crystallises in lustrous plates, melts at 70—71°, and on reduction with phosphorus and hydriodic acid, yields *β-paratolylisoquinoline*, $C_6H_4<\begin{matrix}CH{:}C\cdot C_7H_7\\ |\\ CH\cdot N\end{matrix}$. The latter crystallises from light petroleum in lustrous, white needles, melts at 78°, and has basic properties. The *hydrochloride* and *hydrobromide* form compact, white prisms, the *hydriodide* long needles, the *chromate* reddish needles, the *picrate* yellow needles, and the *platinochloride*, $(C_{16}H_{13}N)_2,H_2PtCl_6$, yellowish-brown, arborescent groups of needles. H. G. C.

Preparation of Nitrososulphonic Acids. By H. Limpricht (*Ber.*, **25**, 75—77).—The method consists in adding metanitrobenzenesulphonic chloride in small quantities at a time to a concentrated solution of sodium sulphite. The sulphonic chloride dissolves with slight development of heat, and the action is completed by heating on the water-bath. Care must be taken that the mixture does not become acid, and from time to time a few drops of concentrated sodium hydroxide is added. The solution is evaporated to dryness, extracted with alcohol (95 per cent.), the alcohol distilled off, the dry residue extracted with absolute alcohol, and the alcoholic solution evaporated to dryness. The product is treated in this way until it contains neither sulphate nor chloride; or the pure substance may be obtained by dissolving the product obtained by extraction with alcohol in water, adding silver nitrate until all the chloride is precipitated, and then converting the nitrososulphonic acid into silver salt by the further addition of silver nitrate.

Sodium nitrosobenzenesulphonate, $NO\cdot C_6H_4\cdot SO_3Na + 2H_2O$, is easily soluble in water and hot alcohol, crystallises in crusts of small, lustrous leaflets, gives Liebermann's reaction, and when treated with potassium permanganate in aqueous solution, is converted into nitrobenzenesulphonic acid. The *silver* salt, which is precipitated in slender, yellowish needles on adding silver nitrate to a dilute solution of the sodium salt, is somewhat sparingly soluble in boiling water, and crystallises, on cooling, in long, slender needles. The *barium* salt crystallises in long, white needles, is easily soluble in cold water, and explodes when heated on platinum foil. The *free acid*, obtained by decomposing the silver salt with hydrochloric acid, crystallises from concentrated solutions in white needles, and is converted into a resin, insoluble in water, by evaporating its solution with hydrochloric or sulphuric acids.

The nitroso-acids obtained from orthonitrotoluenesulphonic acid and nitronaphthalenesulphonic acid by this method have properties similar to the above.

Experiments to obtain the nitroso-acids from the salts of the nitrosulphonic acids, instead of from the chlorides, gave negative results; as also did experiments to obtain the nitroso-acids from the chlorides of ortho- and meta-nitrobenzoic acids. E. C. R.

Action of Sulphurous Acid on Isonitroso-compounds. By M. Schmidt (*J. pr. Chem.* [2], **44**, 513—535; compare Abstr., 1887,

549, 635; 1888, 913; 1890, 1305).—*Benzylamidosulphonic acid*, $C_7H_7{\cdot}NH{\cdot}SO_3H + \frac{1}{2}H_2O$, is the product of the action of sulphurous anhydride on an aqueous solution of β-benzylhydroxylamine hydrochloride (Behrend and Leuchs, *Annalen*, **257**, 223; Abstr., 1889, 500, 703); it forms white, crystalline aggregates, melts at 180° with decomposition, and is unstable, the sulphonic group readily forming sulphuric acid with the water of crystallisation; its alkali salts are soluble in water.

Dibenzylamidosulphonic acid, $N(C_7H_7)_2{\cdot}SO_3H + H_2O$, is prepared by adding finely-powdered β-dibenzylhydroxylamine (Behrend and Leuchs, *loc. cit.*) to a boiling 40 per cent. aqueous solution of sodium hydrogen sulphite, as long as it dissolves pretty freely, and filtering while hot. A copious separation of felted, thin, tabular crystals, together with some needles, occurs on cooling the solution; the tables are separated from the needles by cold water, which dissolves the former, the solution yielding the sulphonic acid on the addition of hydrochloric acid. When freshly prepared, it is soluble in cold water, but, after drying, it is only soluble in hot water, whereby it loses sulphur; the solution is precipitated by hydrochloric acid, but not by acetic acid. It melts at 160°, or, when quickly heated, at 170° with decomposition. It dissolves in ammonia, hot alcohol, and glacial acetic acid; the ammoniacal solution does not reduce silver nitrate. Attempts to prepare its salts were unsuccessful on account of its instability; when alcoholic silver nitrate is added to its solution in alcohol, silver sulphate is precipitated; ammonia and sodium hydroxide both give white precipitates, soluble in excess, when added to its solution. When the ammonia precipitate is dissolved in nitric acid, white needles of *dibenzylamine nitrate*, melting at 190° and soluble in water, crystallise out.

When an aqueous solution of acetoxime is saturated with sulphurous anhydride, amidosulphonic acid (m. p. 200°) is formed (compare Pechmann, Abstr., 1887, 1103; 1888, 146).

No definite results were obtained from the action of sulphurous anhydride on nitrosophenol, nitrosoresorcinol, or dinitroso-orcinol; a brown liquid, which strongly reduced ammoniacal silver nitrate, was produced in each case, but attempts to crystallise the contained compound failed. Nitrosothymol is not attacked by sulphurous acid, whether applied in the form of sulphurous anhydride in water, or of sodium hydrogen sulphite.

α-Amido-β-naphtholsulphonic acid is best obtained by adding finely-powdered α-nitroso-β-naphthol to a boiling 35 per cent. solution of sodium hydrogen sulphite, as long as it dissolves to a bright, yellow solution, filtering, and adding concentrated hydrochloric acid to the hot filtrate; prismatic needles separate when the liquid cools, and are purified by recrystallising from sodium hydrogen sulphite solution, when they are obtained as pale yellow needles, which become reddish when exposed to air. The acid is insoluble in water, alcohol, ether, and benzene, but dissolves in sodium acetate solution, ammonia, and other alkalis, from which it is precipitated by hydrochloric acid; it also dissolves in concentrated sulphuric acid. Its alkaline solutions readily oxidise on exposure to air, and it reduces am-

moniacal silver solutions very readily. When it is heated with concentrated hydrochloric acid at 150—160° in a sealed tube, the sulphur is entirely converted into sulphuric acid, ammonia and a black nitrogenous mass being at the same time produced. When heated on platinum foil, it intumesces and decomposes with evolution of a deep violet vapour. The author compares the above properties with those of the four known amido-β-naphtholsulphonic acids, and shows that his acid is different from any of the others.

When oxidised, α-amido-β-naphtholsulphonic acid yields sulphuric acid, but no other definite product has been isolated. No success attended efforts to prepare its salts. When treated with sodium nitrite and sulphuric acid, it yields yellow needles of what seems to be a nitro-derivative.

α-Amido-β-naphtholsulphonic acid is also the main product when sulphurous acid acts on chloro-β-naphthaquinone-α-oxime and on trichloro-β-ketohydronaphthalene-α-oxime (Zincke, Abstr., 1890, 1146).

β-Amido-α-naphtholsulphonic acid is obtained by adding hydrochloric acid to a solution of β-nitroso-α-naphthol in 35 per cent. sodium hydrogen sulphite; it crystallises from dilute sodium hydrogen sulphite solution in white aggregates of needles (with $1\frac{1}{2}$ mols. H_3O), which become pale-grey in air. It is more stable than the isomeride described above; it can be heated at 120° without decomposition, is difficultly combustible, and does not lose sulphuric acid when treated with oxidising agents. The whole of its sulphur is not removed by hydrochloric acid at 150°. It dissolves in boiling water and sodium hydrogen sulphite solution; the latter solution has a blue fluorescence when dilute, but less blue than that of the isomeride. It is insoluble in alcohol, ether, and benzene; its solutions in the alkalis are easily oxidised, and it reduces ammoniacal silver solution. No nitro-derivative was obtained. This acid differs from Witt's amido-α-naphtholsulphonic acid in colour, form, and solubility.

Sulphurous acid is without action on α-nitroso-α-naphthol or ethylnitrolic acid.

The author deduces the following generalisations from the foregoing facts:—

Isonitroso-derivatives of the general formula $HO{\cdot}N{<}^{HR_1}_{R_1}$ form substituted amidosulphonic acids when acted on by sulphurous acid.

Isonitroso-derivatives of the general formula $R_{11}{\cdot}NOH$ may be divided into three classes, according to their behaviour with sodium hydrogen sulphite solution, viz.:—(1) Such as are easily soluble therein; these yield no amidosulphonic acid. (2) Such as are soluble in a boiling solution thereof; these yield amidosulphonic acids, at the same time undergoing a reduction analogous to the conversion of quinone into quinol. (3) Such as are unattacked by the solution thereof.

A. G. B.

Aromatic Thiosulphonic Acids. By R. Otto and A. Rössing (*Ber.*, **24**, 3874—3883).—The authors have made experiments with the object of obtaining the tetrathio-compound mentioned in a former paper (Abstr., 1891, 924) in an easier manner, but without success.

A concentrated aqueous solution of potassium toluenethiosulphonate (2 mols.) was allowed to remain in a closed space exposed to the vapours of bromine (2 mols.) at the ordinary temperature until the bromine was absorbed. The product consisted of a mixture of the pentathio- and trithio-compounds with a small quantity of the tetrathio-compound.

When a cold solution of potassium benzenethiosulphonate is mixed with an excess of copper sulphate solution, a crystalline precipitate of a double salt, $3PhSO_2SK,2(PhSO_2S)_2Cu_2,3H_2O$, is obtained, which, when extracted with the usual solvents for polythio-compounds, yields the pentathio- and trithio-compounds. The double salt is stable in air; when heated with potassium hydroxide, it is decomposed with formation of cuprous hydroxide, the latter being quickly converted into copper sulphide, and, when heated alone, it is decomposed above 100°.

When treated with copper sulphate, potassium toluenethiosulphonate behaves in an exactly similar way.

The authors have examined the action of phosphorus pentachloride on the polythio-compounds to determine if a chloride of the formula $PhSO_2{\cdot}SCl$ is formed.

The trithio-compound of benzene, $(PhSO_2)_2S$, when treated with phosphorus pentachloride, yields phosphorus trichloride, sulphur dichloride, and benzenesulphonic chloride. The product of the reaction was boiled with ammonia, when benzenesulphonamide was obtained, but no trace of an amine or salt of the acid $PhSO_2S{\cdot}SH$ could be detected.

The pentathio-compound of toluene, $(C_7H_7SO_2S)_2S$, behaves in a similar way, and yields toluenesulphonic chloride, sulphur dichloride, and phosphorus trichloride.

The authors have also studied the action of phosphorus trichloride and oxychloride on alkali salts of thiosulphonates, in the hope of obtaining chlorides from which, by the action of potash, the thio-acid could be regenerated. The action, however, takes a different course.

Dry potassium benzenethiosulphonate is mixed to a thin paste with phosphorus oxychloride, gently warmed for some hours, then heated to boiling, and the cold product poured into excess of cold, dilute soda solution. A thick, insoluble oil is thus obtained which, when treated with ammonia, partially dissolves, and yields benzenesulphonamide and a very small quantity of benzenethiosulphonate. The product insoluble in ammonia consists of benzene disulphoxide, $PhSO_2{\cdot}S{\cdot}Ph$. It is converted into phenyl bisulphide and potassium benzenesulphinate by boiling with potash. The benzenethiosulphonic acid is thus chiefly converted into the sulphonic chloride. In order to determine if the benzenesulphonic chloride is obtained through the formation of sulphinic acid, dry sodium benzenesulphinate was heated with excess of phosphorus oxychloride, when condensation products of the sulphinic acid were obtained, and only a very slight smell of benzenesulphonic chloride could be detected.

Potassium benzenethiosulphonate and phosphorus trichloride gave benzenesulphonic chloride, only traces of salts of thiosulphonic acid, and phenyl bisulphide. Sodium benzenesulphinate and phosphorus trichloride yielded phenyl bisulphide. E. C. R.

Nitrosulphobenzoic Acid. By Hausser (*Bull. Soc. Chim.* [3], **6**, 391—395).—Hart has obtained salts of the acid

$$SO_3H\cdot C_6H_3(NO_2)\cdot COOH\ [= 2:4:1]$$

by the oxidation of calcium nitrotoluenesulphonate with potassium permanganate. The author oxidises the corresponding potassium salt. 50 grams of potassium nitrotoluenesulphonate, 86 grams of potassium permanganate, and 4500 c.c. of water are heated together on the water-bath for 8—10 hours. The product is cooled, filtered, and concentrated to 500 c.c., when it yields a crop of silky needles. The filtrate is concentrated to 250 c.c.; crystals like those of the first crop first appear; when these begin to appear opaque, the liquid is rapidly filtered, and it then yields the dipotassium salt of nitrosulphobenzoic acid. The yield from the foregoing quantities is 19 grams of nearly pure, dry salt from the third crystallisation. About 15 grams of the original substance is recovered from the first crystallisation, and a further quantity of the dipotassium salt may be obtained from the second crystallisation by treatment with boiling alcohol, which dissolves out the potassium nitrotoluenesulphonate. The total yield of oxidised salt is from 45 to 50 per cent.

Dipotassium nitrosulphobenzoate, $SO_3K\cdot C_6H_3(NO_2)\cdot COOK$, is difficult to purify by crystallisation. The acid salt may easily be purified; it is mixed with a slight excess of potassium carbonate, and the product recrystallised from 60 per cent. alcohol, when it forms large, short prisms free from water. The *monopotassium* salt, $SO_3K\cdot C_6H_3(NO_2)\cdot COOH + H_2O$, is obtained by the action of sulphuric acid on the dipotassium salt, from which it may be distinguished by the longer crystals formed. Excess of sulphuric acid does not decompose this salt. The *lead* salt, $2C_7H_3NSO_7Pb,5H_2O$, is obtained by heating equivalent quantities of the dipotassium salt and normal lead acetate with 15 times their weight of water, filtering rapidly, and allowing to crystallise; it forms short, large prisms. It loses its water with difficulty; but 2 mols. are eliminated on boiling for two hours with water. It is insoluble in cold water; hydrogen sulphide barely produces a coloration in the mother liquors. It has not been obtained free from potassium; several hours boiling with water fails to abstract the whole of this impurity.

The free acid, $SO_3H\cdot C_6H_3(NO_2)\cdot COOH$, is obtained from the lead salt by suspending the latter in 15 times its weight of water and boiling for 20 minutes with the theoretical quantity of sulphuric acid. The product is cooled, filtered, and evaporated down as far as possible. On cooling, it forms a crystalline mass which is treated with a little 95 per cent. alcohol. The alcoholic solution when crystallised over alcohol, gives long, prismatic needles melting at 71—72°; by very slow evaporation, tables are obtained. The acid is very hygroscopic; it loses water in a vacuum over sulphuric acid, when

a form containing $2H_2O$ is obtained, which fuses at 120—125°, loses water, and resolidifies. The anhydrous acid formed fuses at 146°. It crystallises in prismatic bundles. W. T.

Acetylhydrindigotin and Acetylindigotin. By C. Liebermann and D. F. Dickhuth (*Ber.*, **24**, 4130—4136).—*Diacetylindigotin*, $C_6H_4<\overset{CO-}{NAc}>C{:}C<\overset{CO-}{NAc}>C_6H_4$, is readily prepared by the action of nitrous acid on diacetylhydrindigotin in glacial acetic acid; it may also be obtained by the action of oxidising agents, such as chlorine, bromine, chromic anhydride, or nitric acid, on diacetylhydrindigotin, or by the treatment of indigo with acetic chloride in acetic anhydride solution. The compound is very sparingly soluble in organic media, and crystallises from benzene in lustrous, red, tetragonal pyramids which melt at a high temperature. In solution, the compound exhibits characteristic absorption bands between D and E; on treating the acetyl derivative with alkalis, indigo is quantitatively regenerated.

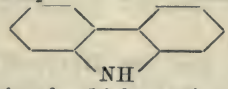
The authors remark on the curious change of colour from blue to red produced by the introduction of two acetyl groups into the indigotin molecule.

Acetylhydrindigotin is insoluble in alkalis; it therefore has the formula $C_6H_4<\overset{CO-}{NAc}>CH{\cdot}CH<\overset{CO-}{NAc}>C_6H_4$, and is termed the ψ-form; an isomeric β-modification,

$$C_6H_4<\overset{C(OH)}{NAc}\!\!-\!\!>C{\cdot}C<\!\!-\!\!\overset{C(OH)}{NAc}>C_6H_4,$$

is obtained by cautiously heating acetylindigotin (17 parts) with phenylhydrazine (11 parts) in benzene solution; there is a considerable evolution of nitrogen, and a heavy, colourless, crystalline powder is formed; this is not acted on by nitrous acid; it dissolves in dilute alkalis at ordinary temperatures with formation of indigo, whilst, on boiling with alcohol, acetylindigotin is produced.

Tetracetylhydrindigotin, $C_6H_4<\overset{CAc}{NAc}>C{\cdot}C<\overset{CAc}{NAc}>C_6H_4$, is formed by the action of zinc-dust, acetic anhydride, and sodium acetate on diacetylindigotin; the compound is very sparingly soluble, and is deposited from glacial acetic acid as a crystalline powder; it melts at 258° with decomposition, is insoluble in alkalis at ordinary temperatures, but, on boiling, the solution yields indigo.

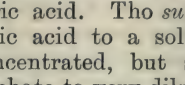


J. B. T.

Synthesis of the Diamidocarbazole obtained from Carbazole. By E. Täuber (*Ber.*, **25**, 128—133).—The diamidocarbazole which is prepared according to a patent of the Bad. Anilin- und Soda-Fabrik, when converted into its tetrazo-derivative, yields with salicylic acid a yellow dye, carbazole-yellow, which dyes unmordanted cotton. From these properties, it was expected that the diamidocarbazole contained both amido-groups in the para-position relatively to the diphenylene

bond. The author has already prepared the diamidocarbazole of this constitution, and has shown that it is not identical with the compound prepared according to the above patent (Abstr., 1891, 227). He has succeeded in synthesising the latter compound as follows:—The acetyl derivative of diorthamidodiphenyl is nitrated, and the product hydrolysed, when a diparanitraniline is obtained; this is reduced to diparaphenylenediamine, and the latter converted into diamidocarbazole by heating with hydrochloric acid.

Dimetanitrodiorthamidodiphenyl is obtained as follows:—Pure diorthamidodiphenyl is acetylated by heating it with acetic acid containing one-third its weight of acetic anhydride (*Ber.*, **24**, 199). The dry acetyl compound is dissolved in five times its weight of ice-cold, concentrated sulphuric acid, and finely-powdered potassium nitrate (2 mols.) added to the solution at 10°. When no further reaction can be detected by the thermometer, the mixture is saturated with aqueous potash and warmed on the water-bath. The yellowish-brown powder thus obtained is dissolved in hot hydrochloric acid (20 per cent.), precipitated with water, and crystallised from a mixture of phenol and alcohol. It crystallises in small, golden-yellow prisms having a violet reflex, melts at about 285°, but darkens at 250°, and becomes tarry at 280°. It is insoluble in ether, benzene, toluene, and light petroleum, very sparingly soluble in water, chloroform, and alcohol, easily so in boiling phenol, and has very feeble basic properties.



Diparaphenylenediamine, $C_{12}H_6(NH_2)_4$ [= 2 : 5 : 2′ : 5′], is obtained in the form of its hydrochloride by reducing the preceding compound with tin and hydrochloric acid. The base is precipitated from the solution of its easily soluble hydrochloride by strong aqueous potash; by ammonia or dilute potash, it is not precipitated. It crystallises from boiling toluene in aggregates of colourless needles, melts at 168°, is easily soluble in water, alcohol, and chloroform, sparingly so in boiling benzene, toluene, and ether, and insoluble in cold benzene, toluene, and light petroleum. Both the hydrochloride and the sulphate are easily soluble. The constitution of the base is deduced from the following observations:—It does not react with orthodiketones such as dibenzoyl and dihydroxytartaric acid; when diazotised with nitrous acid, it does not yield a dye; hence the amido-groups are not in the ortho- or para-position relatively to each other. It gives the indamine and indophenole reactions characteristic of paradiamines.

Diamidocarbazole, 

, is obtained by heating diparaphenylenediamine for 10 hours in a sealed tube with five times the quantity of hydrochloric acid (15—20 per cent.) at 180—190°. The product is diluted with water, warmed with a little stannous chloride, the tin precipitated with hydrogen sulphide, the filtered, colourless solution evaporated until it contains 3—5 per cent., and mixed then with an equal volume of hydrochloric acid (25 per cent.). On cooling, the hydrochloride separates in tufts of long, white, lustrous needles. The free base is obtained in silvery leaflets by precipitating

a hot solution of the hydrochloride with ammonia; it darkens at 260°, does not melt at 290°, is insoluble in ether, almost so in cold water, sparingly soluble in hot water, somewhat sparingly so in benzene, toluene, and alcohol, and when damp is acted on by the air. The *hydrochloride* is somewhat easily soluble in water, and quite insoluble in cold 10 per cent. hydrochloric acid. Tho *sulphate* is not precipitated by the addition of sulphuric acid to a solution of the hydrochloride unless the latter is concentrated, but separates in beautiful needles on adding sodium sulphate to very dilute solutions, and is easily soluble in dilute hydrochloric acid, sparingly so in water.

E. C. R.

Diphenylenazone. By E. Täuber (*Ber.*, **24**, 3883—3886; see also this vol., p. 183).—Diphenylenazone,  , sublimes with difficulty in bright, greenish-yellow needles, melts at 156°, and is not volatile with steam. The *aurochloride* and *platinochloride* are very sparingly soluble in water, and crystallise in yellow needles. The *chromate* is obtained in beautiful, red needles by adding a hot solution of chromic acid to a hot solution of the phenazone in dilute sulphuric acid, and is very sparingly soluble. The *picrate* is obtained by mixing very dilute, hot benzene solutions of the two components; on cooling, it separates in feathery, brown needles, is very sparingly soluble, coagulates at 190°, and melts at 194°. The *hydrochloride* is obtained by adding a hot saturated solution of the phenazone to excess of hydrochloric acid and allowing the mixture to cool slowly. It crystallises in flat prisms, having a bronze lustre, and can be dried in the air without decomposing, but in a vacuum, or on gently warming, it loses hydrogen chloride; it is also decomposed by water. Diphenylenazone is extremely stable towards oxidising agents. When treated with zinc and hydrochloric acid or tin and hydrochloric acid, the azo-group is converted into the hydrazone group. Stannous chloride and alcoholic ammonium sulphide are without action on it. When treated with bromine in benzene solution, it yields a brick-red, crystalline precipitate, which turns yellow on drying.

It is distinguished from phenazine by the following properties, besides those given above:—It dissolves in concentrated sulphuric acid with a sulphur-yellow coloration, and its hydrazone gives the same colour; whilst phenazine gives a blood-red and its hydrazone a green coloration.

E. C. R.

Benzaldiphenylmaleïde and its Derivatives. By G. Cohn (*Ber.*, **24**, 3854—3874).—The author, in conjunction with Gabriel, has shown that benzaldiphenylmaleïde is formed by the action of diphenylmaleïc anhydride on phenylacetic acid with elimination of water and carbonic anhydride (this vol., p. 178).

Paraxylaldiphenylmaleïde, $\begin{matrix}\mathrm{CPh{:}CPh}\\ |\\ \mathrm{CO}\text{---}\mathrm{O}\end{matrix}\!>\!\mathrm{C{:}CH{\cdot}C_7H_7}$, is obtained in the same way by the condensation of paratolylacetic acid and diphenylmaleïc anhydride. It crystallises from acetic acid in yellow

needles, melts at 165°, and is more easily soluble in alcohol and acetic acid than benzaldiphenylmaleïde.

Dibromobenzyldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}\!>\!\text{CHPhBr}$, is obtained by adding bromine (2 c.c.) to benzaldiphenylmaleïde (5 grams) suspended in chloroform (50 c.c.), and allowing the mixture to evaporate in a dish for 5—10 hours in a cold place. It is purified by washing with acetone and then dissolving in chloroform and precipitating with acetone. It forms large, hard, rhombic crystals when allowed to crystallise slowly, melts at 154° with evolution of gas, and is easily soluble in hot benzene, chloroform, and acetic acid, very sparingly so in hot acetone.

Bromobenzaldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}\!>\!\text{C:CPhBr}$, is obtained by heating the preceding compound at 155—160°; it crystallises from acetone in well-formed, measurable crystals, belonging to the rhombohedral system, and melts at 165°.

Hydroxybenzaldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}\!>\!\text{C:Ph·OH}$, is obtained by dissolving the finely-powdered dibromo-compound in alcoholic potash and boiling the solution for 5—10 minutes; the product is poured into water, the alcohol distilled off, and the cold solution precipitated with hydrochloric acid. It crystallises in long, yellow needles, melts at 205°, but sinters at a somewhat lower temperature, is insoluble in ammonia, easily soluble in potassium hydroxide, and is quantitatively reprecipitated by carbonic anhydride.

Benzylhydroxydiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}\!>\!\text{C(OH)·CH}_2\text{Ph}$, is obtained by warming benzaldiphenylmaleïde (5 grams) with concentrated potassium hydroxide (25 grams) for some hours on the water-bath or by boiling the mixture until the compound has melted to a brown oil. The oil, which is the potassium salt of the new compound, is dissolved in hot water; the cold solution precipitated with hydrochloric acid, and the precipitate crystallised from dilute alcohol or dissolved in benzene and precipitated with light petroleum. The potassium salt can easily be obtained pure by allowing the finely-powdered maleïde to remain with a molecular proportion of absolute alcoholic potash for 24 hours with frequent shaking; the yield is, however, not so good as by the first method. It sinters at 170°, melts at 183—185°, is easily soluble in alcohol, less so in benzene, very slightly so in light petroleum, and insoluble in ammonia, but easily soluble in sodium hydroxide. It is precipitated from solution by excess of soda, and from alcoholic solution by carbonic anhydride. It does not yield an acetyl derivative or methyl ether, but, under these experimental conditions, is reconverted into benzaldiphenylmaleïde.

β-Phenacetyl-αβ-diphenylacrylamide,

$$\text{NH}_2\text{·CO·CPh:CPh·CO·CH}_2\text{Ph},$$

is obtained by heating benzaldiphenylmaleïde (5 grams) with 10 per cent. alcoholic ammonia (20 c.c.) at 100° for four hours. It is purified

by crystallisation from alcohol, forms microscopic, rhombic plates, and melts at 203—204°.

Benzaldiphenylmaleïmidine, $\begin{matrix}\text{CPh:CPh}\\ \text{CO—NH}\end{matrix}\!>\!\text{C:CHPh}$, is obtained by adding the above amide in fine powder to boiling acetic acid. It is purified by crystallisation from acetic acid, melts at 241—242°, and is very sparingly soluble in boiling alcohol.

Bromobenzaldiphenylmaleïmidine, $\begin{matrix}\text{CPh:CPh}\\ \text{CO—NH}\end{matrix}\!>\!\text{C:CPhBr}$, is obtained by adding bromine as long as it is absorbed to the preceding compound suspended in chloroform. It is purified in the same way as bromobenzaldiphenylmaleïde, crystallises in white, felted needles, and melts at 213—214°.

β-Phenacetyl-αβ-diphenylacrylethylamide,

$$\text{NHEt·CO·CPh:CPh·CO·CH}_2\text{Ph},$$

is obtained by the action of ethylamine on the maleïde in the same way as the above amide is by the action of ammonia. It crystallises from benzene in aggregates of slender, white needles, and melts at 172—173°. When boiled with acetic acid, it is converted into *benzaldiphenylmaleïnethylimidine*. The latter crystallises from alcohol, melts at 144—146°, and is easily soluble in most organic solvents.

Benzyldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO —— O}\end{matrix}\!>\!\text{CH·CH}_2\text{Ph}$, is obtained by gradually adding a mixture of benzaldiphenylmaleïde (10 grams) and amorphous phosphorus (5 grams) to 50 c.c. of boiling hydriodic acid (sp. gr. = 1·7—1·96). After heating for some time in a reflux apparatus, a brown oil is obtained floating on the liquid; the mixture is then boiled for 1—2 hours, and, on cooling, the oil solidifies. It is treated with very dilute sodium hydrogen sulphite, dissolved in alcohol, and sulphurous anhydride passed through the solution, filtered, and the alcohol allowed to evaporate. It forms small, hard, white crystals, melts at 127—128°, is easily soluble in chloroform, alcohol, and benzene, sparingly so in light petroleum. It does not give an additive compound with bromine, and is insoluble both in ammonia and aqueous potassium hydroxide.

αβδ-Triphenyl-γ-hydroxypropylidenacetic acid,

$$\text{COOH·CPh:CPh·CH(OH):CH}_2\text{Ph},$$

is obtained by dissolving the preceding compound in warm alcoholic potash. It crystallises from dilute alcohol or acetic acid in compact needles, sinters at 120—140°, melts at 173—174°, is easily soluble in ammonia and dilute sodium hydroxide and carbonate, and is precipitated as sodium salt by excess of sodium hydroxide or carbonate. The *silver* salt is obtained in white flocks on adding silver nitrate to a faintly ammoniacal solution of the acid. No definite compound was obtained from it by heating. It is converted into benzyldiphenylmaleïde by the action of phosphorus oxychloride.

Benzyldiphenylmaleïmidine, $\begin{matrix}\text{CCPh:Ph}\\ \text{CO—NH}\end{matrix}\!>\!\text{CH·CH}_2\text{Ph}$, is obtained by

heating benzyldiphenylmaleïde with alcoholic ammonia in a sealed tube at 180° for seven hours. If the tube is slowly cooled, it crystallises in aggregates of rhombic plates which are measurable. It is purified by crystallisation from dilute alcohol, melts at 169—170°, dissolves in chloroform, and is reprecipitated on the addition of ether. The *nitrosamine* is obtained by suspending the maleïmidine in benzene and passing nitrous anhydride into the mixture until it dissolves; the benzene is allowed to evaporate off and the product crystallised from methyl and then from ethyl alcohol. It melts at 135—136°, gives Liebermann's reaction, is somewhat easily soluble in alcohol, and yields benzaldiphenylmaleïmidine with evolution of nitrous oxide when boiled with potassium hydroxide.

If benzyldiphenylmaleïmidine is warmed with dry phosphorus oxychloride, it is converted into a compound which dissolves with a deep-violet colour in alcohol, and is obtained as a brownish-red base on precipitating the hot alcoholic solution with ammonia. The base is sparingly soluble in alcohol, does not dye either wool or silk, gives a brown solution with concentrated sulphuric acid and forms salts, which are decomposed by water. It is probably analogous to the compound obtained by Gabriel (*Ber.*, **20**, 2865) from benzylphthalimidine.

αβδ-Triphenyl-γ-hydroxypropylidenacetethylamide,

$$NHEt\cdot CO\cdot CPh{:}CPh\cdot CH(OH)\cdot CH_2Ph,$$

is obtained by heating benzyldiphenylmaleïde with 10 per cent. alcoholic ethylamine for 3—4 hours at 180°; it crystallises from alcohol in white needles, and melts at 194—196°.

Benzyldiphenylmaleïnethylimidine, $\begin{matrix} CPh{:}CPh \\ | \\ CO-NEt \end{matrix}\!>\!CH\cdot CH_2Ph$, is obtained in small quantities by boiling the preceding compound with acetic acid. It is, however, best obtained by reducing the corresponding benzal derivative with hydriodic acid and phosphorus. It crystallises from alcohol in pale-yellow, nodular crystals and melts at 125°. The pure substance gives no coloured product with phosphorus oxychloride; when impure, it yields a compound which dissolves in alcohol with a blue coloration, and on precipitation with ammonia it yields a yellow base.

Hydroxynitrobenzyldiphenylmaleïde, $\begin{matrix} CPh{:}CPh \\ | \\ CO-\!-\!-O \end{matrix}\!>\!C(OH)\cdot CHPh\cdot NO_2$, is obtained by treating benzaldiphenylmaleïde (5 grams) suspended in benzene (30 c.c.) with a stream of nitrous anhydride, produced by the action of arsenious anhydride on nitric acid (sp. gr. = 1·33). The temperature must not be allowed to rise above 60°, and care must be taken that all the maleïde dissolves. After a time, a white, crystalline compound separates from the dark-green solution. It is collected, dried on a porous plate, and crystallised from ether. The yield amounts to 35 per cent. A somewhat larger yield is obtained by suspending the lactone in 10 times the quantity of benzene, adding two to three times the theoretical quantity of nitrogen tetroxide, and allowing the mixture to remain. The best yield, about 65 per

cent., is obtained by nitrating in five times the volume of glacial acetic acid, to which a few drops of water have been added. It melts at 123—125°, is sparingly soluble in cold benzene and acetic acid, easily so in ether, is very unstable, and is decomposed by hot acetic acid and alcohol, by prolonged boiling with benzene, or by heating with water. When subjected to steam distillation, it is decomposed into phenylnitromethane and diphenylmaleïc anhydride. The *acetyl derivative*, $C_{23}H_{16}NO_5Ac$, is obtained on heating it in a sealed tube with four times the quantity of acetic chloride for four hours at 100°; it crystallises from alcohol in rhombic, six-sided leaflets, melts at 166°, sinters about 10° lower, and explodes when strongly heated.

Dinitrobenzyldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}>\text{C}(\text{NO}_2)\cdot\text{CHPh}\cdot\text{NO}_2$, is obtained by evaporating the green benzene solution obtained in the preparation of the preceding compound at about 30°, and purifying the semi-solid mass thus obtained by washing it with ether and precipitating the chloroform solution with ether. It forms a lustrous, crystalline powder, melts at 146° with decomposition, and is easily soluble in chloroform and acetic acid, sparingly so in ether, and only very sparingly in alcohol, which decomposes it. It is also obtained by nitrating benzaldiphenylmaleïde in boiling acetic acid.

Nitrobenzaldiphenylmaleïde, $\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{---}\text{O}\end{matrix}>\text{C:CPh}\cdot\text{NO}_2$, is obtained by boiling the preceding compound with acetic acid or alcohol or by heating it at its fusion point until evolution of nitrous fumes ceases. It crystallises in yellow leaflets, melts at 175—177°, is easily soluble in hot chloroform, somewhat sparingly so in ether and alcohol, begins to decompose at 190°, and explodes violently when heated in a test tube, yielding phenyl isocyanate and diphenylmaleïc anhydride. When dissolved in warm alcoholic potash, it is converted into the above hydroxynitro-compound. When reduced with hydriodic acid and phosphorus, it is converted into a compound which the author believes to be *isobenzaldiphenylmaleïde*, $\begin{matrix}\text{CPh:CPh}\cdot\text{CH}\\ \text{CO}\text{---}\text{O}\cdot\text{CPh}\end{matrix}$, melting at 118°. If the latter is heated with alcoholic ammonia for some time at 100°, it yields a compound which crystallises in long, white needles, melts above 260°, and is very sparingly soluble in alcohol; the author believes this to be *isobenzaldiphenylmaleïmidine*, $\begin{matrix}\text{CPh:CPh}\cdot\text{CH}\\ \text{CO}\text{–}\text{NH}\text{–}\text{CPh}\end{matrix}$, and has obtained triphenylpyridine from it by treatment with phosphorus oxychloride and subsequent reduction.

Hydroxynitrobenzyldiphenylmaleïmidine,

$$\begin{matrix}\text{CPh:CPh}\\ \text{CO}\text{—}\text{NH}\end{matrix}>\text{C}(\text{OH})\cdot\text{CHPh}\cdot\text{NO}_2,$$

is obtained as a crystalline powder by passing nitrous anhydride into an ice-cold mixture of benzaldiphenylmaleïmidine (5 grams) suspended in 20 c.c. of acetic acid and $\frac{1}{2}$ c.c. of water. It is collected on an asbestos filter, well washed with acetic acid, and dried on a

porcelain plate and then in a vacuum. It is also obtained in small quantity by nitrating in chloroform solution. By slowly evaporating the ethereal solution, it is obtained in stellate groups of large crystals, is sparingly soluble in cold acetic acid and benzene, easily so in hot chloroform and ether, but insoluble in light petroleum; it is decomposed by boiling with benzene and alcohol, and is very unstable, turning yellow on exposure to air and also in a vacuum. When subjected to steam distillation, it is decomposed into phenylnitromethane and diphenylmaleïc anhydride.

Nitrobenzaldiphenylmaleïmidine, $\begin{matrix}\text{CPh:CPh}\\ \text{CO—NH}\end{matrix}\!\!>\text{C:CPh}\cdot\text{NO}_2$, is obtained by allowing the preceding compound to remain 24 hours with acetic chloride or by boiling it for a short time with this reagent. It crystallises in yellow needles, melts at 201—202°, dissolves in concentrated sulphuric acid with a red coloration, which changes to yellow on gently heating, and explodes about 260° with formation of phenyl isocyanate and diphenylmaleïc imide. When treated with alcoholic potash, it is converted into a potassium salt, sparingly soluble in alcohol, and, on adding water and distilling off the alcohol and then adding hydrochloric acid to the cold solution, a yellow precipitate is obtained which, on boiling, yields phenylnitromethane and diphenylmaleïc anhydride.

By nitrating benzaldiphenylmaleïmidine in benzene, a product is obtained, together with nitrobenzaldiphenylmaleïmidine, which crystallises in beautiful, yellow, pointed forms built up of thin, quadratic plates. It gave, on analysis, numbers agreeing with the formula $C_{30}H_{22}N_2O_5$, melts at 173°, decomposes at 195—198°, and behaves towards concentrated sulphuric acid and soda like nitrobenzaldiphenylmaleïmidine.

When benzaldiphenylmaleïnethylimidine is nitrated in benzene, it yields a compound of the formula $C_{18}H_{14}N_2O_4$, which crystallises from alcohol in beautiful, bright-yellow plates, melts at 151°, and sublimes without decomposition. The author believes it to be a nitro-derivative of the unknown diphenylmaleïnethylimide, $C_{16}H_{10}O_2\text{:}N\cdot Et$.

E. C. R.

Influence of Substituting Radicles on the Configuration of Aromatic Ketoximes. By A. W. Smith (*Ber.*, **24**, 4025—4058; compare Hantzsch, this vol., p. 426).—The author has prepared the oximes of a great number of benzophenone derivatives in order to study the influence of the substituting groups, both with regard to their nature and position, on the properties and stability of the two theoretically possible stereoisomeric modifications.

The alkyl derivatives of benzophenone were prepared by treating a hydrocarbon, such as propylbenzene, with an acid chloride, such as benzoic chloride, in carbon bisulphide solution in presence of aluminium chloride; the yield of the pure ketone usually amounted to 60 to 80 per cent. of the theoretical. The oximes were prepared by Auwers' method, and in cases where two stereoisomeric modifications were formed, their separation was effected by fractional precipitation from acetic acid or from alcohol. The configuration of the oximes was determined by treating the compound with phosphorus penta-

chloride and water successively, as described by Hantzsch (Abstr., 1891, 445); under these conditions, the stable isomeride is completely converted into the corresponding anilide, the labile modification yielding, as a rule, a mixture of two structurally isomeric anilides. When necessary for identification, the anilides were converted into the corresponding acids by treatment with concentrated hydrochloric acid at about 150°, the base produced at the same time being, as a rule, identified by means of its acetyl derivative; these experiments are not described in this abstract, except in cases where new compounds were obtained.

Antiparethylbenzophenone oxime, $C_6H_4Et\cdot\overset{\overset{N\cdot OH}{\|}}{C}\cdot Ph$, is obtained, together with an approximately equal quantity of the isomeric synoxime, when parethylbenzophenone (b. p. 330—332°) is treated with hydroxylamine and soda in dilute alcoholic solution; it crystallises from alcohol in short, thick, monoclinic prisms, melts at 142°, and is readily soluble in ether and glacial acetic acid, but more sparingly in cold alcohol and benzene, almost insoluble in cold light petroleum, and insoluble in water. The *acetyl* derivative crystallises from alcohol in colourless, monoclinic prisms, melts at 95°, and is reconverted into the oxime (m. p. 142°) on treatment with soda. When the antioxime is heated at 120° for 20 hours with soda and hydroxylamine, it is almost completely converted into the synoxime.

Parethylbenzanilide, $C_6H_4Et\cdot CO\cdot NHPh$, prepared by treating the antioxime with phosphorus pentachloride and water successively, crystallises from alcohol in lustrous needles, melts at 121°, and is readily soluble in alcohol and ether, but insoluble in water; no other anilide is produced from the antioxime.

Synparethylbenzophenone oxime, $C_6H_4Et\cdot\overset{\overset{OH\cdot N}{\|}}{C}\cdot Ph$, crystallises from alcohol in long, thin needles, melts at 108°, dissolves freely in ether and glacial acetic acid, and is much more readily soluble in alcohol and dilute acetic acid than the stereoisomeride. The *acetyl* derivative, prepared in the cold, is a thick oil, and is reconverted into the synoxime by treatment with cold soda; when warmed with alcohol, it is completely converted into the acetyl derivative of the antioxime. When the synoxime is treated with phosphorus pentachloride and water successively, it is almost entirely converted into benzoylparethylanilide, only traces, if any, of parethylbenzanilide being formed.

Parapropylbenzophenone, $C_6H_4Pr\cdot COPh$, is a thick, yellowish liquid boiling at 203° under a pressure of 180 mm.; on treatment with hydroxylamine, it yields two oximes.

Antipropylbenzophenone oxime, $C_{16}H_{17}NO$, crystallises from dilute alcohol or acetic acid in slender needles melting at 104°; it is not converted into the synoxime by treatment with acids, or with soda and hydroxylamine. The *acetyl* derivative separates from alcohol in crystals, melts at 66°, and is reconverted into the antioxime on hydrolysis with soda. The *anilide*, $NHPh\cdot CO\cdot C_6H_4Pr$, is formed when the antioxime is treated with phosphorus pentachloride and

water successively; it crystallises from alcohol in flat prisms, melts at 138°, and is only sparingly soluble in alcohol, ether, and benzene.

Synpropylbenzophenone oxime, $C_{16}H_{17}NO$, crystallises from alcohol in long, lustrous prisms, melts at 130°, and is more sparingly soluble in alcohol than the isomeride, but almost as readily soluble as the latter in ether and glacial acetic acid. The *acetyl* derivative crystallises in slender needles, melts at 116°, and is reconverted into the synoxime by alkalis; when warmed with acetic chloride, it is transformed into the acetyl derivative of the antioxime. When the synoxime is treated with phosphorus pentachloride and water successively, it yields parapropylbenzanilide, $C_6H_4Pr{\cdot}NH{\cdot}COPh$.

Parisopropylbenzophenone, $C_6H_4Pr^{\beta}{\cdot}COPh$, is a thick oil boiling at 343° under a pressure of 738 mm.; when treated with hydroxylamine, it gives two oximes.

Antiparisopropylbenzophenone oxime, $C_{16}H_{17}NO$, crystallises from alcohol or glacial acetic acid in long, monoclinic prisms, melts at 132°, and is not changed by boiling soda even in presence of hydroxlamine. The *acetyl* derivative crystallises from alcohol in short, monoclinic prisms, melts at 90°, is readily soluble in alcohol and ether, and is reconverted into the antioxime on hydrolysis with sodium carbonate.

Cuminylanilide, $NHPh{\cdot}CO{\cdot}C_6H_4Pr^{\beta}$, is formed when the antioxime is treated with phosphorus pentachloride and water successively; it crystallises from alcohol in long, lustrous needles, melts at 159°, and is readily soluble in alcohol, but more sparingly in ether and benzene.

Synparisopropylbenzophenone oxime, $C_{16}H_{17}NO$, crystallises from alcohol, in which it is much more readily soluble than the isomeride, in long needles melting at 106°. The *acetyl* derivative is an oil, and is reconverted into the synoxime on hydrolysis with sodium carbonate; when heated alone, or with alcohol, it is transformed into the acetyl derivative of the antioxime. When the synoxime is treated with phosphorus pentachloride and water successively, it yields a mixture of cuminylanilide and benzoylcuminide; when treated with hydrogen chloride in ethereal solution, or with acetic acid, it is completely transformed into the antioxime.

Paramidobenzophenone combines with hydroxylamine, yielding two *oximes* of the composition $C_{13}H_{12}N_2O$; the one, probably the antioxime, melts at 168°, crystallises from alcohol in long, monoclinic prisms, and is only sparingly soluble in alcohol and benzene, but more readily in ether and glacial acetic acid; the other oxime, probably the syn-isomeride, crystallises in slender, colourless needles, melts at 126°, and is more readily soluble in alcohol than the compound of higher melting point.

Parahydroxybenzophenone is best obtained by heating paramethoxybenzophenone at 145—150° for 3—4 hours with an aqueous solution of hydrogen choride, saturated at 0°; when boiled with hydroxylamine and potash in alcoholic solution for 4—5 hours, it yields two oximes.

Antiparahydroxybenzophenone oxime, $C_{13}H_{11}NO_2$, crystallises from dilute acetic acid in slender, monoclinic prisms, melts at 125°, and is

readily soluble in ether and alcohol, but rather more sparingly in glacial acetic acid, benzene, and chloroform, and very sparingly in water; it dissolves in alkalis and in concentrated acids. The *acetyl* derivative crystallises in prisms, melts at 141° with decomposition, and is readily soluble in alcohol, but more sparingly in ether and benzene; on hydrolysis with sodium carbonate, it is reconverted into the antioxime. When the oxime is treated with phosphorus pentachloride in the usual manner, it yields parahydroxybenzanilide and smaller quantities of other products; on prolonged boiling with alkali, it is quantitatively converted into the synoxime.

Synparahydroxybenzophenone oxime, $C_{13}H_{11}NO_2$, crystallises in needles, melts at 81°, and is very readily converted into the antioxime when heated alone for a short time at about 80°, or when treated with hydrogen chloride in ethereal solution; it reacts with acetic chloride and with acetic anhydride in the cold, yielding a syrup, which, on hydrolysis with sodium carbonate, gives a mixture of the anti- and syn-oximes, and which, when heated alone, is completely transformed into the acetyl derivative of the antioxime. When the synoxime is treated with phosphorus pentachloride and water successively, it yields benzoylparamidophenol (m. p. 205—207°) and smaller quantities of other products.

Metahydroxybenzophenone, $C_{13}H_{10}O_2$, can be prepared by diazotising the corresponding metamido-compound; it crystallises in lustrous plates, melts at 116°, and is very readily soluble in alcohol and ether, but only sparingly in hot, and almost insoluble in cold, water; when boiled with hydroxylamine in alcoholic solution, it yields the synoxime as sole product.

Synmetahydroxybenzophenone oxime, $C_{13}H_{11}NO_2$, separates from benzene in crystals, melts at 75—76°, and is converted into the antioxime when heated at its melting point, or when treated with hydrogen chloride at the ordinary temperature.

Antimetahydroxybenzophenone oxime, $C_{13}H_{11}NO_2$, prepared by gradually heating the synoxime to 80—90°, crystallises in slender needles, melts at 126°, and is very readily soluble in alcohol, chloroform, and ether, but more sparingly in benzene; it is converted into the synoxime by boiling potash.

Antiorthotolylphenylketoxime, $C_{14}H_{13}NO$, is obtained when orthotolyl phenyl ketone is treated with hydroxylamine and potash in alcoholic solution at the ordinary temperature; it melts at 105°, and, on treatment with phosphorus pentachloride in the usual manner, it yields *orthotoluylanilide*, $C_6H_4Me{\cdot}CO{\cdot}NHPh$ (m. p. 125°). The *acetyl* derivative is a thick syrup, which, on hydrolysis with sodium carbonate, is reconverted into the antioxime.

Synorthotolylphenylketoxime, $C_{14}H_{13}NO$, is formed in small quantities (about 20 per cent.), together with the antioxime (about 80 per cent.), when the ketone is boiled with an alcoholic solution of hydroxylamine and potash for 10 hours; it melts at 69°.

Antixylylphenylketoxime, $C_{15}H_{15}NO$, is formed, together with a small quantity of the synoxime, when xylyl phenyl ketone [$CO : Me_2 = 1 : 2 : 4$] is treated with hydroxylamine and potash in alcoholic solution at the ordinary temperature; if the crude product be warmed

with glacial acetic acid for a long time, the synoxime is completely transformed into the isomeride. It crystallises in flat prisms or plates, melts at 126°, and is very readily soluble in glacial acetic acid, ether, and alcohol, but more sparingly in benzene, and almost insoluble in water. The *acetyl* derivative crystallises in long, flat prisms, melts at 91°, and, on hydrolysis, is reconverted into the antioxime. When the oxime is treated with phosphorus pentachloride and water successively, it yields metaxyloylanilide (m. p. 139°).

Synxylylphenylketoxime, $C_{15}H_{15}NO$, crystallises from alcohol in short prisms, melts at 152°, and is more sparingly soluble in alcohol than the antioxime. The *acetyl* derivative, prepared in the cold, separates from alcohol in crystals melting at 103°, and, when hydrolysed in the cold, is reconverted into the synoxime; it is readily converted into the isomeride on warming, and, on prolonged treatment with acetic chloride at the ordinary temperature, it yields a mixture of the anti-acetyl derivative and *benzoylxylide*, $COPh{\cdot}NH{\cdot}C_6H_3Me_2$. The last-named compound is also produced almost exclusively when the synoxime is treated with phosphorus pentachloride in the usual manner at −20°, but when the reaction is carried out at the ordinary temperature, a mixture of benzoylxylide and xyloylanilide is obtained.

Xylyl orthotolyl ketone, $C_6H_3^{2,4}Me_2{\cdot}CO{\cdot}C_6H_4^{1\ \ 2}Me$, prepared from orthotoluic chloride and metaxylene, is a thick, yellowish oil boiling at 329—330° under a pressure of 728 mm.; it does not combine with hydroxylamine when boiled therewith in neutral, acid, or alkaline solution, but when the solution (acid or alkaline) is heated at 120° in sealed tubes for five hours, 50—60 per cent. of the ketone is converted into a mixture of xyloyltoluide and *orthotoluylxylide;* the last-named compound crystallises from alcohol in small, seemingly orthorhombic plates melting at 165°.

Mesityl phenyl ketone is not acted on by hydroxylamine even at 120°.

The author draws the following conclusions from the results of the above experiments:—An alkyl group has a repellent action on the hydroxyl group of the hydroxylamine molecule, in consequence of which the anti- is more stable than the syn-oxime; as the molecular weight of the alkyl group increases, its influence decreases, as is shown by the relative stability of the synoximes of methyl-, ethyl-, and propyl-benzophenone. The intensity of the repellent action varies with the constitution of the alcohol radicle, a normal radicle having less influence than an iso-radicle. Halogens and hydroxy- and amido-groups exert an influence similar to that of alcohol radicles, that is to say, the syn- are less stable than the anti-oximes. The terms stable and labile, as applied to oximes, are, however, purely relative, as a change of conditions or of chemical influences may reverse the relative stability; in the case of halogen derivatives of benzophenone, for example, one modification of the oxime is relatively the more stable in presence of acids, the other in presence of alkalis. The influence of various groups on the configuration of aromatic oximes is practically the same, whether the group be in the meta- or the para-

position to the carbon atom of the carbonyl radicle, and is only very slight in either case; when, however, the substituting group is in the ortho-position, its influence is very considerable, the syn- being far less stable than the anti-oxime. F. S. K.

Indulines. By E. Istel (*Chem. Zeit.*, **14**, 1535).—A blue dye, soluble in water, has been mentioned as being present among the products of the action of aniline hydrochloride on amidoazobenzene hydrochloride in concentrated aqueous solution. The author has studied this substance together with other compounds which are likewise formed at the same time.

If 2·5 parts of aniline hydrochloride and 1 part of amidoazobenzene hydrochloride are digested with 6 parts of water, at a temperature of 70—80°, the colour, at first yellow, changes to violet, and later to blue. After 24 hours, the strength of the coloration does not increase. Water is then added, the insoluble portion filtered off, and the blue dye precipitated with salt. Obtained in this way, it is a brown powder, only sparingly soluble in cold water, but readily in hot water, forming a blue solution with reddish-brown fluorescence. It dissolves in alcohol, forming a blue solution, but it is insoluble in ether. Addition of concentrated hydrochloric or sulphuric acid to the aqueous solution causes a reddish coloration, but the dye dissolves in the concentrated acid with blue coloration. Soda precipitates the dye as a blackish-brown powder. Zinc reduces it. Unbleached cotton is dyed a beautiful blue, as also are wool and silk, the former with a somewhat reddish tinge. The author considers the substance an induline, but different from that described in D.R.P. 50,534 (*Chem. Zeit.*, **14**, 353).

The material from which the above substance was dissolved out by water was now extracted with alcohol, by means of which another substance, soluble in alcohol with blue coloration, was separated. It forms a blackish-brown powder, and is a beautiful, grey-coloured nigrosine. In addition, azophenine was found as a product of the reaction, although this was hardly to be expected at so low a temperature. J. W. L.

Methylnaphthylenes. By H. Wichelhaus (*Ber.*, **24**, 3918—3921).—The methylnaphthalenes, as obtained from coal-tar oil by the usual process of distillation, or of freezing-out, are always contaminated with diphenyl. They may, however, be obtained pure in the following manner:—The higher boiling portion of the oil is cooled in a special apparatus, described in the paper, first to 0°, then to −21°, and finally to −36°, the solid substance which separates being drained, at each successive temperature, from the still liquid portion by means of the pump. The solid and liquid hydrocarbons thus obtained are separately dissolved in alcohol, and treated with an alcoholic solution of picric acid; the picrate which separates out is washed with alcohol and decomposed with ammonia, and the hydrocarbon distilled over with steam.

α-Methylnaphthalene is a colourless, fluorescent oil, boiling at

240—242°, and remaining liquid at −36° ; it has a sp. gr. = 1·013 at 19°, and its picrate melts at 117°.

β-Methylnaphthalene forms white, lustrous plates, soluble in alcohol, α-methylnaphthylene, &c.; it melts at 37—38°, and boils at 240—241° ; its picrate melts at 115°. It may also be obtained from the coal-tar oil by cooling it to −15°, treating the solid substance which then separates with picric acid, and decomposing the picrate with an insufficient quantity of ammonia. This decomposes the α- in preference to the β-picrate; the latter is freed from ammonium picrate by washing with water, and from α-methylnaphthalene by pressing on unglazed porcelain; it is then decomposed with ammonia, and the resulting β-methylnaphthalene distilled over with steam, rendered solid by cooling to 0°, and recrystallised from alcohol.

C. F. B.

Action of Chlorine and of Nitric Acid on the Methylnaphthalenes. By O. Scherler (*Ber.*, **25**, 3921—3932).—When chlorine is passed at the ordinary temperature over β-methylnaphthalene, it liquefies, chlorine is absorbed, and some hydrogen chloride is evolved. The product is washed with water, dried, extracted with light petroleum, and crystallised from ether. *Chloro-β-methylnaphthalene tetrachloride*, $C_{10}H_6MeCl,Cl_4$, is thus obtained in lustrous, colourless, monosymmetric prisms or tables; $a : b : c = 1·3696 : 1 : 1·4852$; $\beta = 81° 47'$; it melts at 148°, and dissolves readily in chloroform, ether, and acetic acid, sparingly in alcohol, not at all in light petroleum. That it has the formula given above appears from the fact that when treated with alcoholic potash it loses hydrochloric acid, and forms *trichloro-β-methylnaphthalene*, $C_{10}H_4MeCl_3$. This crystallises from alcohol in small, white needles, melts at 182°, and dissolves readily in ether, chloroform, acetic acid, and hot alcohol, less readily in cold alcohol. When boiled with dilute nitric acid, it yields phthalic anhydride; hence the three chlorine atoms must be contained in the same ring as the methyl group. When the tetrachloride in acetic acid solution is treated with just sufficient permanganate to oxidise the methyl group, small needles melting at 70° are obtained; these appear to be *trichloronaphthoic acid*, $C_{10}H_4Cl_3{\cdot}COOH$.

When the crude product of the action of chlorine on β-methylnaphthalene is extracted with light petroleum, an oil is dissolved, and from this, by treatment with alcoholic potash, a substance is obtained which crystallises from alcohol in yellowish needles, and melts at 140—146° ; it appears to be *tetrachloro-β-methylnaphthalene*, $C_{10}H_3MeCl_4$. It can also be obtained if the above-mentioned crude product is distilled under a pressure of 20 mm., as the fraction boiling at 220—227°. The yellow oil that comes over at 189° is *dichloro-β-methylnaphthalene*, $C_{10}H_5MeCl_2$.

Chlorine was also passed into α-methylnaphthalene, and the resulting viscid oil treated with alcoholic potash; an oil was formed, from which finally small, yellowish needles of *trichlor-α-methylnaphthalene*, $C_{10}H_4MeCl_3$, were obtained; they melt at 145—146°, and dissolve in all solvents except water. No other definite compound could be isolated.

When chlorine is passed into boiling β-methylnaphthalene, the already known β-naphthylmethyl chloride, $C_{10}H_7 \cdot CH_2Cl$, melting at 47°, is obtained; no other more highly chlorinated compounds appear to be formed.

When chlorine is passed into α-methylnaphthalene heated to 250°, and the product distilled in a vacuum, *α-naphthylmethyl chloride*, $C_{10}H_7 \cdot CH_2Cl$, is obtained as a yellow oil boiling at 167—169° under 25 mm. pressure, and dissolving in all solvents except water; when boiled at the ordinary pressure, it loses hydrochloric acid. α-Naphthylmethylene chloride, $C_{10}H_7 \cdot CHCl_2$, appears to be also formed, but cannot be separated by distillation in a vacuum, as it readily decomposes.

When bromine is added to α-methylnaphthalene in direct sunlight, the already known brom-α-methylnaphthalene, boiling at 178—179° under 30 mm. pressure, is formed. When β-methylnaphthalene is chlorinated in direct sunlight and the product distilled in a vacuum, *chloro-β-methylnaphthalene*, $C_{10}H_6MeCl$, is obtained as a colourless oil, boiling at 159—161° at 25 mm. pressure, and dissolving in all solvents except water; the *picrate*, $C_{10}H_6MeCl,C_6H_3N_3O_7$, crystallises from alcohol in yellow needles melting at 106—107°. By treating α-methylnaphthalene with chlorine in direct sunlight, and fractionating the product in a vacuum, *chlor-α-methylnaphthalene*, $C_{10}H_6MeCl$, is obtained; it boils at 167—169° under 30 mm. pressure. The *picrate*, $C_{10}H_6MeCl,C_6H_3N_3O_7$, forms orange-yellow needles melting at 101—102°.

When α-methylnaphthalene is dissolved in acetic acid and treated with strong nitric acid, *mononitro-α-methylnaphthalene* is formed. It is a yellow oil boiling at 194—195° at 27 mm. pressure, and easily soluble in alcohol, ether, and acetic acid. C. F. B.

Action of Hypochlorous Acid on β-Naphthaquinone. By E. Bamberger and M. Kitschelt (*Ber.*, **25**, 133—136).—*Dihydroxy-β-naphthaquinone* [$O_2 : (OH)_2 = 1 : 2 : 3 : 4$], is obtained by the action of hypochlorous acid on β-naphthaquinone. The reaction probably takes place through the formation of a chlorhydrin and a glycol, although these two intermediate compounds have not been detected. The dihydroxyquinone is isomeric with naphthazarin, and the author names it *isonaphthazarin*. It is extremely like naphthazarin in both physical and chemical properties. The following is the method of preparation:—Bleaching powder (35 grams) is suspended in water (135 grams), allowed to remain one hour, and then mixed with a solution of potassium carbonate (26 grams) in water (40 grams). After remaining two hours, the mixture is filtered, and boric acid (20 grams) added to the filtrate with shaking, and then allowed to remain one hour, filtered, and finely powdered β-naphthaquinone (2·5 grams) added to the filtrate with constant shaking. The pale-yellow solution is then mixed with concentrated hydrochloric acid and heated, until it suddenly changes to a dark red. On allowing the solution to remain, the isonaphthazarin crystallises out, mixed with boric acid, from which it is separated by boiling with water. The product is also mixed with a trace of a dye, soluble in alkali

with a red coloration, from which it is separated by crystallisation from acetone. It crystallises in beautiful, orange-red leaflets having a green lustre, sublimes in needles of metallic lustre, melts at 276°, is easily soluble in acetone, somewhat sparingly so in hot water, chloroform, and alcohol, and only very sparingly in cold water, ether, and benzene; it dissolves in concentrated sulphuric acid with a dark, cherry-red coloration; in fixed alkalis with a cornflower-blue, and in alkaline carbonates and ammonia with a violet-blue coloration. The alkaline solution is completely decolorised by long exposure to light. The sodium and copper salts are dark blue, the barium and zinc salts bright blue, the lead, cadmium, and nickel salts indigo-blue, the mercury and cobalt salts greenish-blue.

If the conditions of preparing the dye be only slightly varied, it is not formed at all, but a beautifully crystalline, colourless acid is obtained, melting at 203°. The authors are investigating the latter compound. E. C. R.

Action of Phosphorus Pentachloride on the Methyl Naphthyl Ketones. By J. A. Leroy (*Compt. rend.*, **113**, 1056—1059).—When methyl α-naphthyl ketone, boiling at 296—298°, is allowed to fall drop by drop on phosphorus pentachloride, hydrogen chloride is disengaged, and *chlor-α-naphthylethylene*, $C_{10}H_7{\cdot}CCl{:}CH_2$, remains as a colourless liquid which boils at 184° under a pressure of 50—60 mm., and has a sp. gr. of 1·179. It forms an additive compound with bromine. When methyl β-naphthyl ketone, melting at 51—52°, is substituted for its isomeride, the corresponding *chloro-β-naphthylethylene* is formed as a colourless solid which melts at 52—53°. Another chlorinated derivative is produced, however, at the same time, which crystallises in slender needles, melts with decomposition at about 165°, and is sparingly soluble in boiling water. By treating either of these ethylene derivatives with alcoholic potash, hydrogen chloride is eliminated, and the corresponding naphthylacetylene formed. An ethoxide, $C_{10}H_7{\cdot}C(OEt){:}CH_2$, is also produced by a second reaction, but its amount may be diminished by using very concentrated, dry, alcoholic potash, and not heating above 120°. The α-naphthylacetylene is purified by means of the silver compound, the copper compound not being adapted for this purpose on account of the readiness with which it is oxidised. The product of the alcoholic potash reaction is treated with alcoholic ammoniacal silver nitrate, and *silver-α-naphthylacetylene*, $C_{10}H_7{\cdot}C{:}CAg$, is precipitated as a yellowish-white powder, from which the hydrocarbon is set free by the addition of the theoretical quantity of hydrochloric acid.

α-Naphthylacetylene, $C_{10}H_7{\cdot}C{:}CH$, is a colourless liquid, which boils at 143—144° under a pressure of 25 mm., and has a sp. gr. of 1·057. It combines with bromine in carbon bisulphide solution to form liquid *dibrom-α-naphthylethylene*, $C_{10}H_7{\cdot}CBr{:}CHBr$. This substance takes up more bromine in the dark, but no definite compound could be isolated from the product. The hydrocarbon is reconverted into the ketone by somewhat dilute (3 : 1) sulphuric acid. When the copper-α-naphthylacetylene is suspended in alcoholic ammonia and shaken with air, yellowish-white crystals of *dinaphthyldiacetylene*,

$C_{10}H_7{\cdot}C{:}C{\cdot}C{:}C{\cdot}C_{10}H_7$, are deposited on the sides of the vessel. This substance melts at 171°, and is very soluble in benzene and carbon bisulphide, but less soluble in alcohol and acetic acid. It is more quickly obtained by oxidising the copper compound with alkaline potassium ferricyanide at a moderate temperature, but is then more difficult to purify. In carbon bisulphide solution, it absorbs an amount of bromine vapour corresponding with nearly eight equivalents, but a crystalline substance could not be isolated from the product. Dinaphthyldiacetylene combines with picric acid to form an additive compound, $C_{24}H_{14},C_6H_2(NO_2)_3{\cdot}OH$, which crystallises in brilliant, red needles, and melts at 180°.

β-Naphthylacetylene, $C_{10}H_7{\cdot}C{:}CH$, as obtained from chloro-β-naphthylethylene by treatment with alcoholic potash, forms colourless crystals, melts at 36°, and can be distilled under reduced pressure. It is soluble in alcohol, ether, and carbon bisulphide, and forms an additive compound with bromine, but this could not be crystallised. Ammoniacal silver nitrate precipitates *silver β-naphthylacetylene*, $C_{10}H_7{\cdot}C{:}CAg$, as a white powder. Ammoniacal cuprous chloride throws down a canary-yellow precipitate. The hydrocarbon is reconverted into the ketone by somewhat dilute sulphuric acid.

Jn. W.

Julole. By A. Reissert (*Ber.*, **25**, 108—119; see also Abstr., 1891, 736).—This paper contains an account of the products of oxidation and reduction of α_1-keto-γ_1-methyljuloline.

$\alpha_1\alpha_2$-Diketo-γ_1-methyljulole, $C_{13}H_9NO_2$, is obtained, together with hydroxylepidinecarboxylic acid, by oxidising ketomethyljuloline with potassium permanganate. It is separated from the crystalline mixture thus obtained by extracting the hydroxylepidinecarboxylic acid with ammonia and crystallising the residue from dilute acetic acid. It crystallises in small, pale-yellow needles, is very electric, melts at 245° (corr.), is easily soluble in alcohol, acetic acid, and chloroform, less so in benzene, sparingly in boiling water, and insoluble in light petroleum. It dissolves in concentrated mineral acids, and is precipitated on the addition of water. When oxidised in acid solution with potassium permanganate, it is converted into hydroxylepidinecarboxylic acid. It does not yield a hydrazone when treated with phenylhydrazine. It is also obtained mixed with hydroxylepidinecarboxylic acid by using chromic acid as the oxidising agent. If potassium dichromate is added to a sulphuric acid solution of ketomethyljuloline, the *chromate* of the latter separates out in yellow needles. This salt is very unstable, cannot be recrystallised, and is easily decomposed by boiling with water or dilute acids.

Ketomethyljuloline is very stable towards acid reducing agents, and is not attacked when boiled for six hours with tin and hydrochloric acid or with zinc-dust and acetic acid. When distilled over zinc-dust, it yields resinous products, and part remains unaltered. It is, however, reduced by sodium amalgam in acetic acid solution, and also by sodium amalgam and alcohol, and by sodium and alcohol. With sodium amalgam and acetic acid, it yields bisketomethyljulolidyl and ketomethyljulolidine; with sodium amalgam and alcohol, it

yields a compound which the author believes to be α_1-hydroxy-γ_1-methyljuloline; and with sodium and alcohol, it yields γ-methyljulolidine.

α_1-Keto-γ_1-methyljulolidine is obtained by adding a large excess of 8 per cent. sodium amalgam to an acetic acid solution of ketomethyljuloline. From time to time more acetic acid is added, so as to keep the solution strongly acid. The solution is filtered and the product precipitated with alkali, the precipitate treated with dilute acetic acid, and the residue dissolved in acetic acid. On adding water to the solution, ketomethyljulolidine separates as a white, crystalline precipitate. It crystallises from dilute acetic acid in small, branching needles, melts at 242° (corr.), is very easily soluble in alcohol, ether, benzene, chloroform, and acetic acid, sparingly so in light petroleum, and insoluble in water.

Bis-α_1-keto-γ_1-methyljulolidyl, $C_{26}H_{28}N_2O_2$, is obtained by adding excess of alkali to the acetic acid mother liquors of the preceding compound. It crystallises from very dilute acetic acid in hard, lustrous crystals, melts at 257·5° (corr.), and has the same solubility as the preceding compound. A molecular weight determination gave the number 412, whilst the above formula requires 400.

α_1-Hydroxy-γ_1-methyljuloline is obtained by adding 8 per cent. sodium amalgam (150 grams) in 30-gram lots to a boiling solution of ketomethyljuloline (5 grams) in 98 per cent. alcohol (200 grams), and boiling the mixture until all the amalgam is destroyed. The mixture is allowed to cool, filtered, diluted with water, neutralised with hydrochloric acid, the alcohol distilled off, and the solution extracted with ether. The greater part of the ether is distilled off, and the remaining liquid dried with potassium carbonate. The dry product is then fractionally distilled, when a colourless oil is obtained boiling above 300°; it solidifies in a desiccator to a crystalline mass of greasy granules, and then melts at 45° (corr.). It is easily soluble in most solvents, always separates from its solutions as an oil, is dissolved by concentrated mineral acids, and precipitated on the addition of water; it is not soluble in alkalis. The presence of the hydroxyl group could not be detected; the compound is not attacked by acetic anhydride and sodium acetate, benzoic chloride or methyl iodide, and sodium.

α_1-Hydroxy-γ_1-methyl-$\beta_1\gamma_1$-dibromojulolidine, $C_{13}H_{15}NOBr_2$, is obtained by gradually adding bromine (1 mol.) dissolved in acetic acid to hydroxymethyljuloline dissolved in 10 times the quantity of acetic acid. The mixture, after a time, deposits small, yellow crystals of the new compound; this darkens on heating in a capillary tube, and melts about 141·5° with decomposition. The product contains the dibromide of monobromohydroxymethyljuloline, but as it cannot be recrystallised without decomposition, it was not obtained pure.

α_1-Hydroxy-β_1-bromo-γ_1-methyljuloline, $C_{13}H_{14}NOBr$, is obtained from hydroxymethyldibromojulolidine and from hydroxymethyltribromojulolidine by boiling them with water, when the former loses hydrogen bromide, the latter, bromine. The same decomposition takes place on boiling it with alcohol. It crystallises from dilute alcohol in small, white, lustrous crystals, melts at 80·5° (corr.), and is extremely

soluble in alcohol, ether, acetic acid, benzene, chloroform, and warm light petroleum, sparingly so in water.

α_1-Hydroxy-$\beta_1\beta_1\gamma_1$-tribromo-γ_1-methyljulolidine, $C_{12}H_{14}NOBr_3$, is obtained by allowing a mixture of the preceding compound (1 mol.) and bromine (1 mol.) dissolved in acetic acid to remain for some time. It crystallises in yellowish-red needles, melts about 140° with decomposition, gives off bromine when dried in a desiccator, and also when boiled with water, and is converted into bromhydroxymethyljuloline.

γ-Methyljulolidine is obtained on adding sodium (25 grams) to a boiling solution of ketomethyljuloline (10 grams) in absolute alcohol (250 grams). The mixture is allowed to cool, mixed with water, the alcohol distilled off, and the residue steam-distilled. A pale-yellow oil is obtained which is extracted with ether, the ether partly distilled off, and the remaining liquid dried with potassium carbonate and fractionally distilled. It boils at 283—287° with slight decomposition, has a characteristic, very unpleasant odour, and is very unstable. It is a strong base, and dissolves easily in mineral acids, but the salts are very unstable and were not obtained pure; the solutions of the salts give sparingly soluble and very unstable double salts with salts of the heavy metals. The free base is coloured blood-red by ferric chloride. The *picrate*, obtained on adding an alcoholic solution of picric acid to an alcoholic solution of the base, crystallises in broad, yellow spears, cannot be recrystallised without decomposition, darkens when dried at 100°, and blackens at 130—140°, when it decomposes and partially melts. E. C. R.

Dyes obtained from Ketomethyljuloline and Methyllepidone. By A. Reissert (*Ber.*, **25**, 119—123).—When ketomethyljuloline is treated with phosphorus pentachloride, 3 mols. of the ketone condense, and a violet dye of the formula $C_{39}H_{36}N_3O_3Cl$ is obtained. This loses hydrogen chloride when boiled with sodium hydroxide, and a dye of the formula $C_{39}H_{35}N_3O_3$ is obtained, which differs but slightly from the chlorinated compound. The author names these compounds "julole-violet" and "julole-violet base" respectively. Methyllepidone treated in the same way yields similar derivatives of the formulæ $C_{33}H_{29}N_3O_2Cl_2$ and $C_{33}H_{27}N_3O_2$.

Julole-violet is prepared by mixing ketomethyljuloline (4 grams) with phosphorus pentachloride (3 grams), adding sufficient phosphorus oxychloride to make the mixture damp, and heating it in an oil-bath at 150° until all action has ceased. The phosphorus oxychloride and trichloride are then distilled off, the product dissolved in concentrated hydrochloric acid, the brown solution filtered, diluted with water, and precipitated with sodium hydroxide. The precipitate is washed with a small quantity of water, then dissolved in hot water, and the solution filtered and evaporated to dryness. It is a violet substance having a strong metallic lustre, and is very easily soluble in water, from which it is precipitated on adding sodium hydroxide; it is soluble in alcohol, benzene, and acetic acid with a beautiful violet coloration, and in mineral acids with a brown coloration, but is only sparingly soluble in

light petroleum and ether. It has only one-tenth the dyeing power of the triphenylmethane dyes.

Julole-violet base is obtained by boiling julole-violet with sodium hydroxide. It is a dark-brown, amorphous mass, is only slightly soluble in water, giving a bright, reddish-violet solution easily soluble in alcohol, acetic acid, and mineral acids, and sparingly so in ether. The acetic acid solution imparts a dirty violet shade to textile fibres. The *platinochloride*, $C_{39}H_{35}N_3O_3,H_2PtCl_6$, is obtained as a dark-blue, amorphous powder on adding platinic chloride to a concentrated solution of the base in hydrochloric acid.

Lepidone-violet is obtained in a manner similar to julole-violet by heating equal weights of methyllepidone and phosphorus pentachloride. It has similar properties to julole-violet.

Lepidone-violet base is a dark-brown, amorphous powder, insoluble in water, and has similar properties to the julole compound. The *platinochloride* has the formula $C_{33}H_{27}N_3O_2,H_2PtCl_6$. E. C. R.

Derivatives of Carvole. By O. Wallach (*Ber.*, **24**, 3984—3991).—By reducing carvoxime with sodium amalgam, Goldschmidt obtained a base which he named carvylamine, and to which he assigned the composition $C_{10}H_{15}\cdot NH_2$ (Abstr., 1887, 475); the same compound was prepared by Leuckart and Bach (Abstr., 1887, 376) by distilling carvole with ammonium formate. According to Lampe (*Inaug. Dissert.*, Göttingen, 1889), carvylamine undergoes decomposition on distillation, yielding ammonia and cymene.

The author finds that *dihydrocarvylamine*, $C_{10}H_{17}\cdot NH_2$, is produced when carvole is heated with ammonium formate, the base obtained from dextrocarvole being dextrorotatory, that produced from lævocarvole, lævorotatory; it boils at 94—95° under a pressure of 16 mm., absorbs carbonic anhydride from the air, and has a sp. gr. of 0·889 at 20°. The hydrochloride is precipitated when hydrogen chloride is passed into an ethereal solution of the dextrorotatory base; this salt melts at about 183—184°, and decomposes when heated, yielding an oil and ammonium chloride, without formation of any bye-products. The oil obtained in this way is readily oxidised by potassium permanganate in the cold, and combines directly with bromine; it is optically active, and its sp. gr. is 0·847 at 20°. It consists of a mixture of terpinene and cymene which cannot be separated by fractional distillation; the first-named compound was identified by means of its nitrosite (m. p. 155°). The cymene remains unchanged on treating the oil with potassium permanganate in the cold, whereas the terpinene undergoes oxidation; after distilling with steam, the cymene was oxidised with boiling potassium permanganate solution, its presence being proved by the formation of terephthalic acid and parahydroxyisopropylbenzoic acid. Unless other compounds are present in the original oil, it follows that terpinene can exist in an optically active modification, which is rendered inactive by treatment with acids, and also on conversion into the nitrosite; assuming the correctness of Goldschmidt's formula for carvole, these results lead to the conclusion that terpinene is a true hydrocymene.

Dihydrocarveol, $C_{10}H_{17}\cdot OH$, is obtained when dihydrocarvylamine is

treated with nitrous acid; it boils at 224°, has a sp. gr. of 0·935 at 22°, and its refractive power is $[n]_D = 1·48506$. Dihydrocarveol is also obtained when carvole is reduced with sodium and alcohol; this substance boils at 224—225°, has a sp. gr. of 0·927 at 20°, and its refractive power is $[n]_D = 1·48168$. Whether these two compounds are identical or not has not yet been decided. When dihydrocarveol is boiled with dilute sulphuric acid, it is readily converted into an oil from which large quantities of terpinene nitrosite are obtained on treatment with nitrous acid; the oil seems also to contain cymene.

F. S. K.

Menthylamine. By O. Wallach (*Ber.*, **24**, 3992—3993).—*Menthylamine*, $C_{10}H_{19}·NH_2$, is formed when menthone is heated at 190—200° for some hours with ammonium formate, and the product decomposed with alcoholic potash. It is a colourless oil, of sp. gr. 0·862 at 20°, boils at 208—209°, and rapidly absorbs carbonic anhydride from the air; its refractive power is $[n]_D = 1·46058$. The *nitrate* and the *sulphate* are very readily soluble, but the *oxalate* and the *platinochloride* are only sparingly soluble in water; the *hydrochloride* crystallises well, is stable in the air, and, like the corresponding salts of other saturated bases (bornylamine, fenchylamine), sublimes with only very slight decomposition. The base combines readily with carbon bisulphide and with aldehydes; its *acetyl* derivative, $C_{10}H_{19}·NHAc$, is crystalline.

F. S. K.

Ethyl Camphorates and Isocamphorates. By C. Friedel (*Compt. rend.*, **113**, 825—832).—The author considers that in the camphoric acids there is only one carboxyl group, the second acid function arising from a hydroxyl group attached to a carbon atom which is connected with the carboxyl group, with the CO group of the original camphor, and with a CH_2 group. The carboxyl group is formed by the oxidation of the methyl group in Kekulé's formula, and the COH, CO, and CH_2 groups occupy the positions 1 : 2 : 6 respectively, the corresponding groups in the original camphor being C, CO, and CH. The proximity of the CO group confers on the OH group an acidic function comparable with that of the OH in a carboxyl group. The author shows that this view of the constitution of the camphoric acids makes it possible to explain the existence of dextro- and lævo-gyrate camphoric and isocamphoric acids, in accordance with the Le Bel-Van't Hoff hypothesis. This view is also supported by the formation of camphosulphonic acids in which the COOH group is replaced by HSO_4, a behaviour analogous to that shown by alcohol acids in which the hydroxyl group is attached to the same atom of carbon as the carboxyl group.

Camphoric acid behaves with phenolphthaleïn and methyl-orange in the same way as lactic acid, glycollic acid, &c. Berthelot has shown that the heat of neutralisation of the first acid function by sodium hydroxide is +13·57 Cal., and that of the second 12·9 Cal. The difference between the two acid functions is also shown by the properties of the ethyl salts.

Diethyl camphorate, obtained by the action of ethyl iodide on silver camphorate in presence of alcohol, is an oil boiling at 155° under a

pressure of 12—14 m.m.; sp. gr. at 0° = 1·0495; rotatory power $[\alpha]_D = +37° 42'$. When boiled with alcoholic potash, it yields a *monethyl camphorate*, a very viscous liquid which boils at 207—208° under a pressure of 22 mm. This monethyl camphorate dissolves in alkalis, and is precipitated by acids, whereas the diethyl salt is insoluble in alkalis; its sp. gr. at 0° is 1·1004, and its rotatory power $[\alpha]_D = +23° 54'$

Monethyl camphorate, obtained by the action of hydrogen chloride on an alcoholic solution of camphoric acid, boils at 216—219° under a pressure of 30 mm.; sp. gr. at 0° = 1·1133; rotatory power $[\alpha]_D = +39° 11'$. It is monobasic when phenolphthaleïn is used as the indicator. With aqueous potash, this compound yields alcohol and potassium camphorate, whereas the first monethyl salt, obtained from diethyl camphorate, is not saponified.

Diethyl isocamphorate, prepared from silver camphorate, boils at 165° under a pressure of 25—28 mm.; sp. gr. at 0° = 1·0473; rotatory power $[\alpha]_D = -48° 32'$. When boiled with alcoholic potash, it yields a *monethyl isocamphorate* which is very difficult to purify; it is a very viscous liquid soluble in alkalis. The *monethyl isocamphorate*, obtained by direct etherification, boils at 195—197° under a pressure of 18—20 mm., and is at first a very viscous liquid; sp. gr. at 0° = 1·1156; rotatory power $[\alpha]_D = -49° 31'$. After some time, however, it crystallises, and from alcohol it separates in rectangular octahedra melting at 75°. The fundamental form of the crystals is a rhombic prism of 96° 13′; $b : h = 0·8375 : 1$ and $d : D : h = 0·8971 : 1 : 1·6040$. This ethereal salt, when treated with aqueous potash, is easily saponified, and in this respect differs from the monethyl salt obtained from diethyl isocamphorate. C. H. B.

Digitonin. By H. Kiliani (*Ber.*, **24**, 3951—3954).—In a recent paper (this vol., p. 222), Houdas states that the portion of the digitalis glucosides which is soluble in water, and was termed by Nativelle digitaleïn, consists almost entirely of a single substance, namely, that described by Schmiedeberg and Kiliani as digitonin. The author states that this is not the case, although the alcoholic solution may, as stated by Houdas, be fractionally precipitated by ether without any separation taking place; by suitable means, it may be shown that Schmiedeberg's digitaleïn is really a mixture of 7 or 8 substances, and contains at most 60 per cent. of digitonin.

Houdas also states, without giving any analyses, that the addition of a fatty alcohol to a solution of digitaleïn, causes the precipitation of a crystalline compound containing alcohol of crystallisation. The author finds that this is quite incorrect so far as ethyl alcohol is concerned. Digitonin, after crystallisation from 85 per cent. alcohol, contains 5 mols. H_2O, which are evolved at 110°, leaving a substance of the composition $C_{27}H_{46}O_{14}$; it does not lose more water without undergoing simultaneous decomposition, whence it appears that the formula of digitonin is $C_{27}H_{46}O_{14}$, and not $C_{27}H_{44}O_{13} + H_2O$, as previously stated. The author also replies to the criticisms of Houdas on his formula for digitonin, and maintains the accuracy of his results.

The drug usually sold as "digitalin crist." consists almost entirely of digitonin, which is quite useless for medicinal purposes. Crystallised digitonin does not give a clear solution with 600 parts of cold water, and forms an opalescent solution with 50 parts of warm water; the solutions show the frothing observed by Nativelle and Schmiedeberg even in a dilution of 1 : 2000. H. G. C.

Linamarin. By A. Jorissen and E. Hairs (*Chem. Centr.*, 1891, ii, 702; from *Pharm. Post*, **24**, 659—660).—The authors have found hydrogen cyanide in the distillates from *Arum maculata*, *Ribes aur.*, *Aquilegia vulg.*, *Poa aquatic.*, and especially in the plumules of *Linum usitatissimum*. A glucoside was separated, named by them *linamarin*, which differs essentially from both amygdalin and laurocerasin. Linamarin forms groups of colourless needles having a cool and bitter taste. The analysis gave the following figures:—C = 47·88, H = 6·68, N = 5·55, O = 39·89. Both dilute mineral acids, as also an emulsion of linseed meal, liberate hydrogen cyanide from it. It is very readily soluble in cold water; it does not lose water at 100°, and is not decomposed at 150°; it melts at 34°. It is not coloured by concentrated sulphuric acid; an emulsion of sweet almonds is without influence on it. When it is decomposed, no benzaldehyde is formed. J. W. L.

Oxidation of Brasilin; New Derivative of Resorcinol. By C. Schall and C. Dralle (*Ber.*, **25**, 18—27; see also Abstr., 1888, 295; 1889, 55, 1004; 1890, 996).—Brasileïn, described by the authors in their last communication, readily unites with aluminium, chromium, and zinc to form crystalline lakes; these are best obtained by passing a current of air through an aqueous alkaline solution of brasilin, containing, in addition, a salt of the metal whose lake is required. An iron lake may be obtained in a similar manner, but the presence of alkali is, in this case, unnecessary. The lakes are soluble in alkalis and acids, but insoluble in indifferent solvents.

The tendency of brasilin to yield derivatives of brasileïn is still more prominent in the brominated derivatives; thus, if in the preparation of tribromobrasilin, acetic acid containing more than 10 per cent. of water is used, large quantities of tribromobrasileïn are formed.

The product obtained by the further oxidation of brasileïn, to which the authors ascribed the formula $C_9H_6O_4$ (Abstr., 1889, 55), is soluble in alkalis, and, therefore, probably contains one or more hydroxyl groups; this view has been confirmed by the preparation of the *methyl* and *acetyl* derivatives. The former is obtained by acting on the alcoholic solution of the oxidation product with sodium, subsequently adding methyl iodide, and heating at 100°. After evaporating off the alcohol and methyl iodide, the residue is extracted with ether, unaltered phenols removed by shaking the ethereal solution with dilute soda, the ether distilled off, and the residue recrystallised from alcohol. It separates in yellow scales, which become white on boiling with nitric acid, and melt at 169—170°. The analysis and molecular weight, as found by Raoult's method, and from the vapour

density under diminished pressure, show that its formula is $C_{11}H_{10}O_4$, or $C_9H_4O_2(OMe)_2$. The acetyl derivative, $C_9H_4O_2(OAc)_2$, is obtained by boiling the oxidation product with acetic anhydride and anhydrous sodium acetate, and crystallises from 50 per cent. acetic acid in long, slender, white needles, melts at 148—149°, is insoluble in cold, slightly soluble in hot water, and more readily in warm acetic acid.

The oxidation product gives precipitates with neutral solutions of the salts of many heavy metals, which may, with care, be obtained crystalline. The lead precipitate dissolves in hot, dilute acetic acid, and if soda be added until turbidity commences, the compound $(C_9H_6O_4)_2PbO + H_2O$ separates out in stellate tufts of needles. The phenol also gives substitution products with bromine, of the composition $C_9H_4Br_2O_4$ and $C_9H_3Br_3O_4$. The former crystallises in flesh-coloured, spear-shaped needles melting at 235°, and the latter in transparent, brownish prisms melting at 257—258°.

The above-mentioned dimethyl derivative yields, on oxidation with potassium permanganate and acetic acid, the paramethoxysalicylic acid described by Tiemann and Parisius (Abstr., 1881, 270). The formula of the oxidation product may, therefore, be resolved into $C_6H_3(OH)_2{\cdot}C_3HO_2$ [OH : OH : C_3HO_2 = 1 : 3 : 4]. So far as the group C_3HO_2 is concerned, no very definite conclusions can yet be drawn; the oxygen is not present as hydroxyl or carbonyl, and the authors suggest that it may possibly be a dioxytrimethylene group, $O<\begin{matrix}C-O\\ |\ \ \backslash\ \ |\\ C-\ CH\end{matrix}$. In favour of the view that the oxygen atoms are combined in some such manner, is the observation that in the preparation of the dibromo-derivative a substance is also formed which appears to be an additive compound, $C_9H_6O_4(HBr)_2$; it crystallises in brownish-white needles, and becomes dark-brown at 210°. H. G. C.

Preparation of Flavin. By V. H. Soxhlet (*Chem. Zeit.*, **14**, 1345—1346).—The natural dye flavin is obtained from the bark of the oak by the following method:—The pulverised bark is digested under a pressure of 1—1½ atmospheres with dilute alkali, the extract is then separated from the residual bark by filtration, best with filter presses, the alkali nearly neutralised by the addition of acids or acid salts, and the precipitated flavin collected, dried, and ground. The extractors used are usually of copper, and are arranged in series of five or six, so connected together that the extract can circulate through the series. About 1000 kilos. of bark and 2000—2500 litres of water, with 50—70 grams of soda crystals, is the charge for each extractor. The contents of each extractor is brought to the boil five or six times, for one hour each, and the extract then has a density of 15—17° Be. (1·116—1·135 sp. gr.). Borax or ammonia liquor of 20° Be. (1·161 sp. gr.) are also employed instead of soda. After separating the exhausted bark, the extract is diluted with water, and again boiled with alkali, after which the latter is neutralised. Different acids are used, but a mixture of 2 parts of sulphuric acid and 3 parts of hydrochloric acid is very common. The alkali is nearly neutralised,

and the liquid heated to boiling; it is then filtered rapidly from the precipitated flavin, and the latter dried at a gentle heat and packed in boxes. From 4 to 10 per cent. of the dye is obtained.

J. W. L

Hydroxyxanthones. By S. v. KOSTANECKI and B. NESSLER (*Ber.*, **24**, 3980—3984; compare Abstr., 1891, 1060).—When β-hydroxymethylxanthone is boiled with acetic anhydride and sodium acetate, it is converted into a crystalline *acetyl* derivative,

$$C_{13}H_6O_2Me\cdot OAc,$$

which melts at 127°.

β-Hydroxyxanthone, $C_{13}H_7O_2\cdot OH$, crystallises in colourless needles, melts at 242°, and dissolves in soda with a very slight yellow coloration.

Isoeuxanthone (m. p. 247°) is readily soluble in ammonia; its alcoholic solution gives a brown coloration with ferric chloride. When treated with sodium amalgam, it gives a faintly blood-red solution, which loses its colour after some time, and then yields a red precipitate on acidifying. *Diacetylisoeuxanthone*, $C_{13}H_6O_2(OAc)_2$, crystallises in colourless needles, and melts at 144°.

Hydroxydixanthone, $C_{20}H_{10}O_5$, is obtained, together with smaller quantities of another condensation product, in the preparation of isoeuxanthone by the method already described; it crystallises from glacial acetic acid in yellow plates, melts at 258°, and is only very sparingly soluble in alcohol; it forms an intensely yellow, almost insoluble sodium derivative, and a colourless acetyl derivative. The second condensation product crystallises from glacial acetic acid in yellow plates, does not melt below 320°, and dissolves in concentrated sulphuric acid with a green fluorescence, but is insoluble in soda; it is possibly a trixanthone.

Euxanthone is formed when quinolcarboxylic acid is distilled with resorcinol, but it is not produced from β-resorcylic acid and quinol under like conditions; in view of these facts, it is possible that euxanthone has the constitution represented by the formula

$$\overset{4}{O}H\cdot C_6H_3<\overset{1}{O}\text{-}CO>C_6H_3\cdot\overset{5}{O}H.$$

When salicylic acid is distilled with quinol, a small quantity of a yellow, crystalline compound is obtained; this substance melts above 320°, dissolves in soda with a yellow coloration, and is probably a hydroxyxanthone of the constitution $\overset{4}{O}H\cdot C_6H_3<\overset{1}{O}\text{-}CO>C_6H_4$.

F. S. K.

Base Obtained from Pyridine. By F. v. HEMMELMAYR (*Monatsh.*, **12**, 533—540; compare Abstr., 1891, 1339). When the so-called chloromethyl alcohol of Lösekann (*Chem. Zeit.*, **14**, 1408—1409) is added, drop by drop, to an equal weight of well-cooled pyridine, a reddish-brown oil separates, which, if allowed to remain in the cold, gradually solidifies. The product cannot be purified, owing to its hygroscopic properties and the readiness with which it is resolved into its generators; but it gives well-characterised compounds with various

salts and acids. With mercuric chloride and platinic chloride, it forms respectively the compounds $OH{\cdot}CH_2{\cdot}C_5NH_5Cl,HgCl_2$, which crystallises from hot water in pale-red scales melting at 162°, and $(C_5NH_5,CH_2{\cdot}OH)_2PtCl_6$, which crystallises in beautiful, yellow prisms melting at 216°. With picric acid, the compound

$$OH{\cdot}CH_2{\cdot}C_5NH_5{\cdot}O{\cdot}C_6H_2(NO_2)_3$$

is obtained. It crystallises from hot water in long, yellow prisms, and melts at 200°. The compound with sulphuric acid has not been isolated in the crystalline form, but the compound with nitric acid, $OH{\cdot}CH_2{\cdot}C_5NH_5{\cdot}NO_3$, is obtained in the form of colourless prisms, when its alcoholic solution, prepared by treating the original substance with silver nitrate, is mixed with ether.

The analysis of its compounds leaves no doubt that the condensation product has the formula $C_5NH_5,CH_2Cl{\cdot}OH$, in which the radicles $CH_2{\cdot}OH$ and Cl are probably separately attached to the nitrogen of the pyridine. When heated with potash, or when distilled, the product is resolved into formaldehyde and pyridine; the latter seems also to be one of the products of oxidation by permanganate. Attempts to displace the chlorine by hydroxyl by the use of silver oxide, give rise to the formation of metallic silver and pyridine.

Quinoline also unites with chloromethyl alcohol, but the product has not yet been obtained in quantity sufficient to determine its properties. G. T. M.

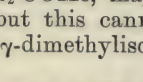
Synthesis of β-Chloroquinaldine. By A. Busch and W. Koenigs (*Ber.*, **24**, 3962—3963).—By the action of butylchloral on aniline in presence of zinc chloride and hydrochloric acid, the authors hoped to obtain γ-methylquinoline or lepidine; instead of this they obtained the β-chloroquinaldine described by Magnanini (Abstr., 1887, 1113), the reaction taking place as follows:—

$$C_6H_4{<}\begin{matrix}H\\NH_2\end{matrix} + \begin{matrix}COH{\cdot}CHCl\\|\\Cl_2CMe\end{matrix} = C_6H_4{<}\begin{matrix}CH{:}CCl\\|\\N{=}CMe\end{matrix} + H_2O + 2HCl.$$

The mixture of butylchloral, aniline hydrochloride, zinc chloride, and hydrochloric acid is heated for eight hours at 160—180°, the product dissolved in hot, dilute sulphuric acid, filtered from resinous matters, and freed from unaltered butylchloral by extraction with ether. The aniline present is converted into phenol by the action of sodium nitrite, and the filtered solution made alkaline, and extracted with ether; the base is then extracted from the ethereal solution by dilute sulphuric acid, the acid solution again made alkaline, and taken up with ether, the latter evaporated, and the residue distilled in a current of steam. The base then passes over in oily drops, which quickly solidify, and on recrystallisation from alcohol forms slender, colourless needles melting at 71—72°. Its *picrate* forms pale-yellow, sparingly soluble needles, and melts at 220—224° with decomposition. The other properties of β-chloroquinaldine were found to be in full agreement with the description given by Magnanini. H. G. C.

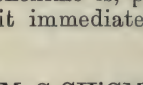
Constitution of Orthohydroxyazo-Dyes. By S. Ganelin and S. v. Kostanecki (*Ber.*, **24**, 3976—3980).—The investigations of Noelting and Trautmann (Abstr., 1891, 325) and of Kostanecki (Abstr., 1891, 579) have shown that derivatives of orthohydroxyquinoline [N : OH = 1′ : 1] have the property of dyeing mordanted cotton only as long as the hydroxyl group in the 1-position remains unchanged; Matheus' phenylazorthohydroxyquinoline (Abstr., 1888, 851), as was to be expected, obeys this rule.

Metaphenylazorthohydroxymethylquinoline,



$$C_9NH_4Me(OH)\cdot N_2Ph\ [Me : OH : N_2Ph = 4 : 1 : 2],$$

can be prepared by treating a hydrochloric acid solution of orthohydroxymethylquinoline with a solution of diazobenzene chloride and then pouring the mixture into dilute alkali. It crystallises from acetic acid in carmine-red needles, melts at 120°, and is only very sparingly soluble in boiling water and hot alkalis, but soluble in concentrated sulphuric acid with a yellowish-red coloration. The fact that this compound has the property of dyeing mordanted cotton is strong evidence that it is an azo-compound and not a hydrazone.



Metamidorthohydroxymethylquinoline, $C_9NH_4Me(OH)\cdot NH_2$, is obtained when the preceding compound is treated with tin and hydrochloric acid; it is also formed when the metanitrosoorthohydroxymethylquinoline described by Noelting and Trautmann is treated in like manner. It separates from benzene, in which it is very readily soluble, in large, broad crystals melting at 139°. The *hydrochloride*, $C_{10}N_2H_{10}O,HCl$, crystallises from hot water in long, red prisms.

F. S. K.

Isoxazoles. By L. Claisen (*Ber.*, **25**, 3900—3918).—This paper contains a general sketch of the various classes of isoxazoles, isoxazolecarboxylic acids, and di isoxazoles, prepared by the author and his collaborators by the action of hydroxylamine on β-diketones and analogous compounds. Further, a slight change is proposed in the nomenclature adopted by Hantzsch for the positions in the isoxazole ring and in other similar rings. As an example of the formation of an isoxazole, the action of hydroxylamine on acetylacetone, $COMe\cdot CH_2\cdot COMe$, may be taken; a monoxime is, presumably, first formed, but this cannot be isolated; it immediately loses water, forming αγ-dimethylisoxazole:—

Acetylacetone monoxime.

αγ-Dimethylisoxazole.

The ketone is dissolved in acetic acid and heated with hydroxylamine hydrochloride for 1—2 hours on the water-bath until it no longer gives a red colour with ferric chloride; the product is then diluted with water, made alkaline with soda, and the isoxazole extracted with ether. The yield varies from 50 to 80 per cent. of the ketone used.

Dunstan and Dymond (Trans., 1891, 410) have shown that when the trimethylisoxazole obtained by the action of alkalis on nitroethane

is reduced with sodium, it yields a compound $C_6H_{11}NO$. They assume that this compound has a ring structure, and, on this assumption, base an argument that the β-diketones are ring compounds. This view is controverted by the author, who, by the reduction of $\alpha\gamma$-dimethylisoxazole with sodium, obtained a substance identical with that formed when ammonia acts on acetylacetone. He also, in a similar manner, obtained Dunstan and Dymond's compound by acting on methylacetylacetone, COMe·CHMe·COMe, with ammonia; this compound has then the constitution COMe·CHMe·CMe:NH or COMe·CMe:CMe·NH_2, and is not a ring compound. Consequently there is no reason to suppose that a β-diketone has a ring structure either. C. F. B.

Dimethyldiazine. By C. Stoehr (*Ber.*, **24**, 4105—4110; compare Abstr., 1891, 581).—Dimethyldiazine, $C_4N_2H_2Me_2$, has been previously described; it boils at 153—153·5° under a pressure of 752·5 mm. The *hydrochloride*, $C_6H_8N_2$,HCl, crystallises from absolute alcohol in colourless needles, and is very readily soluble in water. The *picrate* is deposited from water in flat, lustrous needles melting at 142—143°. The *nitrate*, *sulphate*, and *chromate* readily dissolve in water. *Dimethyldiazine methiodide*, $C_6H_8N_2$,MeI, is formed at ordinary temperatures from dimethyldiazine and methyl iodide, and crystallises from absolute alcohol in pale-yellow prisms which melt at 230°; it yields a *periodide* crystallising in reddish-brown needles, and also a colourless, crystalline double salt with cadmium iodide. The corresponding *methochloride* is very soluble in water, and yields crystalline salts with platinic chloride, auric chloride, and mercuric chloride.

Dimethyldiazine combines with anhydrous bromine with evolution of heat; the product is crystalline and decomposes at 170°; in aqueous solution, a second additive compound is formed, which crystallises in long needles and undergoes dissociation at ordinary temperatures.

Diazinedicarboxylic acid, $C_4N_2H_2(COOH)_2 + 2H_2O$, is prepared by the oxidation of the base with potassium permanganate, and melts at 255—256°, not at 250° as previously stated; it is soluble in dilute mineral acids, and resembles the α-pyridinecarboxylic acids in its colour reactions. The *ammonium salt* crystallises from alcohol in needles; the *silver salt* is amorphous; the *barium salt* is deposited in colourless, lustrous plates; the *calcium* and *lead salts* are also crystalline.

Hexahydrodimethyldiazine, $C_6N_2H_{14}$, is obtained by the reduction of the diazine with sodium in alcoholic solution; it is volatile with steam and miscible with water in all proportions, but is precipitated as a colourless oil on the addition of potash; it combines with sodium and potassium hydroxides and also with barium dioxide, and is insoluble in ether. The *hydrochloride*, $C_6N_2H_{14}$,2HCl, is deposited from water in large, lustrous crystals, and from alcohol in colourless needles which decompose above 300°. The *platinochloride*, $C_6N_2H_{14}$,$H_2PtCl_6 + 3H_2O$, crystallises in long prisms; the *aurochloride* is crystalline; and the *mercurochloride* readily soluble in water. The *picrate* is deposited in small, lustrous, yellow needles which decompose without melting. The *dinitrosamine*, $C_6N_2H_{12}(NO)_2$, is obtained by the action

of sodium nitrite on the hydrochloride, and crystallises from alcohol in long, colourless, lustrous, prismatic needles melting at 170—171° the compound gives a blue colour with phenol and sulphuric acid.

J. B. T.

Biazolones. By M. Freund and others (*Ber.*, **24**, 4178—4204; compare Freund and Kub, Abstr., 1890, 1440).—*β-Naphthylmethylbiazolone*, $C_{10}H_7\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot O\end{matrix}$, is obtained by heating acetylnaphthylhydrazine (m. p. 167°) with an excess of carbonyl chloride dissolved in toluene, in a sealed tube at 100° for 2—3 hours, and, after evaporating the solvent, crystallising the product several times from dilute alcohol; it forms white, silky needles, melts at 125°, and is readily soluble in alcohol, ether, benzene, and chloroform, but almost insoluble in water.

β-Naphthylmethyl-ψ-thiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=CMe\\ |\\ CS\cdot O\end{matrix}$, is prepared by boiling acetylnaphthylhydrazine with an excess of thiocarbonyl chloride dissolved in benzene in a reflux apparatus, and, after allowing the solvent to evaporate, repeatedly crystallising from alcohol with the addition of animal charcoal; it crystallises in small, faintly yellow, lustrous needles, melts at 109°, and is somewhat sparingly soluble in boiling water.

Phenyl-β-naphthylthiosemicarbazide, $C_{10}H_7\cdot N_2H_2\cdot CS\cdot NHPh$, obtained by mixing molecular proportions of naphthylphenylhydrazine and phenylthiocarbimide dissolved in alcohol, crystallises from alcohol in white leaflets, melts at 202°, and is readily soluble in alcohol and chloroform, sparingly in benzene and ether, and insoluble in water.

β-Naphthylanilidothiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NHPh\\ |\\ CO\cdot S\end{matrix}$, is produced by allowing finely-powdered phenyl-β-naphthylthiosemicarbazide to remain in a closed flask with an excess of carbonyl chloride dissolved in toluene at the ordinary temperature for 24 hours, shaking at intervals; the solvent is allowed to evaporate, the residue extracted with alcohol to remove the unaltered carbazide, and crystallised from benzene; it forms white, flocculent crystals, melts at 198—199°, and is almost insoluble in water, sparingly soluble in alcohol and ether, but readily so in benzene and chloroform.

β-Naphthylamidobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NH_2\\ |\\ CO\cdot O\end{matrix}$, prepared in the same manner as the last-mentioned compound from β-naphthylsemicarbazide and carbonyl chloride, crystallises from alcohol in small, almost white, prismatic needles, melts at 227°, is sparingly soluble in ether and benzene, and insoluble in water and chloroform.

β-Napthylamidothiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NH_2\\ |\\ CO\cdot S\end{matrix}$, is obtained in the form of yellowish leaflets by shaking β-napthylthiosemicarbazide with a solution of carbonyl chloride, allowing the solvent to evaporate, and repeatedly crystallising from alcohol; it melts at 220°,

and is readily soluble in alcohol, chloroform, and benzene, but insoluble in water and ether.

Oxalyl-β-naphthylhydrazine, $C_2O_2(N_2H_2\cdot C_{10}H_7)_2$ (?), is formed when β-naphthylhydrazine and ethyl oxalate are boiled together in molecular proportion; after adding absolute alcohol and allowing the product to cool, reddish-brown crystals separate, which are dried on a porous plate and extracted with absolute alcohol, when the compound, which is insoluble in ordinary solvents and melts at 277°, remains; whilst *ethyl oxalate β-naphthylhydrazide*, $C_{10}H_7\cdot N_2H_2\cdot CO\cdot COOEt$, separates on allowing the alcoholic filtrate to remain; this melts at 159°, and is almost insoluble in water. When the last-mentioned compound is dissolved in alcohol, and alcoholic potash added, the potassium salt of the corresponding acid separates, and the *acid* is precipitated on adding concentrated hydrochloric acid to its solution in a little water; it forms small, white needles, melts at 202°, and is readily soluble in glacial acetic acid, very sparingly in benzene, chloroform, and ether, and insoluble in water.

Acetyl-α-naphthylhydrazine, $C_{10}H_7\cdot N_2H_2Ac$, prepared by mixing the dried base (m. p. 115—116°) with an excess of acetic anhydride, crystallises from dilute alcohol in colourless needles, melts at 143°, and is sparingly soluble in hot water.

α-Naphthylmethylbiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot O\end{matrix}$, is obtained by heating the last-mentioned compound with an excess of carbonyl chloride dissolved in toluene in a sealed tube at 100° for about two hours; it crystallises from alcohol in colourless needles, melts at 89°, and is insoluble in water.

α-Naphthylmethyl-ψ-thiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=CMe\\ |\\ CS\cdot O\end{matrix}$, is produced by dissolving acetyl-α-naphthylhydrazine in chloroform (10 parts) and boiling it for an hour with the gradual addition of a slight excess of thiocarbonyl chloride; the solvent is allowed to evaporate, the residue repeatedly redissolved in chloroform, and precipitated with light petroleum, and finally crystallised from dilute alcohol, when it separates in bright-yellow needles, melts at 86°, and is readily soluble in alcohol and benzene, sparingly in ether, and insoluble in light petroleum and water.

Benzoyl-α-naphthylhydrazine, $C_{10}H_7\cdot N_2H_2Bz$, separates as a yellowish precipitate on adding the calculated quantity of benzoic chloride to a cooled solution of α-naphthylhydrazine dissolved in ether (10 parts); after washing with water, it is crystallised from dilute alcohol, and forms needles, melts at 184°, and is readily soluble in alcohol, ether, and benzene, but insoluble in water and light petroleum.

α-Naphthylphenylbiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=CPh\\ |\\ CO\cdot O\end{matrix}$, is prepared by heating the last-described benzoyl derivative with an excess of carbonyl chloride dissolved in toluene in a sealed tube at 100° for an hour, decanting the clear, brown solution from the accompanying resin, allowing it to evaporate, and crystallising the residue first from benzene and afterwards from alcohol; it forms colourless, felted

needles, melts at 136°, is readily soluble in ether and light petroleum, but insoluble in water, and is not decomposed by boiling with sodium hydroxide solution.

α-Naphthylphenyl-ψ-thiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=CPh\\ CS\cdot O\end{matrix}$, is obtained by gradually adding the calculated quantity of thiocarbonyl chloride to benzoyl-α-naphthylhydrazine dissolved in chloroform (10 parts), heating in a reflux apparatus until the evolution of hydrogen chloride ceases, allowing the solution to evaporate, redissolving the residue in chloroform, shaking with light petroleum to precipitate the resinous substances, again evaporating, and crystallising from dilute alcohol, when it separates in colourless needles, melts at 164°, and is insoluble in water.

α-Naphthylthiocarbizine, $C_{10}H_7\cdot N<\begin{matrix}CS\\ NH\end{matrix}$, is prepared by heating α-naphthylthiosemicarbazide (see below) (10 grams) with 20 per cent. hydrochloric acid (30 c.c.) in a sealed tube at 130° for 12 hours, washing the crude melt with water, boiling it with water and animal charcoal, and adding concentrated hydrochloric acid to the filtrate, whereby the hydrochloride is precipitated in white needles melting at 230°; it yields the free base when treated with sodium carbonate solution; the latter crystallises from alcohol in colourless needles, melts at 184—185°, does not reduce Fehling's solution, gives a violet colour with bleaching powder and sulphuric acid, and is almost insoluble in water. The *acetyl* derivative, $C_{10}H_7\cdot N<\begin{matrix}CS\\ NAc\end{matrix}$, crystallises from alcohol in long, colourless needles, and melts at 283°; the *benzoyl* derivative separates from benzene in almost colourless crystals, and melts at 175—176°.

α-Naphthylamidobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NH_2\\ CO\cdot O\end{matrix}$, is produced by allowing α-naphthylsemicarbazide (Pinner, *Ber.*, **20**, 2358) to remain with an excess of carbonyl chloride dissolved in toluene in a closed vessel for 24 hours with frequent shaking; it crystallises from alcohol in colourless leaflets which become brown in the air, melts at 212°, and is insoluble in water.

α-Naphthylamido-ψ-thiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NH_2\\ CS\cdot O\end{matrix}$, is obtained by heating α-naphthylsemicarbazide with thiocarbonyl chloride in molecular proportion together with benzene in a closed vessel at 80° for half an hour, and then keeping the mixture at a moderate temperature for 12 hours; it crystallises from alcohol in microscopic, yellowish needles, melts at 218°, and is insoluble in water, ether, and carbon bisulphide.

α-Naphthylthiosemicarbazide, $C_{10}H_7\cdot N_2H_2\cdot CS\cdot NH_2$, is prepared by boiling ammonium thiocyanate and α-naphthylhydrazine hydrochloride (equal weights) with 2½ times the weight of absolute alcohol for 15 hours, collecting, washing with water, and crystallising from

alcohol, when it separates in colourless, hexagonal tablets, melts at 209°, and is insoluble in ether, chloroform, and water.

α-Naphthylamidothiobiazolone, $C_{10}H_7N<\begin{matrix}N=C\cdot NH_2\\ CO\cdot S\end{matrix}$, formed when the last-described compound is mixed with an excess of carbonyl chloride dissolved in toluene and the mixture kept in a closed vessel with frequent shaking for 48 hours, is a white, amorphous compound almost insoluble in the ordinary solvents, and melts at 250°.

α-Naphthylphenylthiosemicarbazide, $C_{10}H_7\cdot N_2H_2\cdot CS\cdot NHPh$, separates when an alcoholic solution of α-naphthylhydrazine and phenylthiocarbimide (equal mols.) is boiled for a quarter of an hour; it crystallises from benzene or dilute alcohol in white, felted needles, melts at 135°, and is insoluble in water and light petroleum.

α-Naphthylanilidothiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=NHPh\\ CO\cdot S\end{matrix}$, prepared by mixing the last-described compound with an excess of carbonyl chloride dissolved in toluene and allowing the mixture to remain for several hours, crystallises from alcohol in colourless needles, melts at 219°, is very readily soluble in acetone, but insoluble in ether and water.

α-Naphthylanilidodithiobiazolone, $C_{10}H_7\cdot N<\begin{matrix}N=C\cdot NHPh\\ CS\cdot S\end{matrix}$, is obtained by gradually adding thiocarbonyl chloride in molecular proportion to a cooled solution of phenylthiocarbimide in benzene (10 parts), and finally heating for a while on the water-bath; it separates from alcohol in small crystals, melts at 255° with decomposition, and is insoluble in water, benzene, and light petroleum.

Ethyl oxalate α-naphthylhydrazide, $C_{10}H_7\cdot N_2H_2\cdot CO\cdot COOEt$, is formed by boiling an alcoholic solution of α-naphthylhydrazine and ethyl oxalate (equal mols.) for two hours, evaporating on the water-bath, collecting the reddish-brown oil, and treating it with ether; the crystals which separate are repeatedly recrystallised from benzene, when it is obtained in small, colourless needles, melts at 163°, and is insoluble in water and ether. It does not react with carbonyl chloride at the ordinary temperature, and when heated with it, a viscid, yellow resin is produced.

The *compounds* $NPh<\begin{matrix}N=C\cdot[CH(OH)]_2\cdot C=N\\ CO\cdot O\qquad\qquad O\cdot OC\end{matrix}>NPh$ and

$$NPh<\begin{matrix}N=C\cdot CH(OH)\cdot CH_2\cdot C=N\\ CO\cdot O\qquad\qquad O\cdot OC\end{matrix}>NPh$$

are obtained by heating tartaric and malic diphenylhydrazides (Bülow, Abstr., 1887, 138) with a solution containing an excess of carbonyl chloride in a sealed tube for two hours at 130°; the former melts at 182° and the latter at 199°, and both are insoluble in water.

Paratolylthiocarbazinic paratolylhydrazide,

$$C_6H_4Me\cdot N_2H_2\cdot CS\cdot SH, C_6H_4Me\cdot N_2H_3,$$

separates when carbon bisulphide is added to an ethereal solution of paratolylhydrazine; it is washed with ether and dried in a vacuum, when it melts at 109°. If the last-mentioned compound is heated in a porcelain dish with frequent stirring at 110°, hydrogen sulphide and ammonia are evolved and *paraditolylthiocarbazide*, $CS:(N_2H_2\cdot C_6H_4Me)_2$, is formed; this crystallises from benzene in white leaflets, melts at 121°, and, on heating with alcoholic potash, gives *paraditolylthiocarbazone*, $C_6H_4Me\cdot N_2\cdot CS\cdot N_2H_2\cdot C_6H_4Me$, a colouring matter which is precipitated on acidifying the solution, and when pure forms dark-brown, amorphous flocks; it melts at 105°, and its solutions in ether, benzene, and chloroform show a beautiful red and green fluorescence.

Paratolylazoparatolylthiobiazolone, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N_2\cdot C_6H_4Me\\ CO\cdot S\end{matrix}$, is prepared by dissolving the last-described colouring matter in benzene, dropping in a solution of carbonyl chloride in the same solvent until the colour is destroyed, and evaporating on the water-bath; it crystallises from alcohol in yellow, felted needles, and melts at 170°. The *hydrazo*-derivative, $C_6H_4MeN<\begin{matrix}N=C\cdot N_2H_2\cdot C_6H_4Me\\ CO\cdot S\end{matrix}$, is obtained by suspending the azo-compound in alcohol, adding alcoholic ammonia, and passing a current of hydrogen sulphide for 10 minutes, when it is precipitated after a while in white needles; after washing with water and crystallising from alcohol, it melts at 168°, being reconverted into the azo-compound when its alcoholic solution is boiled with ferric chloride.

Paratolylazotolyldithiobiazolone, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N_2\cdot C_6H_4Me\\ CS\cdot S\end{matrix}$, is formed when thiocarbonyl chloride is added to a solution of paraditolylthiocarbazone in benzene; it crystallises from benzene in red, felted needles, melts at 237—238°, and is insoluble in water. The hydrazo-derivative, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N_2H_2\cdot C_6H_4Me\\ CS\cdot S\end{matrix}$, produced by boiling its alcoholic solution with aqueous ammonium sulphide, forms white leaflets, and melts at 155°.

Paraditolylcarbazide, $CO(N_2H_2\cdot C_6H_4Me)_2$, prepared by boiling paratolylhydrazine (2 mols.) with ethyl carbamate (1 mol.), crystallises from alcohol in rhombic tablets, melts at 201°, and is insoluble in water.

Paratolylazoparatolyl-ψ-thiobiazolone,

$$C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N:N\cdot C_6H_4Me\\ CS\cdot O\end{matrix},$$

obtained by gradually adding the calculated quantity of thiocarbonyl chloride to a boiling solution of the last-described compound in benzene, and heating for an hour, crystallises from benzene in yellow needles, melts at 215°, and is very sparingly soluble in alcohol.

Ethyl oxalate paratolylhydrazide, $C_6H_4Me\cdot N_2H_2\cdot CO\cdot COOEt$, produced by boiling molecular proportions of paratolylhydrazine and ethyl

oxalate in alcoholic solution, separates, on cooling, in leaflets, and when crystallised from alcohol or benzene, melts at 133°.

Ethyl paratolylbiazolonecarboxylate, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot COOEt\\ CO\cdot O\end{matrix}$, is formed by heating the last-described compound with carbonyl chloride (1 mol.) dissolved in benzene, at 100° for an hour; it is very soluble in boiling alcohol, and separates from it in prisms, but is almost insoluble in the cold liquid, and melts at 83°.

Ethyl phenylbiazolonecarboxylate, $NPh<\begin{matrix}N=C\cdot COOEt\\ CO\cdot O\end{matrix}$, is formed by treating ethyl oxalate phenylhydrazide (Bülow, *loc. cit.*) with carbonyl chloride; it crystallises from absolute alcohol in prisms, and melts at 87°.

β-Dinaphthylthiocarbazide, $CS(N_2H_2\cdot C_{10}H_7)_2$, is prepared in the same manner as the above-described ditolylthiocarbazide, from naphthylthiocarbazinic naphthylhydrazide (Hauff, Abstr., 1890, 61); it crystallises from benzene in needles, melts at 137—140°, and is insoluble in water; alcoholic potash converts it into the *carbazone*.

Orthotolylthiocarbazinic orthotolylhydrazide, $CS_2(N_2H_3\cdot C_6H_4Me)_2$, is obtained by adding the calculated quantity of carbon bisulphide to an ethereal solution of orthotolylhydrazine (m. p. 53°), when it separates in white crystals, and is washed with ether; it decomposes at 82°, leaving a residue which melts at 102—103°. *Diorthotolylthiocarbazide*, $CS(N_2H_2\cdot C_6H_4Me)_2$, is formed by heating the last-described compound at 90°, and crystallising the product from dilute alcohol, when it is obtained in small, white, felted needles; it becomes green at 120°, melts at 129—130° with decomposition, and is insoluble in water. Both of the last-described compounds resemble the phenyl derivatives (E. Fischer, Abstr., 1878, 308). *Diorthotolylthiocarbazone*,

$$C_6H_4Me\cdot N_2\cdot CS\cdot N_2H_2\cdot C_6H_4Me,$$

is produced by heating the carbazide with alcoholic potash for 20 minutes, diluting, and neutralising, whereby it is precipitated; it is dissolved in chloroform, and methyl alcohol added, when it separates; when quite pure it melts at 168°, dissolving in concentrated sulphuric acid with a bluish-green colour.

Orthotolylazorthotolylthiobiazolone, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N_2\cdot C_6H_4Me\\ CO\cdot S\end{matrix}$, is formed by slowly adding carbonyl chloride dissolved in toluene to a cooled solution of the last-described compound in benzene (5 parts); after purification, it crystallises from dilute alcohol in reddish-brown needles, melts at 144°, and is insoluble in water. The *hydrazo*-compound is formed by dissolving the azo-derivative in absolute alcohol, adding saturated alcoholic ammonia, and passing dry hydrogen sulphide through the cold solution; it crystallises from absolute alcohol in colourless prisms, and melts at 159—160°.

Orthotolylazorthotolyldithiobiazolone, $C_6H_4Me\cdot N<\begin{matrix}N=C\cdot N_2\cdot C_6H_4Me\\ CS\cdot S\end{matrix}$, is obtained by cautiously adding a solution of thiocarbonyl chloride to one of diorthotolylthiocarbazone in the same solvent cooled by ice; it

forms, when pure, yellowish-red, silky needles, melts at 155°, and is soluble in alcohol, benzene, and ether. The corresponding *hydrazo*-derivative crystallises in colourless, microscopic tablets, and melts at 180—184°. A. R. L.

Quinine Hydrochlorides. By O. Hesse (*Annalen*, **267**, 142—144).—Quinine hydrochloride crystallises in long needles having the composition $C_{20}H_{24}N_2O_2,HCl + 2H_2O$, and also in large octahedra having the composition $2C_{20}H_{24}N_2O_2,HCl + 3H_2O$; the needle-shaped crystals lose their water at 120°, the anhydrous salt melting at 158—160°. The acid salt of the composition $C_{20}H_{24}N_2O_2,2HCl$ is easily prepared by adding the theoretical quantity of hydrochloric acid to a solution of the normal salt; on evaporating at a moderate temperature, the anhydrous salt is partly deposited in needles, partly as a gelatinous mass. F. S. K.

Action of Hydriodic Acid on Cinchonine. By G. Pum (*Monatsh.*, **12**, 582—588; compare Lippmann and Fleissner, this vol., p. 81, and Skraup, this vol., p. 83).—The author has obtained the compound $C_{19}H_{22}N_2O,3HI$ by warming cinchonine (30 grams) with colourless hydriodic acid (150 grams) of sp. gr. 1·7 for four hours on a water-bath. On cooling, a mass of yellow crystals was obtained, and this was further purified by recrystallisation from alcohol. The compound evolves vapours of iodine at 223°, and melts at 230°, whilst, on treatment with alcoholic ammonia, only 1 mol. of hydriodic acid is eliminated (compare Lippmann and Fleissner, Abstr., 1891, 1517). The resulting compound, dihydriodocinchonine,

$$C_{19}H_{22}N_2O,2HI,$$

crystallises from alcohol in nearly colourless needles which turn yellow on exposure to light, melts at 187—190°, and combines with with nitric and sulphuric acids, forming the crystalline compounds $C_{19}H_{22}N_2O,2HI,HNO_3$ and $(C_{19}H_{22}N_2O,2HI)_2,H_2SO_4$ respectively. Alcoholic soda converts dihydriodocinchonine into cinchonine and another base, probably isocinchonine, whilst silver nitrate decomposes it with formation of cinchonine alone. G. T. M.

Sulphonic Acids of Cinchona Alkaloïds. By O. Hesse (*Annalen*, **267**, 138—142).—When quinine, conchinine, cinchonidine, and cinchonine are separately treated with anhydrosulphuric acid, they are first converted into the corresponding iso-bases, and then into sulphonic acid derivatives of the latter.

Isoquininesulphonic acid, $C_{20}H_{23}N_2O_2{\cdot}SO_3H$, is readily soluble in water; the solution is strongly lævorotatory, shows a blue fluorescence, and gives an intense dark-green coloration with chlorine and excess of ammonia. The *platinochloride* is readily soluble; the *aurochloride*, $3C_{20}H_{23}N_2O_2{\cdot}SO_3H,HAuCl_4$, is a yellow, flocculent compound.

Isoconchininesulphonic acid resembles the preceding compound in all respects, except that its aqueous solution is feebly dextrorotatory.

Isocinchonidinesulphonic acid, $C_{19}H_{21}N_2O{\cdot}SO_3H$, is dextrorotatory in

aqueous solution; the *aurochloride*, $C_{19}H_{21}N_2O\cdot SO_3H,HAuCl_4$, is a yellow compound, readily soluble in dilute hydrochloric acid.

Isocinchoninesulphonic acid is readily soluble in water; its *aurochloride* has the composition $C_{19}H_{21}N_2O\cdot SO_3H,HAuCl_4 + 2H_2O$.

Quininesulphonic acid, $C_{20}H_{23}N_2O_2\cdot SO_3H$, is obtained in the form of its sulphate, when quinine tetrasulphate is moistened with acetic anhydride; it crystallises in colourless prisms, and is only sparingly soluble in hot water, but more readily in hot alcohol. The air-dried substance contains 1 mol. H_2O, which is expelled at 120°, the anhydrous compound melting at 209°. The *platinochloride*,

$$(C_{20}H_{23}N_2O_2\cdot SO_3H)_2,H_2PtCl_6 + 8H_2O,$$

crystallises in needles.

Cinchonidinesulphonic acid, $C_{19}H_{21}N_2O\cdot SO_3H + H_2O$, prepared in like manner, crystallises in small, colourless needles, melts at 225°, and is only sparingly soluble in hot water and alcohol, and insoluble in ether. The *platinochloride*, $(C_{19}H_{21}N_2O\cdot SO_3H)_2,H_2PtCl_6 + 3H_2O$, crystallises in orange needles. F. S. K.

Crystalline Egg Albumin. By F. Hofmeister (*Zeit. physiol. Chem.*, **16**, 187—191; compare Abstr., 1890, 182; 1891, 476, 1122).—These crystals are practically free from ash if adherent ammonium sulphate which has been used in preparing them is carefully washed away. They have the following percentage composition :—C, 53·28; H, 7·26; N, 15·00; S, 1·09; O, 23·37. W. D. H.

Decomposition of Albumin. By E. Drechsel (*Chem. Centr.*, 1891, ii, 712; from *Arch. Physiol.*, 1891, 248—265).—The author finds that the bases which he obtained from caseïn and described as having the formulæ $C_7H_{12}N_2O_2$ and $C_8H_{14}N_2O_2$ are in fact identical, and that the substance has the formula $C_6H_{14}N_2O_2$. The base is isomeric with diamidocaproic acid, and forms two hydrochlorides, the one containing two, the other only one molecule of hydrogen chloride. The former has a strongly acid reaction on litmus, whilst the latter behaves as a neutral substance. (See also Abstr., 1891, 95.) J. W. L.

Physiological Chemistry.

Nasse's Experiments on the Excitability of Frog Muscle in Salt Solutions. By G. Tammann (*Zeit. physikal. Chem.*, 8, 685—689).—Nasse found that frog muscle retained its sensibility to electric stimulation longer in a 0·6 per cent. solution of sodium chloride than in stronger or weaker solutions. The same phenomenon occurred in the case of other salt solutions. The author finds that the solutions of various salts most favourable for the preservation of the excitability

are of such strengths that they have equal osmotic pressures. Favourable solutions of other salts have, some greater, some, smaller, osmotic pressures. Probably the excitability is due to a definite turgor in the muscle cells. J. W.

Digestion of Starch by Dogs. By Ellenberger and Hofmeister (*Chem. Centr.*, 1891, ii, 713—715; from *Arch. Physiol.*, 1891, 212—296).—The authors have made a series of experiments with a view of determining the rapidity of the digestion of starch by dogs. The animals (dogs) were fed on known quantities of boiled rice, the percentage of starch in which had been determined, whilst pigs were fed on potatoes, for comparison's sake. At different intervals, after being fed, the animals were killed, and the contents of the stomachs examined for starch, dextrin, and sugar. The results obtained show that the dog digests boiled rice starch much more rapidly than the pig does either potato starch or boiled meat. Moreover, the dog was found to digest the rice starch at first more slowly, and later much more rapidly, than it digests boiled meat. These experiments explain too why hunger is experienced so much sooner after a meal of boiled rice than after a meal of boiled meat.

In none of the eleven experiments in which dogs were fed on rice, could any sugar be detected in the contents of the stomach, and the authors conclude that this is owing principally, on the one hand, to the fact that dogs swallow their food without giving much opportunity for the saliva to pass into the stomach, whilst on the other hand, the food, having been boiled, would contain no diastase; the formation of sugar from starch in the stomach being attributed by the authors to the action of these two ferments.

The acidity of the stomach contents was also determined, and it was found that the left division contained less acid than the middle or right divisions; the amount of hydrogen chloride in the left division was very small. The total acidity of the dog's stomach when fed on cereal food is distinctly greater than that of the horse, the pig, or ruminants. Towards the conclusion of the digestion, the total acidity diminishes again. J. W. L.

The Intake of Iron by the Fœtus. By G. Bunge (*Zeit. physiol. Chem.*, **16**, 173—186).—The small percentage of iron in milk, compared to that in the body of young animals, has led previously (Abstr., 1889, 789) to the conclusion that the fœtus receives a store of iron through the maternal placenta previous to birth. This contention is supported by further analyses. The proportionally large percentage of iron in the fœtus gradually sinks as the animal grows, until it reaches the normal level; after this time, milk is no longer a suitable diet, and unless the milk is supplemented by substances rich in iron, such as vegetables, the animal becomes anæmic. W. D. H.

The Presence of Cystin and Xanthine in the Horse's Liver. By E. Drechsel (*Chem. Centr.*, 1891, ii, 712; from *Arch. Physiol.*, 1891, 243—247).—The author has detected cystin and

another substance in horse's liver. The latter is either xanthine or a substance of the formula $C_{24}H_{20}N_{18}O_{10}$. The author suggests that the changes of the sulphur compounds play an important part in the horse's liver, in support of which theory is mentioned the presence of crystals of sulphur, which he has noticed while separating jecorin. J. W. L.

Variations in Glycolytic and Saccharific Powers of Blood in Asphyxial Hyperglycæmia and Diabetes. Localisation of the Saccharific Ferment. By R. Lépine and Barral (*Compt. rend.*, **132**, 1014—1015).—The authors have previously shown that the glycolytic power of dog's blood is diminished by asphyxia (Abstr., 1890, 1172); they now find that it is altogether destroyed if the asphyxia is extended over at least three-quarters of an hour by supplying small quantities of air to the animal. The saccharific power of both the blood and the urine is diminished under these conditions, although it is increased by rapid asphyxia. The glycolytic and saccharific powers of the blood are increased in the artificial diabetes brought about by the injection of phloridzin into the circulation (Abstr., 1890, 1336), and the saccharific power of the urine is also increased in this state, although in ten cases of natural diabetes it suffered a more or less notable diminution.

The saccharific ferment exists in the serum, and not in the white corpuscles, as is the case with the glycolytic ferment; this explains the ease with which it passes into the urine. Jn. W.

Formation of Glucose and Lactic Acid. By T. Araki (*Zeit. physiol. Chem.*, **16**, 201—204; compare Abstr., 1891, 1125, 1392; this vol., 362).—The claim of A. Dastre to priority in connection with this subject is disputed. W. D. H.

Analyses of Human Milk. By J. Szilasi (*Chem. Zeit.*, **14**, 1202—1203).—The author has analysed 36 samples of human milk, and tabulated the results. As an instance how the milk may vary in quality the following two analyses may be quoted:—*Milk No.* 31: sp. gr. 1·0329; fat, 1·00; sugar, 7·35; proteïds, 1·26; ash, 0·20; total solids, 9·81. The mother's age was 30; she had her fourth child; was of strong constitution, and gave plenty of milk. The child was 8 months old, and its average daily increase in weight was 50 grams. *Milk No.* 35: sp. gr. 1·0318; fat, 4·13; sugar, 7·14; proteïds, 1·99; ash, 0·19; total solids, 13·45. The mother's age was 25; she had her first child; a weak constitution, and but little milk. The child was 20 days old, and its daily increase in weight 20 grams.

The analyses were all done by Ritthausen's process, which the author has slightly modified as follows:—

10 grams of milk is diluted up to 200 c.c., and then mixed with 5 c.c. of solution of cupric sulphate (103·92 grams per litre). Sodium hydroxide (1·018 sp. gr.) is now carefully added until the fluid is almost neutralised. The curdy precipitate which forms contains the fat and the proteïds, and is collected on a weighed filter, washed,

dried at 100°, and weighed. It is then extracted with ether in the Soxhlet's apparatus, dried, weighed, and the fat found by difference. The whole is now again dried, but this time at 125°, weighed, then burnt to ash, and reweighed. The loss in weight (after allowing for the weight of the filter) represents the proteïds. The filtrate, which contains the milk-sugar, is made up to 500 c.c. and in 100 c.c. (= 2 grams of sample) the sugar is estimated by Fehling's solution, the precipitated cuprous oxide being finally reduced to metal by ignition in a current of hydrogen. The ash is estimated by evaporating and burning 10 grams of milk.

L. DE K.

Improvement in Soxhlet's Milk-sterilising Apparatus. By SOXHLET (*Bied. Centr.*, **20**, 718—719; from *Milchzeit.*, **20**, 623—624).—The flask used for sterilising milk is now provided with a kind of india-rubber valve instead of the bored india-rubber stopper, which had to be closed after the flask had been heated the first time with a pieee of glass rod.

A series of experiments made by the author show that samples of milk from various sources are not equally readily sterilised. Completely sterilised milk will remain for six months unchanged, even when kept at 35°; milk which is difficult to sterilise, curdles in three or four days.

Pasture grass is preferable to dry fodder for cows, and when it is used the milk is freer from germs; moreover, the germs which emanate from dry fodder are those which are most difficult to kill, and hence milk infected with them is not readily sterilised. Hay, when employed, should therefore be wetted so that there is no dust from it.

N. H. M.

Putrefaction of Bile. By C. ERNST (*Zeit. physiol. Chem.*, **16**, 205—219).—The antiseptic properties of bile are, if existent, very slight. Bile itself rapidly undergoes putrefaction; and various meat infusions, if mixed with bile, also readily putrefy. The products of such putrefactions were investigated, the most striking result being that those mixtures containing most bile, or bile alone, contained most indole. Further, some experiments appear to show that the source of this indole is the so-called mucin of the bile. The pancreatic juice does not seem to hasten the formation of indole from bile mucin. Further, in the intestine most indole is obtainable from the lower portions, where the bile has acted longest.

W. D. H.

Carbamic Acid. By J. J. ABEL and E. DRECHSEL (*Chem. Centr.*, 1891, ii, 713; from *Arch. Physiol.*, 1891, 236—243).—The authors have found carbamic acid in horse's urine, and, since its presence has previously been observed by Drechsel in the blood of both carnivoræ and herbivoræ, the authors conclude that the conversion of carbamic acid into urea in the case of carnivorous animals must progress much more rapidly than it does in the case of herbivoræ.

J. W. L.

Diamines in Diseases. By E. ROOS (*Zeit. physiol. Chem.*, **16**, 192—200).—Two cases of malaria with dysentery are recorded in

which the stools contained in one case cadaverine, in the other putrescine. The method followed was that adopted by Baumann and Udránzsky (Abstr., 1889, 1024) in their researches. In a third case, no diamines were found. It is, however, regarded as doubtful whether these ptomaïnes are the poisons that irritate the intestinal canal.. It seems that the free bases act differently from their salts.

W. D. H.

Peptones in the Blood and Organs of Leucæmic Patients. By R. v. Jaksch (*Zeit. physiol. Chem.*, **16**, 243—254).—In many cases of leucæmic blood, especially where the eosinophile cells are abundant, there is a considerable quantity of "peptone." After death it is always found, and increases as putrefaction sets in. The spleen and liver are also overladen with peptone; but in some cases the normal spleen is also rich in peptone.

The word peptone, as used, appears to include propeptone (proteoses); the methods employed were Hofmeister's (precipitation with ferric acetate) and Devoto's modification of the ammonium sulphate method (Abstr., 1891, 1304). The two methods give corresponding results with exudations and urine, but when applied to the tissues Hofmeister's often gives a positive and Devoto's a negative result.

Chemistry of Vegetable Physiology and Agriculture.

Distribution of Sugar in Boletus edulis and B. aurantiacus. By E. Bourquelot (*J. Pharm.* [5], **24**, 521—524; compare Abstr., 1889, 740).—Histologically the tissue of the cap of the fungus is a continuation of that of the foot, and the filaments of which it is composed descend into the hymenophore. In the full-grown and freshly-gathered state, the author has shown that *B. edulis* contains trehalose, mannitol, and glucose; whilst *B. aurantiacus* contains trehalose and glucose only. The three portions of the plant indicated above were separately examined, as follows:—Extraction by boiling 90° alcohol, distillation of the solution obtained, concentration of the liquid residue to one-tenth of the weight of the material treated, precipitation of the residue by means of 90° alcohol, filtra-

tion after settling, and, finally, evaporation of the filtered liquor to a syrupy consistency. Trehalose and mannitol readily crystallise; they are drained, washed with 90° alcohol, dried, and weighed. The glucose is estimated in the purified mother liquor by means of copper potassium solution. The results given in the table, p. 519, were obtained. J. T.

Amount of Proteïds in Green and in Etiolated Leaves. Acquisition of Green Colour and Growth of Etiolated Leaves. By W. Palladin (*Bied. Centr.*, **20**, 756—760; from *Ber. deut. bot. Ges.*, **9**, 194—198, 229—232).—No exact comparison of the amount of proteïds in green and etiolated leaves has hitherto been made, the older results (those, for instance, of Karsten, *Landw. Versuchs-Stat.*, **13**, 176) being founded merely on the percentage of total nitrogen. In the author's experiments, the seeds were sown in garden soil, the green plants being exposed to normal conditions, and the etiolated plants grown in large, wooden boxes covered with black cloths. The separation of proteïds was effected by Stützer's method. The leaves (without stalks) were heated to boiling in water containing some alum, and treated in the usual manner with copper hydroxide, &c. Total nitrogen was determined by Kjeldahl's method.

The following table shows the percentage of nitrogen and proteïd nitrogen in the leaves of field beans and wheat:—

	Nitrogen.			
	In fresh.		In dry.	
	Total.	Proteïd.	Total.	Proteïd.
1. *Vicia faba*, 21-day green plants—				
Newer leaves	—	—	9·7	7·1
Older leaves (with 12·7 per cent. of dry matter)	—	—	9·2	6·2
2. *Vicia faba*, 22-day etiolated plants—				
Leaves	—	—	10·3	7·5
Stalks	—	—	7·7	1·8
3. *Vicia faba*, 18-day etiolated leaves	1·94	1·34	—	—
4. „ 16- „ „ „	1·86	1·22	10·5	6·8
Wheat leaves, green 15-day plants (average)	—	0·3188	—	—
Wheat leaves, etiolated 15—16-day plants (average)	—	0·2056	—	—

Tables are also given showing the amount of proteïd and of non-proteïd nitrogen in 100 parts of total nitrogen, and the amount of proteïds in the fresh and dry substances. The results point to the conclusion that etiolated leaves may be divided into two classes, according to the amount of proteïds they contain. Leaves of etiolated plants without stalks are poorer in proteïds than green plants, whilst etiolated leaves of plants with stalks are considerably richer in pro-

teïds than the green leaves. Etiolated stalks are very poor in proteïds. The results thus support the author's theory regarding the reasons of the change of form of etiolated plants. Leaves of *Vicia faba*, rich in proteïds, do not remain in the dark in an undeveloped state for want of organic nutriment. Lessened transpiration gives rise to a very slight taking up of minerals, and this causes the leaves of etiolated plants with stalks to remain undeveloped. Etiolated leaves of wheat and etiolated stalks of *Vicia faba* develop quickly, because, in spite of the small amount of albumin they contain, they are able to acquire from the soil much water containing the requisite minerals.

In order to study the effect of light on etiolated leaves, the leaves (of *Vicia faba* and wheat) were placed on distilled water and solutions of various substances, and kept in diffused light. The bean leaves on distilled water grew very little, and all died without becoming distinctly green. On a cane-sugar solution (10 per cent.), most of the leaves became green in 24 hours, and all within 48 hours; but they grew but little, and died in three days. Aqueous calcium nitrate (0·3 per cent.) alone caused the leaves to die without chlorophyll formation; but with nitrate and sugar together, the leaves became green, grew considerably, and remained healthy more than three days. Wheat behaved quite differently: the etiolated leaves became very soon green when kept in pure water, and the presence of sugar had no effect, clearly because the leaves of wheat contained sufficient carbohydrate. The results point to the following conclusions:—(1.) Chlorophyll cannot be formed without sugar. (2.) The chlorophyll first formed in leaves of germinating plants is formed at the expense of the sugar supplied to them by the seed. (3.) Absence of lime is one reason why etiolated bean leaves do not develop.

N. H. M.

Composition of the Leguminosæ. By L. F. Nilson (*Bied. Centr.*, **20**, 734—736; from *Kongl. svenska landtbruksakad. handling.*, 1—12).—The chemical composition, as regards nitrogenous substances, of 38 kinds of leguminous plants was determined in 50 different samples, and also the composition of 10 plants of various kinds. The amount of digestible proteïds was determined by Stützer's method. The plants of the *Lathyrus* group come first, as containing the most nitrogen and being of the most value for feeding: the large amount of amides in *L. silvestris* makes it necessary that it should be used with care. Both the plants of the *Lathyrus* and *Vicia* orders are much more valuable than the clovers, and it is noteworthy that, among the clovers, red clover by no means holds the first place. *Melilotus alba* and *officinalis*, and *Ervum lens*, are to be compared with the better kinds of *Vicia*, whilst *Orobus niger* and *Pisum arvense* resemble the best clovers. *Lotus uliginosus* approaches more nearly the *Gramineæ*. In the following table, the numbers show percentages in the dry matter:—

	Amides.	Proteïds.	Crude proteïn.	Assimilable.

N. H. M.

Fixation of Atmospheric Nitrogen by Arable Soils. By A. Gautier and R. Drouin (*Compt. rend.*, **113**, 820—825).—The authors point out that as the results of their researches some years ago (Abstr., 1886 and 1887) they came to the conclusion that the lower forms of vegetable life play an important part in the fixation of free nitrogen by soils.

The same series of experiments showed, however, that if the soil was quite free from organic matter, there was an actual loss of total nitrogen, even in presence of the lower forms of vegetation. The fixation of atmospheric nitrogen under the influence of vegetation is, therefore, dependent on the presence of organic matter, and if humus is present a smaller but distinct quantity of free nitrogen is absorbed, even though all vegetation is absent.

The authors hold that, in presence of organic matter, which is essential to their development, the aërobic microbes oxidise the organic matter, whilst, at the same time, they convert a small quantity of the surrounding atmospheric nitrogen into nitric or nitrous compounds. The latter are subsequently attacked by anaërobic microbes, and converted into ammonia and amido-compounds (with possibly some free nitrogen), which would eventually be removed in the drainage water or escape into the atmosphere, were it not that the algæ and other low organisms at the surface of the soil retain them, and use them for the building up of their tissues. The function of the algæ, &c., is to act as magazines for the nitrogen which has been absorbed under the influence of microbes developing in the presence of organic matter.

In the experiments of Schloesing and Laurent (this vol., p. 378), the humus present had already been in the soil, had been subjected to the action of microbes, and, consequently, had, in all probability, become saturated with nitrogen. Moreover, in their experiments, one had not free access to the soil. Hence, doubtless, their failure to observe the fixation of nitrogen, except in presence of algæ, &c.

The authors consider that it has yet to be proved that algæ are capable of absorbing free nitrogen in the absence of microbes and organic matter. C. H. B.

Fixation of Free Nitrogen by Plants. By T. Schloesing Jun., and E. Laurent (*Compt. rend.*, **113**, 1059—1060).—In reply to a note by Gautier and Drouin (preceding abstract), the authors emphasise the facts (this vol., p. 378) that they did not observe any fixation of free nitrogen when the soil was bare, but that they did observe such fixation when the soil was covered with cryptogamous growth. Jn. W.

Fertility of Heavy Loam Increased by Lime. By M. Johnstone (*Bied. Centr.*, **20**, 713; from *Naturw. Rundsch.*, **6**, 322).—The potassium silicate present in heavy loam is liable to be rendered soluble by the action of water and carbonic anhydride, and to be then taken up by the roots of plants, on which it acts injuriously. The beneficial effect of lime depends on its power of liberating the potash (which is of great value to plants) with formation of calcium silicate. N. H. M.

Analytical Chemistry.

A New Desiccator. By W. Hempel (*Zeit. ang. Chem.*, 1891, 200—201).—The author has some time ago explained that, as moist air is lighter than dry air, the practice of having the drying agent at the bottom of the desiccator is objectionable. By placing the drier (sulphuric acid, calcium chloride) as high as possible and above the substance, the drying proceeds rapidly and effectively, owing to circulation of the air. The author has now given a definite shape to his apparatus, which is composed of a glass cylinder fitted with a lid, in the shape of the well-known flycatcher, in which the sulphuric acid is placed. The top part of the lid is provided with an arrangement to connect the apparatus with an air-pump, if desired. To prove the superiority of this desiccator, the author took two watch-glasses of exactly equal size, filled each with 10 c.c. of water, and placed one in an ordinary desiccator and the other in the cylinder of the new apparatus. The result was, that whilst the first lot took nine days to evaporate, the second had dried up in three.

L. de K.

Improvement in Gasvolumetric Analysis. By G. Lunge (*Zeit. ang. Chem.*, 1891, 197—200).—The old-fashioned clamps used to support the author's gasvolumeter soon get worn out, or sometimes break down during the experiments, causing great annoyance to the operator. By the new arrangement this source of failure is eliminated. Figs. 1 and 2 represent the new compound screw and forked

Fig. 1.

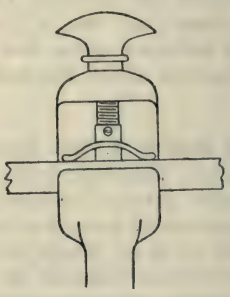

Fig. 2.

clamp; *a* and *b* being respectively a small and large cork-lined clamp, whilst *c* is a species of thumbscrew, shown on a larger scale in Fig. 2.

L. de K.

Simple and Rapid Method of Gravimetric Analysis. By G. H. Bailey and J. C. Cain (*J. Soc. Chem. Ind.*, **10**, 329—330).—A

100 c.c. flask is used, which is made in two parts, the neck being in a separate piece, and accurately ground into the body of the flask. It is desirable to make the neck almost capillary, for the purposes of accurate reading. The flask is first filled with the liquid and precipitate, after which the capillary neck is fitted in, and a little more liquid added, until a given mark on the stem is reached. The latter is graduated in millimetres. These serve, not only to adjust accurately 100 c.c. of liquid at 4°, but also (the capacity of the stem being, once for all, determined) enabled the authors to get rid of the troublesome cooling (or warming) process used in specific gravity determinations. For instance, if the liquid at 4° stood at division 6 for 100 c.c. liquid, and at 10° it stood at division 9, it is evident that when working at 10° the flask must be filled up to division 9, to represent 100 c.c. of liquid at the point of maximum density of water.

Method of Working.—First, the specific gravity of the substance precipitated is carefully determined by ascertaining (*a*) weight of flask and air, and then deducting from this the weight of 100 c.c. of air; (*b*) weight of flask and 100 c.c. of water at 4°; (*c*) weight of flask filled to 100 c.c. mark with water and the substance whose specific gravity was to be determined. The following values were obtained:—

Silver chloride precipitated hot, 5·298.
Silver chloride precipitated in the cold, 5·287.
Copper oxide precipitated hot, 6·514.
Ferric hydroxide precipitated hot, 2·583.
Barium sulphate precipitated hot, 4 651.
Barium sulphate precipitated in the cold, 4·612.

In order to make use of these numbers in the inverse manner for ascertaining the weight of a given precipitate, it is not necessary to replace the supernatant liquor by water, for, by using two similar flasks, 100 c.c. of the clear, supernatant liquor may be run off into one flask, leaving the precipitate and supernatant liquor occupying 100 c.c. in the other flask. Some of the supernatant liquid may also be transferred to a small wash-bottle for washing down any precipitate which remains attached to the sides of the funnel. The actual determination of the weight of the precipitate W now takes this form:—

$$W = \frac{(w' - w)Vs}{Vs - W},$$

where w' = weight of supernatant liquid and precipitate.
w = weight of known volume (say 100 c.c.) of liquid.
s = specific gravity of precipitate.
V = volume of the flask (say 100 c.c.). D. B.

Use of Potassium Hydrogen Tartrate for Titrating Standard Acids and Alkalis. By A. Bornträger (*Zeit. anal. Chem.*, **31**, 43—57).—After giving a summary of most of the methods in use, or suggested, for the standardisation of acid and alkaline solutions, and

pointing out the objections to each of them, the author proposes potassium hydrogen tartrate for the purpose. It is easily prepared and preserved in a pure and definite condition, is anhydrous and not hygroscopic; used directly, it serves as an acid for standardising alkalis, and if ignited it yields a definite quantity of potassium carbonate, by which an acid can be titrated. The author's material was prepared by heating white cream of tartar with dilute hydrochloric acid, cooling with stirring, washing the precipitate completely, recrystallising from water, and drying at 100°. It was regarded as pure when the alkali obtained by calcining a weighed quantity exactly neutralised an equal amount of the uncalcined substance. Sensitive violet litmus-paper was used as indicator. M. J. S.

Gasometric Alkalimetry and the Employment of Potassium Ferricyanide in Gasometry. By J. Quincke (*Zeit. anal. Chem.*, **31**, 1—43).—The reaction $K_6Fe_2Cy_{12} + 2KHO + H_2O_2 = 2K_4FeCy_6 + 2H_2O + O_2$ takes place with quantitative exactness, the amount of oxygen evolved being an accurate measure of the reagent present, so that it can be employed for the estimation of ferricyanides, alkaline hydroxides, or hydrogen peroxide. Assuming that the volume of gas evolved can be read to 0·05 c.c., the error of reading is about equal in magnitude to that involved in measuring a N/10 solution in a burette with float. The potassium hydroxide of the above equation can be replaced by sodium or barium hydroxide with equally accurate results; calcium hydroxide gives results of slightly less accuracy, but still amply sufficient for most purposes. Ammonia is inadmissible, since it decomposes far more of the peroxide than would correspond with an analogous equation. Neither can the alkali or alkaline earthy carbonates be estimated, since they only slowly and imperfectly decompose the peroxide. Weak solutions of the carbonates indeed act so slowly, whilst the reaction with the hydroxides is so rapid (being complete in from one to five minutes), that the presence of a little carbonate does not interfere with the estimation of a hydroxide. The reaction $K_6Fe_2Cy_{12} + BaO_2 = BaK_6Fe_2Cy_{12} + O_2$ also takes place, but not very energetically. By dissolving the barium peroxide in dilute hydrochloric acid, and mixing this solution with excess of strongly alkaline ferricyanide, the reaction becomes rapid and exact.

There are many substances which are oxidised by alkaline solution of ferricyanide, as grape sugar, phosphorous acid, &c.; and, in cases where the products of the oxidation have no action on hydrogen peroxide, an estimation of the residual ferricyanide can be employed for their determination. Arsenious and antimonious trioxides in particular give highly satisfactory results. The potash solution should be strong, and used in large excess. The ferricyanide may be used in the form of standard solution, which, if kept in a bottle of yellow glass, retains its strength for some months. No warming is required. A precipitate of antimony trisulphide may be titrated by dissolving it in concentrated hydrochloric acid, boiling to expel hydrogen sulphide, and then treating the solution with the alkaline ferricyanide. Arsenic trisulphide presents difficulties. The author's

experiments were made with an improved form of Knop's azotometer, in which all parts of the apparatus could be plunged into the same mass of water. The hydrogen peroxide used was "commercial," containing 2·4 per cent. The numerous test analyses reported are highly satisfactory, and tables are given in the paper for facilitating the calculations. M. J. S.

Estimation of Soluble Chlorides, Bromides, and Iodides. By L. L. de Koninck and E. Nihoul (*Zeit. ang. Chem.*, 1891, 294—298).—When a perfectly neutral solution of a chloride, bromide, or iodide (free from barium) is shaken with freshly precipitated silver chromate, the silver combines with the halogen, and the filtrate contains a chromate. The chromic acid may be readily estimated by adding sulphuric acid and potassium iodide, and titrating the liberated iodine with sodium thiosulphate. 3 mols. of this salt or 3 atoms of free iodine correspond with 1 atom of either combined chlorine, bromine, or iodine. Very small traces of chromate may also be estimated colorimetrically. The test analyses are satisfactory.

L. de K.

A New Method for the Estimation of Organic Nitrogen. By J. H. Smith (*Chem. Zeit.*, **14**, 1223—1229).—A preliminary communication as to an indirect process for the determination of organic nitrogen. It is based on the complete oxidation of the organic compound and the conversion of its nitrogen either into nitrogen or nitric acid or both, according to the substance oxidised.

The process is carried out by heating the substance with potassium permanganate, potassium bromide, and sulphuric acid. The amount of the bromide need not be large, as bromine is constantly being regenerated. After cooling, the excess of permanganate is titrated back in the usual manner, after the bromides have been first precipitated with argentic nitrate; and from the difference between the oxygen absorbed in this case, and that absorbed in a like oxidation in absence of bromide, the nitrogen is calculated. L. de K.

Estimation of Nitrogen in Nitrates. By E. Fricke (*Zeit. ang. Chem.*, 1891, 239—241).—A process which the author has successfully employed for some years is as follows:—20 grams of the sample is dissolved in a litre of water, and 50 c.c. is put into a 600 c.c. flask and diluted with an equal bulk of water. 20 grams of potassium hydroxide is now added, and after this has dissolved, 15 grams of zinc and iron dust, also 75 c.c. of alcohol. To prevent frothing, it is as well to add a few granules of animal charcoal. The flask is now closed and connected with a 200 c.c. Peligot's tube which contains 10 c.c. of normal sulphuric acid, and is partially immersed in cold water. After three or four hours, the spirit, which of course carries over the ammonia, is distilled off. The acid is then titrated back with N/4 soda. The process is really an excellent one, provided the potash is free from nitrates. Stützer's process, reduction by means of aluminium wire, cannot be recommended, as the pure metal nowadays, prepared by electrolysis, is far less active than the metal made

by the old process, which yields a product containing both sodium and silicon.

After mentioning Schmitt's process, based on the reduction of nitric acid by hydrogen in acetic acid solution, a process which would be an excellent one if it were not for the frothing and spurting, the author remarks: "This and similar processes must, however, make room for a method lately proposed by Ulsch, which is characterised by simplicity, economy, and celerity." 25 c.c. of a solution containing about 0·5 gram of the nitrate is put into a 600 c.c. flask, and reduced by means of 5 grams of reduced iron and 10 c.c. of dilute sulphuric acid (1—3). To prevent loss by spurting, the flask must be covered with a pear-shaped glass bulb. The liquid is now gradually heated to boiling, and, after six minutes, allowed to cool. After diluting with about 150 c.c. of water, 30 c.c. of aqueous soda is added, besides a few lumps of granulated zinc, and the ammonia is distilled off as usual. On trying this process on a sample of chemically pure sodium nitrate, the author found 16·44 instead of 16·47 per cent. of nitrogen. The process may also be employed for the estimation of nitrates in potable waters. L. DE K.

Estimation of Nitrogen in Pure and Mixed Nitrates. By A. SÜLLWALD (*Chem. Zeit.*, **14**, 1673—1674, 1748).—The author has made several experiments to compare his own process (a modification of Jodlbauer's) with the one recommended by Förster.

The author's process is as follows:—0·5 gram of nitre, or 1 gram of a mixed nitrate, is put into a 150 c.c. flask and moistened with 0·5 c.c. of water. The object of this is to make the nitrate dissolve more easily in the acid, and it also prevents too violent an action. 25 c.c. of sulphuric acid containing 40 grams of phenol per litre is now put into the flask, and, after cooling, 2·5 grams of zinc-dust is added. After waiting for about 15 minutes, a few drops of mercury are added, and the mass gradually heated to boiling. All the nitrogen will thus be converted into ammonium sulphate. The ammonia is then estimated volumetrically as usual.

Förster's process is as follows:—0·5 gram of the nitre is dissolved in 15 c.c. of sulphuric acid containing 6 per cent. of salicylic acid. When the substance has dissolved, 5 grams of sodium thiosulphate is added, and when the action is over, 10 c.c. of pure sulphuric acid and a few drops of mercury are introduced. The conversion of the nitrogen into ammonia is generally accomplished in about 1½ hours.

The results of the experiments proved that the author's process is quite as accurate as Förster's method, although the latter is more simple and is performed in less time. In order to avoid loss, the author recommends treating the nitrate with the acid in the same flask, which is afterwards used for the ammonia distillation. When, however, Chili saltpetre has to be tested, the author prefers his own process to that of Förster, as this substance refuses to properly dissolve in the sulphosalicylic acid. L. DE K.

Estimation of Phosphorus in Iron and Steel. By C. MALOT (*Zeit. anal. Chem.*, **31**, 78—79; from *Compt. rend. mens. de la Soc. de*

l'ind. minér., Avril, 1887).—The phosphorus is precipitated as ammonium phosphomolybdate in the usual way; the precipitate is dissolved in ammonia and reprecipitated by magnesia mixture. The magnesia precipitate is dissolved in nitric acid of 1·2 sp. gr., a drop or two of cochineal tincture (prepared by treating cochineal with boiling water) is added, then ammonia just to violet coloration, which is again removed by one or two drops of nitric acid. There is then added 5 c.c. of a solution containing in the litre 100 grams of sodium acetate and 50 c.c. of acetic acid, the whole is heated to 100°, and titrated with a neutral uranium nitrate solution of known value. As soon as all the phosphoric acid is precipitated, the excess of uranium forms a green lake with the cochineal, so that the colour changes from red to greenish-blue. The uranium solution is of convenient strength if 1 c.c. precipitates 2 milligrams of phosphoric anhydride. Duplicate estimations do not show greater differences than 0·2 milligram.

M. J. S.

Estimation of Phosphorus in Pig Iron, Steel, and Iron Ores. By F. A. Emmerton (*Zeit. anal. Chem.*, **31**, 71—75).—The phosphorus is converted into the yellow ammonium phosphomolybdate, and the amount of the latter ascertained by volumetric estimation of the molybdic acid. 5 grams of steel is dissolved in 75 c.c. of nitric acid (sp. gr. 1·2) in a covered basin, the solution boiled to dryness, and the residue heated for 30 minutes. The cooled residue is taken up by 40 c.c. of strong hydrochloric acid, and the solution evaporated to 15 c.c., taking care that none of the ferric chloride dries on the side of the basin. 40 c.c. of strong nitric acid is now added and again evaporated to 15 c.c., the basin being covered by a clock glass of smaller diameter than itself, placed with the concave side downwards, so that the condensed vapours flowing back prevent the formation of a crust at the edges. A highly concentrated, clear solution free from hydrochloric acid is thus obtained. This is washed into a 400 c.c. flask with about 60 c.c. of water, mixed gradually with a small excess of ammonia, and the precipitate just redissolved by strong nitric acid. The temperature is now brought to 85°, and 40 c.c. of molybdate solution added at once. The flask, stoppered and wrapped in a cloth, is shaken for five minutes, which completes the precipitation. The precipitate is now collected on a suction filter, washed with dilute nitric acid, and then rinsed with 30 c.c. of dilute ammonia through the pierced filter into a flask containing 10 grams of zinc; 80 c.c. of dilute sulphuric acid (1 : 4) is added, and the liquid boiled for 10 minutes, to complete the reduction of the molybdic acid, the colour of the liquid passing through pale-red to olive-green. It is then rapidly filtered and washed through a ribbed filter, and standard permanganate run in until the liquid is perfectly colourless. Since the reduction of molybdic acid by zinc produces a mixture of oxides corresponding with the composition $Mo_{12}O_{19}$, the equation for the titration is $5Mo_{12}O_{19} + 34KMnO_4 = 60\ MoO_3 + 17K_2O + 34MnO$, and since the phosphorus in the precipitate amounts to 1·794 per cent. of the molybdic acid present, a permanganate solution of which 1 c.c. oxidises 0·006141 gram of iron will correspond with 0·0001 gram of phosphorus per c.c.

Pig iron is dissolved in hydrochloric acid, and, after making up and filtering from insoluble matter, an aliquot part is treated as above. Iron ores are dissolved in hydrochloric acid, the solution evaporated to dryness, taken up with hydrochloric acid, concentrated, boiled with nitric acid, then made up, filtered, and an aliquot part of the filtrate employed. M. J. S.

Separation of Phosphoric and Arsenic Acids from Mercury, and of Nitric Acid, Chlorine, and Sodium from Mercury, Phosphoric, and Arsenic Acids. By K. Haack (*Zeit. anal. Chem.*, **31**, 79—81).—1. *Separation of Arsenic and Phosphoric Acids from Mercury.*—If a mercuric salt, the substance is dissolved with hydrochloric acid; if a mercurous salt, it is dissolved in nitric acid with the addition of hydrochloric acid and potassium chlorate, and warming until the odour of chlorine is removed. An excess of ammonia is added, and then, drop by drop, a rather strong solution of potassium cyanide until the precipitate is redissolved. Ammonia is now added until it amounts to one-fourth of the whole volume, and then an equal bulk of absolute alcohol. The arsenic or phosphoric acid can now be precipitated by magnesia mixture in the usual way, and the mercury from the filtrate by hydrogen sulphide.

2. *Nitric Acid from Mercury and Phosphoric and Arsenic Acids.*—The solid substance is boiled for a quarter of an hour with an excess of barium hydroxide. From the filtrate, the excess of barium is precipitated by carbonic anhydride and boiling. The remaining barium is precipitated as sulphate and calculated to nitrate. If alkali metals are present, part or the whole of the nitric acid will remain as alkali nitrate, and, should the alkali be in excess, this method is inapplicable. If otherwise, the alkali must also be determined and calculated as nitrate. For this purpose, the filtrate from the barium sulphate is evaporated, and the residue weighed as alkali sulphate. To separate sodium from mercury and arsenic acid, the substance may be ignited with excess of solid ammonium chloride in a porcelain crucible.

3. *Separation of Chlorine.*—The substance is boiled with baryta as above, and the chlorine estimated in the filtrate. The baryta precipitate is free from chlorine. M. J. S.

Direct Estimation of Arsenic in Minerals and Metals. By J. Clark (*J. Soc. Chem. Ind.*, **10**, 444—445).—In 1867, the author, in conjunction with Esilman, showed that ferric salts decomposed the sulphides of a large number of metals, separating sulphur, and forming a salt of the metal, which was accompanied by the reduction of the ferric salt employed to the corresponding ferrous salt. It occurred to the author to utilise this action for the estimation of arsenic when in the form of sulphide. For this purpose, known quantities of pure arsenic sulphide were distilled with a concentrated solution of ferric chloride in strong hydrochloric acid in an ordinary flask connected with a worm condenser, to the end of which a wide tube was attached which dipped into water. The arsenic was

then precipitated with hydrogen sulphide in the cold, and collected on a weighed filter, with the following results:—

(1.) 5 grams As_2S_3 gave 5·02 = 100·40 per cent.
(2.) 5 grams As_2S_3 gave 4·95 = 99·00 „

It is absolutely necessary, in estimating the arsenic in this way, that the hydrochloric acid should be concentrated, and it is always advisable to evaporate down the solution three times with a considerable quantity of strong hydrochloric acid. The ferric chloride decomposes the hydrogen sulphide which would be produced by dissolving the arsenic sulphide in hydrochloric acid, facilitates the solution, and enables the arsenic to be estimated directly.

The author has made numerous experiments with ferric chloride on mixed sulphides of arsenic, antimony, and tin with satisfactory results, and has found this to be the simplest and most trustworthy process for estimating arsenic in antimony ore. It is also applicable for the direct estimation of arsenic in iron and copper pyrites.

D. B.

A New Apparatus for the Estimation of Combined and Free Carbonic Acid. By G. Lunge and L. Marchlewski (*Zeit. ang. Chem.*, 1891, 229—234).—In Fig. 1, which shows the apparatus in its proper proportions, but at about one-ninth of its actual size, A represents the generating flask. If used for the analysis of limestone, soda-ash, &c., it has a capacity of about 30 c.c.; but if required for the estimation of carbonic anhydride in water, or carbon in iron, it must have a larger size. The flask, which is shown on a larger scale in Fig. 2, has a side tube *a*, which is connected with a stop-cock *b* and a funnel *c*; it is closed by means of a ground, hollow stopper, which ends in a rather thin, capillary tube *d*, 35 cm. in length This leads to the side tube of a Lunge's gasvolumeter. The bulb underneath the stop-cock *f* holds about 100 c.c., and is connected with a tube holding another 50 c.c., and calibrated into 0·1 c.c. The Friedrich's stop-cock *f* communicates with the capillary tubes *e* and *g*, which run at a right angle to one another. The tube *g* is connected by means of an india-rubber tube with another capillary tube which terminates in a doubly perforated stop-cock *h*. The latter is connected with the Orsat tube E, which is filled with aqueous potash or soda, and is conveniently supported by the same forked clamp (shown in the figure). All the india-rubber joints, except the one at *e*, are wired. The tube E is also fitted with a soda-lime tube *i*, which prevents the entrance of respiratory carbonic anhydride when the potash is blown up. C is the duction tube, which terminates in a sealed capillary *k*, and D the pressure tube, which should be 3·5 cm. wide; both are supported by the forked clamp *l*. To adjust the apparatus, the temperature and pressure must be, once for all, observed, the great advantage of the instrument over similar ones being that it serves as its own barometer. The gas is expelled from B by raising D; *f* is then closed and D lowered until the distance of its mercury level is over 760 mm. from *f*. D should be lowered sufficiently to cause the mercury to

sink below the bulb in B. D is then made fast, and one must wait a short time to see whether f fits tightly, and if the mercury level in B

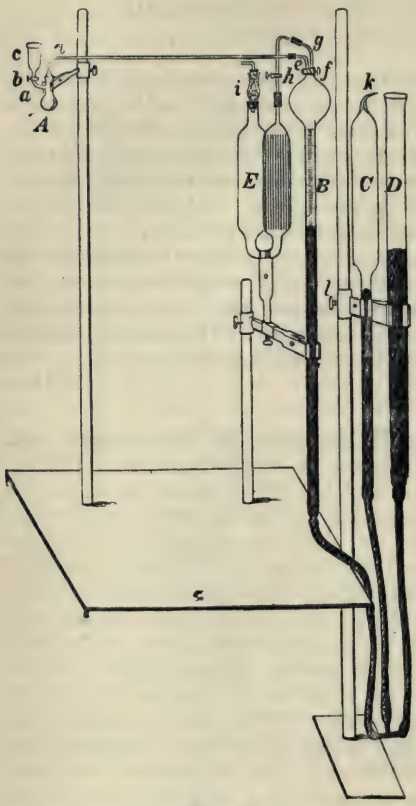

Fig. 1.

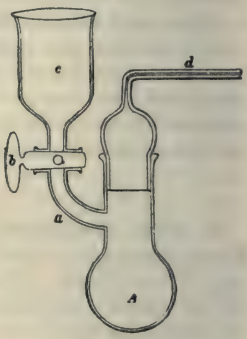

Fig. 2.

remains unchanged. The distance in millimetres between the two mercury levels in B and D is now ascertained by means of any suitable rule. 1 mm. is deducted on account of the tension of mercury vapour at temperatures under 12°, 2 mm. for 13—19°, and 3 mm. for 20—25°, and this corrected pressure is called b. The volume which 100 c.c. of dry air would occupy under these conditions is calculated by the formula

$$\frac{100.(273 + t)760}{273.(b - f)},$$

in which f is the tension of water vapour, which may be taken approximately as $(t - 2)$ for temperatures between 12° and 25°, thus:—

$$\frac{100.(273 + t)760}{273(b - t + 2)}.$$

f is now opened, the mercury in C adjusted to the division corresponding with the calculated volume, and the columns in B and D are brought to the same height. In order to saturate the air with water vapour, a minute drop of water is introduced by means of the capillary K into C. K is now sealed by means of a spirit flame, and, to prevent C getting warm, a screen of cardboard is used. If the mercury still stands at the same division, the apparatus is ready for use, and no corrections need be made for alterations in temperature and pressure.

Before commencing an analysis, it is necessary to conduct a blank experiment to see whether the apparatus is tight. 0·1 gram of fine aluminium wire is introduced into the flask A. B is filled with mercury by raising D, and is made to communicate with A by the stop-cock f, b being closed. D is then lowered, h opened, and D again raised to expel the air in B through E. When this has been repeated about three times, the apparatus is sufficiently exhausted. Hydrochloric acid, diluted with four times its bulk of recently boiled water, contained in the funnel c, is now allowed to run through b into A until this is one-third filled. On applying a gentle heat, a strong evolution of gas sets in, but care must be taken to have the mercury level in D lower than in B. After all the aluminium has dissolved, the stop-cock b is opened, and more acid is allowed to enter until it reaches the neck of the capillary d, and the stop-cock f is then closed. The three tubes are adjusted to the same level, the mercury in C standing at the 100 division, and allowed to remain so for 10 minutes to equalise their temperatures. In the meanwhile, the soda is forced by blowing through i as far as the stop-cock h, which is then closed. A is now detached and cleaned, so as to be ready for the actual analysis. After adjusting, if necessary, the levels of the tubes, the volume indicated by B is read off; f is now turned to make B communicate with g, and h is opened. D is then raised, the gas driven from B into E, and again lowered, which operation is repeated several times. Finally, the soda-ley is again forced up until it reaches h, which is then immediately closed, and the tubes are again brought to the same level, C standing at the 100 division. If the whole apparatus has been air-tight, and the acid been free from carbonic anhydride, the mercury will occupy the same height before and after treatment with the soda.

After driving the gas completely out of B by raising D, the analysis of any carbonate may be performed. An accurately weighed quantity of the substance, together with about 0·8 gram of aluminium, is dissolved in A, as before. The hydrogen completely expels the last traces of carbonic anhydride from the fluid. All the operator has now got to do is to measure the gas both before and after the action of the soda-ley. The difference represents the volume of the carbonic anhydride, which multiplied by 1·966 gives its weight in milligrams. L. DE K.

Apparatus for the Estimation of the Carbonic Anhydride of the Atmosphere. By O. SCHULZ (*Chem. Centr.*, 1891, ii, 726—727;

from *Münchener med. Wochenschr.*, **38**, 641—643).—The apparatus consists of a 500 c.c. cylinder which is graduated for each 20 c.c. At each end it is drawn out. The lower orifice is connected, by means of an india-rubber tube, with a movable reservoir. The upper orifice is closed by a three-way tap. One of the openings of the latter communicates with the air, whilst the other is connected with a stout glass test-tube. The latter is closed by an india-rubber stopper, through one of the holes of which passes a tube drawn out to a capillary at its lower end and reaching to the bottom of the test tube, whilst the other is in connection with the three-way cock of the cylinder. In the test-tube is placed 20 c.c. of a millinormal soda solution, with phenolphthaleïn as indicator. In using the apparatus, the movable reservoir is raised until the water flows from it into the measuring cylinder up to the zero mark, the three-way tap being in connection with the atmosphere. The tap is then reversed so as to come into connection with the test-tube, and the reservoir is now lowered and air allowed to bubble through the soda solution until it is just colourless. The volume of air passed through may then be read off on the cylinder and compared with the weight of carbonic anhydride which exactly neutralises the soda. J. W. L.

Estimation of Calcium in Phosphates by Glaser's Process. By J. H. Vogel (*Zeit. ang. Chem.*, 1891, 357—359).—The author, after carrying out a large number of experiments, has come to the conclusion that the original process recommended by Glaser gives the calcium too low. Excellent results are, however, obtained by using the modified process recommended by Jones (compare this vol., p. 99). Nothing is gained by first drying and separating the calcium sulphate from the filter before calcining it, but too strong a heat should be avoided.

If the phosphate contains much magnesium, there is a danger of this substance coming down with the iron and aluminium phosphates. In this case, Stützer's plan (as explained in Jones's article) must be adopted. L. de K.

Volumetric Estimation of Zinc. By L. Blum (*Zeit. anal. Chem.*, **31**, 60—61).—The author has pointed out (Abstr., 1890, 1191) that in Donath and Hattensauer's method for the titration of zinc, the presence of manganese leads to incorrect results. Moldenhauer prefers to omit the tartrate, and to titrate the zinc in a simple ammoniacal solution, in which the precipitated ferric hydroxide is suspended. If, before making alkaline with ammonia and boiling, a little bromine water has been added to the solution, the manganese will be all precipitated with the iron, and will no longer interfere with the titration of the zinc. Moldenhauer's ammoniacal reagent (5 c.c. for 50 c.c. of solution) consists of 50 grams of ammonium carbonate, 50 grams of ammonium chloride, and 100 c.c. of ammonia in the litre.

M. J. S.

Separation of Copper and Cadmium. By J. S. C. Wells (*Chem. News*, **64**, 294).—Copper and cadmium may be separated, in the absence of ammonium salts, in the following manner:—The

neutral solution containing the two metals is rendered colourless by treating with sodium thiosulphate; the addition of sodium carbonate then precipitates the cadmium as carbonate, which is filtered off. The copper is obtained as sulphide by boiling the filtrate with hydrochloric acid. D. A. L.

Assay of Aluminium and its Alloys. By F. Regelsberger (*Zeit. ang. Chem.*, 1891, 360—363).—Although an experienced dealer can readily distinguish a good sample of aluminium from an inferior one by its appearance and some physical tests, a chemical analysis is more satisfactory. The impurities almost exclusively present are iron and silicon; but it is as well to also make a direct estimation of the aluminium, so as to make sure there can be no other impurities to speak of. The author now recommends the following process:—*Silicon.*—From 2 to 4 grams of cut-up metal is dissolved, with the usual precautions, in 50 c.c. of water containing 12—24 grams of potassium hydroxide. A platinum basin is used, and when the bulk of the metal has dissolved, a gentle heat is applied. The solution is acidified with hydrochloric acid, evaporated to dryness to render silica insoluble, and the residue treated in the well-known manner. *Iron.*—3 grams of the metal is treated in a flask with 50 c.c. of 40 per cent. aqueous potash, and the action assisted by a gentle heat. 200 c.c. of dilute sulphuric acid (1·16 sp. gr.) is now added, and, after boiling to dissolve the iron, the liquid is rapidly cooled and titrated with permanganate. *Aluminium.*—This estimation has already been described (this vol., p. 102).

As regards alloys, the author found that the treatment with aqueous potash completely dissolves out the aluminium from its alloy with 6 per cent. of copper or 20 per cent. of nickel. Even an alloy of aluminium and silver may be so separated, but in this case treatment with nitrohydrochloric acid is preferable. L. de K.

Volumetric Estimation of Alumina. By C. F. Cross and E. J. Bevan (*J. Soc. Chem. Ind.*, **10**, 202).—Lunge (Abstr., 1891, 365) contends that the authors are in error in supposing that the change of colour takes place when the proportion $5SO_3 : 2Al_2O_3$ is reached, the real ratio being $3SO_3 : Al_2O_3$. The authors have repeated their former experiments with precisely the same results. D. B.

Volumetric Estimation of Alumina. By G. Lunge (*J. Soc. Chem. Ind.*, **10**, 314—317).—Referring to the preceding abstract, the author states that he has repeated his former experiments, and has confirmed his results and those of all previous observers, according to which the change in the colour of methyl-orange occurs when $3H_2SO_4$ has been used for $1Al_2O_3$. D. B.

Commercial Assay of Alums. By M. Kretzschmar (*Chem. Zeit.*, **14**, 1223).—Five grams of the sample is dissolved in 500 c.c. of water, 50 c.c. is taken, and the acidity estimated by means of N/2 potash with methyl-orange as indicator. The alumina is then approximately estimated by continuing the titration after addition of phenolphthaleïn. Another 50 c.c. is now taken and boiled with a few drops

of bromine. After cooling, sodium acetate is added, and then a known volume of sodium phosphate of known strength, in order to completely precipitate the alumina and any ferric oxide. As the washing of the precipitate is troublesome and slow, the author prefers to estimate the excess of phosphate volumetrically, in the cold liquid, by means of uranium nitrate solution. As the precipitate also contains ferric phosphate, it is necessary to estimate the iron in another 50 c.c. by reduction with zinc and titration with permanganate. From the amount of alumina obtained by the titration with uranium is then deducted the quantity of alumina corresponding with the ferric oxide.

The process is convenient and rapid. As the amount of alumina is already fairly accurately known by the titration with phenolphthaleïn, the operator knows almost exactly how much uranium will be required to precipitate the excess of phosphate. A single titration will therefore be sufficient. If the alum contains ammonia, the greater part of this must be expelled by heating with excess of alkali. L. DE K.

Glaser's Process for the Estimation of Iron and Aluminium in Phosphates. By T. MEYER (*Chem. Zeit.*, **14**, 1730).—A joint committee of German manure makers and agricultural analysts has reported in favour of Glaser's spirit method, instead of the conventional ammonia and acetic acid process. The weak point in Glaser's process is, however, his complete ignoring of the magnesia. Although magnesium sulphate is practically insoluble in absolute alcohol, it is far from insoluble in a mixture of alcohol and dilute sulphuric acid. Manures containing much magnesia always yielded, in the author's hands, a mixture of aluminium, magnesium, and ferric phosphates. Without a serious modification, Glaser's method is therefore not yet fit to become the recognised trade process. (Compare, however, R. Jones, this vol., p. 99.) L. DE K.

Estimation of Manganese in its Ores and Alloys. By J. PATTINSON and H. S. PATTINSON (*J. Soc. Chem. Ind.*, **10**, 333—338).—The authors had occasion to repeat to a certain extent the investigations of Wright and Luff, and of Pickering, on the products obtained by heating hydrated manganese dioxide in air. Their experiments were made with manganosomanganic oxide of known composition, prepared either from crystallised manganese sulphate, or from ferromanganese containing about 82 per cent. of manganese. It is shown that (1) manganosomanganic oxide is only formed from these substances by ignition for about an hour at almost a white heat, in a gas muffle furnace or other apparatus in which the oxide is protected from reducing agents; (2) an ordinary red heat, such as is obtained over a Bunsen burner, is not sufficient to reduce the oxide to the state of Mn_3O_4, and that an error of $1\frac{1}{2}$ per cent. of manganese too much may be made in this way if the percentage of manganese is calculated on the assumption that the product obtained is manganosomanganic oxide; (3) there is a risk in all cases when the oxides are heated over a gas blowpipe of obtaining an oxide containing less

oxygen than Mn_3O_4, probably due to the action of reducing gas permeating the heated platinum or entering the crucible under the lid, and that an error of as much as $3\frac{3}{4}$ per cent. of manganese too little may be made in this way; (4) all determinations of manganese made by weighing the product yielded by igniting manganous carbonate or hydrated manganese dioxide in air are untrustworthy, unless the available oxygen in the product is also determined and taken into consideration.

The authors conclude from their investigations and experience, that, just as in the case of the estimation of iron, the volumetric methods of estimating manganese are far superior to the gravimetric methods, both as regards accuracy and ease of execution. The volumetric method described by one of the authors in 1879 (Trans., 1879, 365), with some slight modifications of detail, is still used by the authors, who have reason to believe that it is now largely adopted by chemists. D. B.

Separation of Metals in Alkaline Solution by Hydrogen Peroxide. By P. Jannasch and R. Niederhofheim (*Ber.*, **24**, 3945—3947).—The method recently described by Jannasch and Franzek (this vol., p. 240) for the quantitative separation of manganese, cobalt, and nickel by treating the alkaline solution of their double cyanides with hydrogen peroxide, may with equal advantage be employed for the separation of manganese and zinc. The solution of manganese and zinc in 50 c.c. of water is mixed with a 10 per cent. solution of potassium cyanide (10 c.c.) and a similar amount of 25 per cent. potash solution, the whole being stirred until the precipitate first formed is redissolved. The manganese is then precipitated by the addition of hydrogen peroxide (50—60 c.c.), the mixture warmed for 15—20 minutes at 100°, and filtered. The filtrate is saturated with hydrochloric acid, evaporated to dryness, warmed at 110—115° in the air-bath for half an hour, dissolved in very dilute hydrochloric acid, and filtered from any silica present. The zinc is then precipitated by sodium carbonate and weighed as oxide.

The analytical data given in the paper show that the method is capable of yielding accurate results. H. G. C.

Action of Alkaline Sulphides on Metals of the Iron Group. By L. L. de Koninck and M. Ledent (*Zeit. ang. Chem.*, 1891, 202—203).—It is a well known fact that when salts of nickel are precipitated with ammonium sulphide in excess, the filtrate has a dark-brown colour, due to some dissolved nickel. According to Lecrenier, this is owing to the ammonium sulphide used for testing nearly always containing polysulphide. The authors thought it would be interesting to try the behaviour of sodium or potassium polysulphide, not only on salts of nickel, but also on the other metals of the same group. Nickel gives a brownish-black, but very clear filtrate, just the same as when using ammonium sulphide. Salts of cobalt give a dirty, violet-brown liquid. With iron, the colour is at first a nondescript dark brown, but gradually changes into a lively green, resembling chromic sulphate or potassium manganate. One

of the authors recommended this reaction some time ago as a delicate test for iron. Manganese salts give no peculiar colour, and, like those of zinc, seem insoluble in an excess of the reagent. The authors will continue the investigation. L. DE K.

Estimation of Chromium in Steel. By T. W. HOGG (*J. Soc. Chem. Ind.*, **10**, 340—341).—It has been objected that in Galbraith's process (Abstr., 1877, 357) the whole of the chromium is not dissolved by the sulphuric acid. This objection has most probably arisen from insufficient boiling with the strength of acid originally given (1 to 6), and the author therefore recommends the use of a stronger acid (1 to 3), and to go on boiling the solution vigorously for a few minutes after all decomposition has apparently taken place. The solution should be filtered through an asbestos filter, as with the use of a filter paper a small quantity of chromic acid is reduced. With regard to the gravimetric method of estimating chromium in steel, Arnold's process (Abstr., 1881, 646) gives the best results.

The method recommended by the author is based on the fact that a solution of chrome steel in sulphuric acid is highly coloured, the intensity of the coloration being greater as the percentage of chromium increases. Ferrous sulphate itself has a green tinge, but the colour intensity of chromium sulphate is so very much greater that the presence of even 0·1 per cent. is sufficient to give a decided increase to the depth of colour of the solution, and the presence of 0·35 per cent. will almost double it. D. B.

Gas-volumetric Analysis. By A. BAUMANN (*Zeit. ang. Chem.*, 1891, 332—339).—Lunge has tried to show that Baumann's new methods of quantitative analyses (this vol., p. 103) do not show any special advantages, and give inaccurate results. The author attempts to prove that Lunge is prejudiced against his process; that, in fact, for the estimation of small quantities of chromic acid and sulphuric acid, no better methods are to be found in the analytical text-books. New gas-volumetric processes for the estimation of arsenious and antimonious acids, and also for the alkalis, will shortly be published. L. DE K.

Gas-volumetric Analysis. By G. LUNGE (*Zeit. ang. Chem.*, 1891, 339—340).—The author remarks that, nothwithstanding Baumann's pretensions as to the accuracy of his process, he still admits that in the estimation of chromic acid an error may occur of 0·98 per cent., and that in the estimation of sulphuric acid an error of even 1·74 per cent. is possible. The author thinks that more accurate results are obtained by the use of his gas-volumeter than by the azotometer, and points to the fact that his own processes have been used successfully for many years by hundreds of analysts. L. DE K.

New Methods in Quantitative Analysis. By A. BAUMANN (*Zeit. ang. Chem.*, 1891, 203—210, 328—332; compare this vol., p. 103).—The reaction between chromic acid and hydrogen peroxide may be taken advantage of in the estimation of lead, bismuth, and barium. With chromic acid, these metals form insoluble salts, which,

during a quantitative analysis, are generally collected on a weighed filter, and dried at 100—120°. The estimation is, however, much more easily performed by the author's mode of procedure.

Estimation of Lead.—If the liquid should contain free nitric acid, it is first mixed with excess of sodium acetate, then heated to boiling. Potassium dichromate is then added in slight excess. The precipitate is collected and washed, the filter spread out on a glass plate, and the precipitate washed down with dilute sulphuric acid into the outer chamber of the evolution flask. After some time, 5 c.c. of 2 per cent. solution of hydrogen peroxide is added, and the process conducted as previously described. 1 c.c. of gas = 0·0049766 gram of lead oxide.

Estimation of Bismuth.—The solution, which must be free from excess of nitric acid, is poured into a warm solution of potassium dichromate. The precipitate is washed by decantation with hot water, and dissolved in a little weak hydrochloric acid. After transferring it to the evolution flask, and adding 10 c.c. of dilute sulphuric acid, the operation is conducted as in the previous case. 1 c.c. of gas = 0·005192 gram of bismuthic oxide.

Estimation of Barium.—The solution is precipitated with ammonium chromate in the presence of ammonium acetate. The precipitate is washed first with a weak solution of ammonium chromate and finally with very weak ammonia. It is then treated like the bismuth precipitate. 1 c.c. of gas = 0·00342 gram of barium oxide.

The estimations may, of course, also be performed by adding a known quantity of potassium or ammonium dichromate, making up to a definite bulk, and estimating the excess of chromic acid in an aliquot part of the filtrate.

The author has also studied the action of iodine and its oxygen acids on hydrogen peroxide, and obtained results which, if confirmed by other analysts, will revolutionise quantitative analysis. A freshly prepared solution of iodine in potassium hydroxide, which is really a solution of potassium hypoiodite, when brought into contact with hydrogen peroxide, evolves one molecule of oxygen for every molecule of iodine, the products being water and potassium iodide. This fact has been made use of by the author for the estimation of free iodine. 40—50 c.c. of a solution of iodine in potassium iodide is placed in the outer chamber of the flask, and 5 c.c. of 5 per cent. hydrogen peroxide is put into the glass cylinder with a solution of potassium hydroxide (1 : 2). After mixing and shaking, oxygen will be evolved, and after about five minutes' cooling, its volume may be read off. 1 c.c. of gas = 0·01133 gram of iodine. As an instance of the applicability of the method, it may be used to estimate with great rapidity mineral, and even organic, acids, by bringing them in contact with a mixture of potassium iodide and iodate, and estimating the liberated iodine in the manner described. L. DE K.

Estimation of Tungsten in Rich Alloys and in Steel. By R. NAMIAS (*Chem. Centr.*, 1891, ii, 728—729; from *Stahl. u. Eisen*, **11**, 757—760).—For the estimation of tungsten in rich alloys, the author prefers to oxidise with bromine in a concentrated sodium hydroxide

or carbonate solution, the finely divided metal being digested in a porcelain dish for 1—2 hours near the boiling point of the solution. The solution is evaporated to dryness several times with hydrochloric acid, the tungstic anhydride is then dissolved from the silica with ammonia, the silica removed by filtration, and the tungstic anhydride again precipitated with hydrochloric acid, and the whole evaporated to dryness. It is then collected, washed with ammonium nitrate solution, and ignited.

The author prefers this method to that of Schneider, by which the tungstic anhydride and silica are fused with potassium hydrogen sulphate. But the mixture of tungstic anhydride and silica may be ignited in a current of hydrogen, and the loss (oxygen) calculated into tungstic anhydride.

In the case of tungsten steel, the metal is digested with hydrochloric acid, in the absence of air, and the insoluble metal collected and washed with ammonium nitrate. A little tungsten passes into the filtrate, and this is recovered by bringing the latter to dryness with hydrochloric acid, sugar is added, and the mass ignited. It is then treated with hydrochloric acid, filtered, washed with hydrochloric acid, ignited, and added to the main portion.

J. W. L.

Analysis of Tin Ores. By J. S. C. Wells (*Chem. News*, **64**, 294).—The author finds that the decomposition of cassiterite can be satisfactorily effected by treating it with dilute hydrochloric acid in the presence of zinc and platinum, heating, and shaking frequently; when the decomposition appears to be complete, the remaining zinc and reduced tin are dissolved in hydrochloric acid and filtered from insoluble matter. The residue is tested for tin, and, if necessary, is treated again. The tin is estimated in the solution by any ordinary method.

D. A. L.

Quantitative Separation of Metals of the Hydrogen Sulphide Group by means of a Stream of Bromine Vapour. By P. Jannasch and P. Etz (*Ber.*, **25**, 124—127; see also this vol., p. 385).—*Separation of Bismuth from Lead.*—A solution of the mixed chlorides is precipitated with hydrogen sulphide, and the precipitated sulphides dried at 100° and heated in a weighed porcelain boat in a stream of air containing bromine. The bismuth bromide completely volatilises, whilst the lead bromide remains behind in a state of purity. The details of the experiments have already been given in a former paper. The special precautions for this separation are, not to allow the precipitated sulphides to remain too long in contact with hydrogen sulphide, and to complete the drying of the sulphides by gently heating them in a stream of dry air before passing the bromine vapour over them. The results obtained were good.

E. C. R.

Application of Electrolysis to Qualitative Analysis. By C. A. Kohn (*J. Soc. Chem. Ind.*, **10**, 327—329).—*Antimony.*—The precipitated sulphide is dissolved in potassium sulphide, and the solution, after warming with a little hydrogen peroxide to decolorise any polysulphides that may be present, electrolysed with a current

giving 1·5—2 c.c. of electrolytic gas per minute, when the antimony is deposited as metal upon the negative electrode. 1 part of antimony in 1,500,000 parts of solution may be thus detected.

Mercury.—This metal is best separated from its nitric acid solution on a small, closely-wound spiral of platinum wire. The solution is electrolysed with a current of 4—5 c.c. The deposited metal is removed from the spiral by heating the latter gently in a test tube, when globules of mercury form on the upper portion of the tube.

Lead.—This metal is precipitated either as peroxide at the anode from a nitric acid solution or as metallic lead at the cathode from an ammonium oxalate solution. In both cases a current giving 2—3 c.c. of gas is sufficient to effect the deposition in one hour. 0·0001 gram of metal in 150 c.c. of solution can be easily detected. With both solutions, this amount gives a distinct discoloration to the platinum spiral, on which the deposition is best effected. As a confirmatory test, the deposited metal is dissolved in nitric acid, and the solution treated with hydrogen sulphide.

Copper.—0·00005 gram of copper can be very readily detected by electrolysing an acid solution in the usual way. A platinum spiral is employed as the cathode, and the presence of the metal confirmed by dissolving it in a small quantity of nitric acid, diluting with water, and adding potassium ferrocyanide.

To detect the above metals in cases of poisoning, it is necessary to destroy the organic matter associated therewith in the usual way by means of hydrochloric acid and potassium chlorate. Urine can, however, be tested directly for these poisons. Mercury or copper may be detected by acidifying the urine with 2—3 c.c. of nitric acid and electrolysing as described. 0·0001 gram of metal in 30 c.c. of urine can be thus detected. Lead does not separate well as peroxide from urine, but if ammonium oxalate be added, the reaction is quite as delicate as in aqueous solution, and 0·0001 gram of lead can be thus detected. Antimony is best detected by precipitation as sulphide and electrolysing with a current of 1·5—2 c.c. In all cases, it is advisable to continue the passage of the current for about twice the time required in the case of aqueous solutions.

Silver.—This metal is precipitated as chloride, dissolved in potassium cyanide, and the solution electrolysed with a current of 1—1·5 c.c. A platinum spiral forms the anode, from which the silver deposit may be dissolved by nitric acid, and tested for by hydrochloric acid or hydrogen sulphide. 0·0001 gram of silver in 150 c.c. can be detected, and one hour is sufficient for the deposition.

Gold is deposited under similar conditions to silver from cyanide solutions. The deposit, which is somewhat dark coloured, can be dissolved in *aqua regia* and tested by the purple of Cassius test. 0·0001 gram of metal in 150 c.c. of solution can be detected without difficulty. D. B.

Separation of Antimony from Arsenic. By F. A. Gooch and E. W. Danner (*Amer. J. Sci.* [3], **42**, 308—312).—A very exact process for the separation of arsenic from antimony consists in distilling their hydrochloric acid solution with ferrous sulphate; but the

conditions are such that the antimony in the residue must be determined gravimetrically. The authors have so arranged the process that the estimation of the antimony may be made by a rapid volumetric method, and this they have accomplished by substituting for the iron salt, which interferes with the direct volumetric estimation, another reducing agent, namely, hydriodic acid. After a great number of experiments, the authors now recommend the following process:—

The solution, which must not contain more than 1 gram of the mixed oxides of antimony and arsenic, is mixed with a slight excess of potassium iodide, diluted with hydrochloric acid to 100 c.c., and then saturated with hydrogen chloride, which is also passed during the subsequent distillation. The apparatus consists of a 250 c.c. flask, provided with a hollow glass stopper tightly fitted in a ground joint, the stopper itself being sealed on a large glass tube bent suitably to connect the interior of the flask with a condenser, whilst through the hollow stopper, and sealed into it, passes a smaller glass tube reaching nearly to the bottom of the flask. By means of this arrangement, a current of gas entering the smaller tube passes nearly to the bottom of the flask, and then out through the hollow stopper into the condenser, without coming in contact with joints, rubber, or cork.

The distillation is continued until fully one-half of the liquid has passed over, when the residue is quickly cooled. Sulphurous acid is added, and, after a little while, the excess of this reagent is destroyed by cautiously adding solution of iodine. After the addition of 1 gram of tartaric acid for every gram of antimony supposed to be present, the free acid is nearly neutralised with sodium hydroxide, and 10 c.c. of a solution of sodium hydrogen carbonate is then added. The antimony is now estimated by titrating the solution with N/10 iodine (compare Gooch and Gruener, this vol., p. 242).

L. DE K.

Estimation of Organic Matters in the Atmosphere. By J. ARCHAROW (*Chem. Centr.*, 1891, ii, 887; from *Arch. Hygiène*, **13**, 229—246.)—The author aspirates measured quantities of the air under investigation through a tube, 39 cm. long and 1 cm. wide, which contains solution of potassium permanganate acidified with sulphuric acid. The tube is closed at one end, and fitted, like a wash-bottle, with two tubes, one of which passes to the closed end, whilst the other merely passes through the stopper, and serves as an exit. The inlet-tube is furnished with a cap at its further end, and is perforated so that the bubbles of air are reduced in size as far as may be. Three such tubes are employed in connection with one another for such experiments, and the apparatus is kept warm (about 43°). The potassium permanganate solution has a strength such that 10 c.c. = 0·02 milligram of oxygen, and it is titrated with oxalic acid.

J. W. L.

Apparatus for Determining the Flashing Point of Heavy Mineral Oils. By J. GRAY (*J. Soc. Chem. Ind.*, **10**, 348).—The apparatus designed by the author is an adaptation of the Pensky-Marten slide and stirrer to the Abel cup.

D. B.

Indirect Estimation of Alcohol. By T. P. Blunt (*Analyst*, 1891, 221—223).—When alcohol is estimated by the indirect or evaporation method, the spirit gravity is calculated, either by Tabarié's formula, which requires the division of the specific gravity of the sample by that of the extract, or by Mulder's formula, which is based on the assumption that the spirit gravity is obtained by deducting from the gravity of the sample the extract gravity minus 1000. The author has satisfied himself that in the case of sweet wines and liqueurs, the last formula is the most accurate. L. de K.

Estimation of Fusel Oil in Spirits. By J. Traube (*Chem. Zeit.*, **14**, 1410).—The author, in reply to Stützer and Reitmair, still believes his process with the stalagmometer to be the most suitable for analysts who have but seldom occasion to perform a spirit analysis. If it is thought advisable to concentrate the fusel oil, the author operates as follows:—500—600 c.c. of aqueous potash, of 1·24 sp. gr., is put into a suitable vessel, and, after warming to 60°, 100 c.c. of the sample, which must contain 80 per cent. of alcohol, is gradually added. The top layer which forms is removed, and the bottom layer is twice extracted with 20 c.c. of (50 per cent.) pure spirit, in order to remove the last traces of fusel oil. The united spirituous fluids are then tested as usual. L. de K.

Decolorisation of Wines. By A. Bornträger (*Zeit. ang. Chem.*, 1891, 340—343).—Vogel (Abstr., 1891, 1557) has found that most Portuguese red wines require an enormous quantity of basic lead acetate, sometimes three times their volume, in order to render them sufficiently colourless and clear for examination in the polarimeter. The author thinks, however, that as a rule a much smaller quantity will suffice if the sample is first exactly neutralised with potassium or sodium hydroxide, and then concentrated to half its bulk. After addition of the lead solution, the original volume must be restored, and the mixture filtered through a dry filter. Should the reaction be alkaline, this shows that too much lead has been added, and, although it may be remedied by adding a drop of strong acetic acid, it is perhaps better to carefully repeat the whole operation. If the wine is suspected to contain cane-sugar, another portion is first heated for 15 minutes with 10 per cent. of hydrochloric acid, cooled, neutralised, and treated as before. L. de K.

Alkalimetric Estimation of Phenol. By R. Bader (*Zeit. anal. Chem.*, **31**, 58—59).—This can be very accurately effected by the use, as indicator, of symmetrical trinitrobenzene (m. p. = 122°), which substance gives a blood-red coloration with aqueous alkalis. The solution of the indicator is prepared by shaking a pinch of the pure substance with 50 c.c. of absolute alcohol and filtering. It should only be feebly yellow; it requires to be protected from light, and must be freshly prepared from time to time. The phenol solution to be titrated should not contain less than 20 grams in the litre. Only two or three drops of the indicator should be added to 50 c.c. of the phenol solution, and then normal soda, drop by drop, with constant

shaking, until the reddish-yellow colour no longer disappears. 1 c.c. of normal soda = 0·094 gram of phenol. The test analyses leave nothing to be desired.

This method does not seem to be applicable to the cresols, or to catechol. M. J. S.

Estimation of Phenols in Human Urine. By Rumpf (*Zeit. physiol. Chem.*, **16**, 220—242).—The gravimetric estimation of phenol as tribromophenol in the distillate from acidified urine gives most inaccurate results; Koppeschaar-Beckurt's (*Arch. Pharm.*, 1886, 561) method of titration with potassium iodide is trustworthy. Paracresol also cannot be estimated as the tribromo-derivative. The substance obtained by adding bromine to the distillate from urine contains a pigment, and two other substances; one of these, insoluble in sodium carbonate solution, is dibromoparacresol; the other, which is soluble, is tribromophenol; it is, however, present in very small quantities. Hence it is inferred that paracresol is the most abundant substance of the phenol group in the urine. W. D. H.

Estimation of Cholesterol. By J. Lewkowitsch (*Ber.*, **25**, 65—66).—In consequence of the communication of Obermüller (this vol., p. 248), the author publishes the methods he has for some time adopted for the estimation of cholesterol. The first method depends on the quantitative formation of a diacetate of cholesterol when the latter is boiled with acetic anhydride; the precipitate formed is collected, and washed with warm water until no longer acid, its amount being determined by boiling with alcoholic potash of known strength, and titrating back with standard acid. In the second method, which depends on the formation of a di-iodo-additive product, the cholesterol is dissolved in chloroform (50 c.c.), mixed with v. Hübl's solution of iodine and mercuric chloride in alcohol (25 c.c.), and the excess of iodine determined by thiosulphate. Good results are obtained by both methods. H. G. C.

Estimation of Glycerol by Alkaline Permanganate. By W. Johnstone (*J. Soc. Chem. Ind.*, **10**, 203—204).—For the estimation of glycerol in butter fat, the author some time ago recommended the process of Benedikt and Zsigmondy, but although it gives accurate results in certain instances, he now finds it to be quite inapplicable for the estimation of glycerol in butter fat or in oils containing soluble fatty acids. He is, therefore, more inclined to support Wanklyn's statement that the theoretical quantity of glycerol cannot be obtained from butter fat, and that the large amount of soluble fatty acids calculated as butyric acid, recently found by the author, goes a long way to support his "iso-glyceride" theory (compare Abstr., 1891, 849 and 868). D. B.

Analysis of Crude Glycerols. By F. Filsinger (*Chem. Zeit.*, **14**, 1729—1730).—Apart from mixed products, there are three different kinds of commercial glycerol:—1. Saponification glycerol obtained from the works where the fats are saponified with milk of

lime. This brand is characterised by a straw-yellow or brownish colour, has an agreeably sweet taste, and emits no smell when rubbed on the hands. The reaction is generally neutral, unless a trace of free lime should be present. The specific gravity should not be less than 1·24, and its boiling point, in Gerlach's apparatus, not below 138°. The ash should not exceed 0·5 per cent., and neither basic lead acetate nor hydrochloric acid should cause much turbidity.

2. Glycerol intended for distillation, the product of the treatment of fats with sulphuric acid with or without pressure.—This generally has a burning, astringent taste, which often completely obscures the sweet one, an unpleasant odour, and leaves several per cent. of ash consisting chiefly of salt and calcium sulphate. Basic lead acetate causes a voluminous precipitate, sometimes large enough to gelatinise the liquid. Hydrochloric acid often gives a copious fusible precipitate chiefly consisting of fatty matter. The boiling point is generally below 125°. Even the best brands of this glycerol are about 10 per cent. lower in price than the worst saponification glycerols.

3. Glycerol recovered from Soap Leys.—This is the most impure of all, and has to be put through many preliminary processes before it can be distilled. When sold for that purpose, it should not contain more than 10 per cent. of ash and 10 per cent. of water.

As regards the assay of these samples, a chemical one is scarcely needed for the purer kinds of glycerol. All that is wanted is to take the specific gravity with some delicate instrument, and the boiling point in Gerlach's apparatus. As regards the chemical analysis of crude samples, the author recommends the permanganate method, originally described by Benedikt and Zsigmondy, as being the only process which has stood the test of many years' experience.

The author communicates another method which certainly has the merit of being a very simple one, and which has been in use for some years in a Hamburg laboratory. To estimate the water, 20 grams of the sample is put into a flask, provided with a ground stopper, and exposed for 10 hours to a temperature of 100°. The loss represents the water. To estimate the fixed impurities, 5 grams of the sample is heated in a flat-bottomed platinum dish up to 180°, which will cause the glycerol to completely volatilise without perceptible charring. To complete the analysis, the ash may be taken.

L. DE K.

Detection and Extraction of Trehalose. By E. BOURQUELOT (*J. Pharm.* [5], **24**, 524—526).—For the rapid extraction of trehalose from fungi, the plant is treated, as soon as possible after gathering, with boiling 90° alcohol. The solution is distilled, and the residue is concentrated to one-tenth of the weight of fungus employed. The residue, cooled and filtered, is treated with 3 or 4 vols. of 90° alcohol to precipitate certain salts and nitrogenous substances; after filtering and distilling, the residue is evaporated to a rather thick syrup. Now a glass plate is lightly rubbed about its centre with a crystal of trehalose, and a drop of the syrup is placed on the part touched. If the fungus contains trehalose, crystallisation occurs almost immediately, and under a slight magnifying power shows octahedra. A few of these crystals transferred to the syrup will immediately induce

crystallisation in the liquids. In the case where the drop on the glass gives no crystals, trehalose is not present in the extract. J. T.

Estimation of Aldehydic and Ketonic Oxygen. By H. Strache (*Monatsh.*, **12**, 524—532; compare Fischer, *Ber.*, **17**, 572).—Phenylhydrazine and its salts are rapidly decomposed when treated with hot Fehling's solution, the whole of the nitrogen being evolved in the free state; on the other hand, the hydrazones which phenylhydrazine forms with aldehydes and ketones give no free nitrogen when treated in a similar way. On a knowledge of these facts, the author has based a method of determining aldehydic and ketonic oxygen, which is as follows:—A known quantity (0·1—0·5 gram) of the substance under investigation is added to an accurately weighed excess of phenylhydrazine hydrochloride and some sodium acetate, the solution is heated at 100° for several minutes, made up to a known bulk, and an aliquot part withdrawn and heated with an excess of Fehling's solution in a specially constructed apparatus, whereby the nitrogen evolved, representing unchanged phenylhydrazine, may be readily measured, and from this the amount of hydrazine used in forming the hydrazone, and subsequently the amount of ketonic oxygen [$CO:N_2H_3Ph$] present, can be calculated. Determinations with opianic acid, acetophenone, acetone, and several other compounds show that the method is on the whole trustworthy, the results, in most cases, coming out a little too high. The author suggests that the method may, perhaps, be usefully employed in estimating the amount of an aldehydic or ketonic compound present in certain mixtures, and is extending his experiments in that direction. G. T. M.

Separation of Resin from Fatty Acids. By J. A. Wilson (*Chem. News*, **64**, 204—205).—The author regards the following as the best method of detecting resin:—Boil 10 drops of the dry fat or fatty acids with 5 c.c. of acetic anhydride, cool, and add 2 drops of sulphuric acid (sp. gr. 1·84); 1 per cent. of resin is sufficient to produce the reddish-violet colour.

For the separation he strongly advocates the use of Twitchell's process (this vol., p. 389). D. A. L.

Detection of Tartaric Acid in Citric Acid. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 23—24).—The test depends on the fact that the yellow coloration produced by citric acid with ammonium molybdate in presence of hydrogen peroxide is unaltered on warming, whereas, if tartaric acid be present, a fine blue colour results. 1 gram of citric acid is added to 1 c.c. of ammonium molybdate solution (10 per cent.) and 2—3 drops of hydrogen peroxide solution ($\frac{1}{4}$—$\frac{1}{5}$ per cent. H_2O_2), and is heated at 100° for three minutes. The reaction will detect 1 milligram of tartaric acid in 1 gram of citric acid. T. G. N.

Estimation of Uric Acid. By E. W. Groves (*J. Physiol.*, **12**, 485—489).—A comparison between various methods of estimating uric acid leads to the conclusion that Ludwig's is the only trust-

worthy method, and that Haycraft's, with which it was especially compared, gives a very considerable and variable error.

W. D. H.

Revision of Constants employed in the Analysis of Fats and Oils. By R. T. Thomson and H. Ballantyne (*J. Soc. Chem. Ind.*, **10**, 233—237).—In the table of "constants in oil analysis," which accompanies the original paper, will be found collected that portion of the authors' results which they regard as useful in oil analysis.

Iodine Absorption.—In a previous communication (*ibid.*, **9**, 587), it was shown that the variation in iodine absorption for different olive oils was greater than usually stated. Since then, it has been found to be $\frac{1}{2}$ per cent. higher still, so that the iodine value ranges from that of Gioja (79 per cent.) to that of Mogadore olive oil (86·9 per cent.). The lowest figure for rape oil now stands at 99·1, and the highest at 105·6 per cent.

Potash Neutralising Power.—The figures respecting olive and rape oils are in close accord with those obtained by Archbutt, and do not represent such a great variation between each individual oil as those given by other observers. The limits of five specimens of linseed oil examined by the authors vary from 19·00 to 19·28, whilst those of nine specimens tested by other observers and recorded by Allen range between 18·74 and 19·52.

Unsaponifiable Matter.—Olive, refined cotton-seed, unrefined arachis, and linseed oils contain about the same proportion of unsaponifiable matter, so that the determination of that constituent in a sample, say, of olive oil would not serve to show any adulteration with either of the other three oils. But the presence of a considerable proportion of rape oil would tend to reduce the percentage of unsaponifiable matter. In marine oils, it is noteworthy that seal oils contain only about one-third of that contained in whale, cod, and menhaden oils.

Specific Temperature Reaction.—This is merely a modification in recording the results of Maumene's reaction with strong sulphuric acid. It consists in mixing 50 grams of water with 10 c.c. of sulphuric acid, each at 20°, and registering the highest temperature reached. The amount of water is best measured from a pipette at 15·5°, and the sulphuric acid should be run in from a pipette which will deliver the 10 c.c. in one minute. During the addition, the mixture should be vigorously stirred with the thermometer, and the highest temperature reached rapidly read off, as it only remains constant for a few seconds. The oil being tested in precisely the same manner, it is only necessary to divide the rise in temperature obtained with water into that obtained by the oil under examination. The answer is the specific temperature reaction compared with water as 100. The oils must be carefully weighed, and the acid added to them exactly as with water, except that even more vigorous stirring is necessary during and after the addition of acid. In this way, the rise in temperature in all the experiments made by the authors was fairly steady up to the highest point, at which the temperature remained constant for 50 to 60 seconds. In the cases of linseed, cod,

seal, and menhaden oils, the tests had to be made with a mixture of 20 grams of these oils and 30 grams of olive oil of known specific temperature reaction. As a rule, an oil having a high iodine absorption has also a high specific temperature reaction, but the rise is not always directly as that in the former. The reason the specific temperature reaction cannot be depended on with the same assurance as the iodine value is that it shows, in some cases, large variations for the same class of oils.

Valenta's Test.—The authors conclude from the results of their experiments that this test is surrounded with too many conditions to be of any practical value in the general analysis of oils.

Oleïc Acid.—Although the percentage of free acid cannot be looked on as a constant, the authors consider that it serves a purpose in indicating to some extent the condition of the oil, and shows how little, if at all, a high free acidity affects the results of analysis.

D. B.

Detection of Rosin Oil in Fatty and Mineral Oils. By A. Grittner (*Zeit. ang. Chem.*, 1891, 265).—The original process proposed by Storch has only a limited application, as, when sulphuric acid is added to the solution of the oil in acetic anhydride, train oil gives a red colour, whilst with cholesterol, present in many fatty oils, a violet one is produced. With dark-coloured mineral oils, the process fails altogether. Morawsky has modified the process by using a weaker acid of 1·53 sp. gr. Holde also made use of this acid (without the acetic), but of late, he has increased the strength to 1·624 sp. gr., as with the weaker acid the violet-red colour takes a long time to develop. The author found that when mixing rape oil with 1 per cent. of rosin oil, the adulteration may be easily detected by Holde's original or modified process; but Morawsky's method was still more delicate, as it showed ½ per cent. Black rosin oil did not give such a characteristic reaction as was observed with oils of a lighter colour. Train oils, before being tested, must be shaken with alcohol, and the alcoholic solution tested for the rosin oil. The reaction is best observed by allowing sulphuric acid to run down the side of the test tube; if rosin oil be present, a red or violet ring will form at the point of contact. With dark-coloured oils, Holde's method is the best; but with light-coloured train oils, Morawsky's process is preferable. As the reaction is also caused by colophony and shellac, the absence of these substances must be ascertained, and should they be present, it is necessary to saponify the oil and to test the unsaponifiable portion. For dark mineral oils, it is advisable to use an acid of 1·53 sp. gr., as the use of a stronger acid often causes a dark-yellow coloration, which renders the reaction less characteristic. Samples of rosin oil examined by the author gave the reaction with this acid just as plainly as with the 1·624 sp. gr. acid.

Schädler remarks that train oil mixed with syrupy phosphoric acid (5—1) gives a red colour, which gradually turns very dark, and is even noticed in mixtures containing only 1 per cent. of the oil. The author never succeeded in obtaining this reaction, and only noticed a dirty-brown colour. The reaction depends on the nature of the rosin oil. The author occasionally succeeded in detecting

an admixture of 5 per cent., but often could not find it at all. The phosphoric acid process is therefore not to be recommended.

L. DE K.

Estimation of Fat in Milk. By E. GOTTLIEB (*Landw. Versuchs-Stat.*, **40**, 1—27).—The method is a modification of Röse's method (Abstr., 1888, 1135), and is carried out as follows:—A weighed amount of milk (about 10 grams) is poured into a measuring cylinder (40 cm. high), exactly divided into 0·5 c.c. The milk is shaken, first with 10 per cent. aqueous ammonia (1 c.c.), and again, after the addition of alcohol (95° Tralles; 10 c.c.); ether (25 c.c.) is then added. The cylinder is closed with a good cork, which has been wetted, and shaken a few times; light petroleum (25 c.c.) is added, the whole shaken and then left for at least six hours. The volume of the upper layer—a solution of fat in ether and light petroleum—is read, and most of it transferred by means of a fine pipette to a weighed flask, when it is evaporated at a low temperature, the flask and residue dried for 1—2 hours at 100° and weighed. If free from foreign matters, the fat remains as a perfectly clear oil. The weight of fat is calculated to the volume of extract, and to the weight of milk used. The chief difference between the above method and Röse's is that the volumes of milk and alcohol are about the same; the result being that the lower layer has a higher sp. gr., and that the upper layer contains hardly any alcohol.

The method may be further simplified. The milk is measured in a 10 c.c. Geissler pipette, instead of being weighed, and treated as described above. The total volume will be 70·5 c.c.; the upper layer being 53 c.c., and the lower 17·5 c.c. If the pipette used to remove the extract is so adjusted in a cork that it will take out just 51·5 c.c., the weight of residue in milligrams multiplied by 10 will give the percentage of fat in the milk. 10 c.c. of milk weighs 10·33 grams, so that 51·5 c.c. of extract (out of 53 c.c.) corresponds with 10 grams of milk.

With regard to the reagents, normal (or even weaker) potash and soda solutions may be used instead of ammonia. The light petroleum is obtained from commercial petroleum after treatment with sulphuric acid; it boils at about 80°; sp. gr. = 0·671 at 15°. The addition of light petroleum causes the complete separation of the water and a nearly complete separation of the alcohol, as well as the small amounts of matter dissolved in them. This is of much importance, as it is difficult to completely dry fat which contains a little water. The fat is always more or less slightly coloured, according to the feeding of the cow, and when kept readily crystallises. The fat extracted in the usual way is white, and will not readily crystallise. The fat gives no ash when burnt, and is free from nitrogen, and the only foreign substance which could be detected was a small amount of a glyceride of the formula $C_{18}H_{36}O_2$ or $C_{20}H_{40}O_2$, which melts at 75—80°. The milk fat was further examined, and the following results obtained: sp. gr. = 0·936 at 13°; the sp. gr. of fat extracted in the usual manner being 0·943. A determination of the saponification number by Koettstorfer's method showed that 1 gram of the fat required 233 milligrams of

potash, which is near the number obtained by Koettstorfer for pure butter fat. The examination for volatile acids, by Reichert and Wollny's method, showed that, using 5 grams of fat, 28·7 c.c. of decinormal baryta was required; fat obtained by the extraction method requiring 29·8 c.c. The fat showed a normal refractive power.

The results of many analyses made by the method, together with results obtained by Soxhlet's method, and by weighing, show that the method is trustworthy, the results agreeing among themselves even better than those obtained by the other two methods. The method is, moreover, very easily and quickly carried out; the author did 30 analyses in one day, a number which is not to be considered as a maximum.

One advantage in the method is that, owing to alcohol being an antiseptic, the milk, after the addition of alcohol, may be kept in an ordinary bottle for six months before the analyses is completed.

The cylinder employed for the analysis may also be used for estimating fat in cream, butter, and finely-powdered cheese.

N. H. M.

The Lactocrite compared with other Methods for Estimating Fat in Milk. By L. F. Nilson (*Bied. Centr.*, **20**, 789; *Chem. Zeit.*, 1891, No. 37).—The estimation of fat by this process does not always give trustworthy results, especially when more or less of the cream has been removed. This is due to the action of the glacial acetic acid and sulphuric acid mixture on the fat. Good results are obtained by the employment of a mixture of ethylidene-lactic acid (90 c.c.) and hydrochloric acid (10 c.c.); the results are then very exact whether the milk is rich or poor in fat.

Kaolin burnt at a high temperature is preferable to pumice, &c., for the absorption of liquids which have to be extracted, and it can always be used again after re-ignition. Adams' method gives concordant and trustworthy results, provided the paper is thoroughly extracted with ether before it is used. The areometric method gives too high results when employed with milk containing under 2·5 per cent. of fat; with milk richer in fat, the results are not uniform, being sometimes too high and sometimes too low. The method is not so good as the gravimetric method (when kaolin or filter-paper are used) or the lactocrite method (compare Abstr., 1890, 1346).

Milk Analysis. By J. Szilasi (*Chem. Zeit.*, **14**, 1202—1203; see this vol., p. 517).

Soap Analysis. By J. Pinette (*Chem. Zeit.*, **14**, 1442).—The author proposes a simple process for the analysis of soap, which, however, involves the use of Röse's milk fat burette.

The analysis is carried out as follows:—2 grams of the sample is dissolved in boiling neutral alcohol, and any insoluble matter is filtered off and tested if required. The filtrate is mixed with a drop of phenolphathaleïn solution, and if this should cause a reddening, the free alkali is estimated by means of N/10 sulphuric

acid. The liquid is now diluted with water to about 80 c.c. and put into the burette. After cooling, 10 c.c. of normal sulphuric acid is added, and then a mixture of equal parts of ether and light petroleum up to nearly the top division. After thorough shaking, the whole is allowed to remain quietly for some time, and the volume of the two layers is recorded. For the estimation of the fatty acids, 25 c.c. of the ethereal layer is pipetted off and evaporated in a tared basin. If desired, the residue may be dissolved in alcohol and titrated with N/10 alkali. To estimate the combined alkali, 25 c.c. of the aqueous layer is taken, and the excess of acid is titrated with N/10 soda. If the soap is supposed to contain both potash and soda, the alkalis may be weighed as mixed sulphates, and their relative proportion calculated from the sulphuric acid. Allowance must, of course, be made for the amount of soda introduced during the titration. The author claims the following advantages for his process :—The troublesome washing and collecting of the fatty acids is avoided, and there is plenty left of both ethereal and aqueous layers in case of an accident. L. DE K.

Assay of Bees' Wax for Vegetable Wax. By H. RÖTTGER (*Chem. Zeit.*, **14**, 1442—1443, 1473—1474).—The author criticises the various processes from time to time proposed. *Rabineaud's Method.*—1 part of wax is shaken with 50 parts of ether until the mass is thoroughly disintegrated. The insoluble portion is collected on a weighed filter, washed with ether, air-dried, and weighed. If the sample is pure, 50 per cent. remains undissolved ; but, suppose it were all vegetable wax, only 5 per cent. of insoluble matter would be found. In regard to this process, Dullo remarks that it is not strictly the case that Japan or vegetable wax is always soluble in ether. There certainly are commercial vegetable waxes which are soluble in ether, but six different samples have been met with which behaved almost like pure bees' wax.

The author repeated the experiment, and tested four samples of Japan wax. Only one gave an unweighable trace of insoluble matter, but the other three completely dissolved in ether. As, however, other wax adulterants, such as stearic acid, paraffin, rosin, tallow, are also soluble in cold ether, the ether test cannot be depended on without further confirmation.

According to Dullo, the best way to test for Japan wax is as follows :—10 grams of the sample is boiled with 120 c.c. of water and 1 gram of soda and potash for *one* minute. If the comparatively easily saponifiable Japan wax is present, a soap is formed, which will more or less solidify on cooling. Pure wax is not affected. The author, however, finds this process to be absolutely useless, as pure wax also gives an emulsion.

According to Hager, Japan wax is sure to be present when the sample, which must be completely soluble in chloroform, has a sp. gr. above 0·980. According to Mène, the adulteration with Japan wax can be detected only by determining the sp. gr., not by taking the fusing or solidifying point.

According to another process by Hager, the fraud is easily detected

by boiling 0·5 gram of borax with 8 c.c. of distilled water and 0·4 gram of the sample. The milky liquid gradually separates into a clear, watery liquid with the wax floating on the top, but when Japan wax is present, it gelatinises more or less. The author tested this process with pure wax, and noticed a clear, watery layer, an emulsion, and a solid mass on the top. In testing for foreign admixtures such as Japan wax, tallow, stearic acid, and rosin, the process is generally very uncertain, as the separation in layers does not always take place as readily as one may think. Stearic acid or rosin may, however, be readily recognised. If the amount of the former is as little as 5 per cent., no solid cake is obtained, but, instead, a pasty emulsion, which, after a few days, separates slightly. In the case of rosin, the liquid also gets pasty, but does not separate at all. The author cannot, however, recommend the process for the detection of tallow or Japan wax, as it will only lead to serious mistakes.

A process lately recommended by the German Pharmacists Association is as follows:—If 1 gram of wax is boiled with 10 c.c. of water and 5 c.c. of sodium carbonate, the wax, after cooling, ought to float on a clear liquid; but if adulterated with Japan wax, stearic acid, or rosin, an emulsion is formed, which, even after remaining for a day, shows no inclination to separate. The author finds that when wax is adulterated with the said substances, or with tallow, a solid cake is obtained, besides an emulsion and a clear liquid. The emulsion is largest when rosin is present, and least in presence of tallow. In conclusion, the author states that by this process, 2 per cent. of Japan wax, stearic acid, or rosin may be detected by the abnormally large emulsion. Tallow does not show well under 5 per cent.

L. DE K.

Salicylsulphonic Acid as a Test for Albumoses and Peptones. By J. A. MACWILLIAM (*Brit. Med. J.*, **1**, 1892, 115; compare Abstr., 1891, 872).—The precipitate produced by adding salicylsulphonic acid to heat-coagulable proteïds (albumin, globulin, myosin, &c.), or to derived albumins (acid-albumin and alkali-albumin) does not dissolve on heating, but becomes coagulated. If it is added to a solution of a primary albumose (proto-albumose or hetero-albumose), the precipitate dissolves on heating, and reappears on cooling. If it is added to a solution of deutero-albumose, this reaction does not take place unless a considerable amount of neutral salt, such as twice its bulk of saturated ammonium sulphate solution, is added also.

True peptone gives no precipitate, unless the solution is fully saturated with ammonium sulphate; the occurrence of this precipitate is stated to be a more delicate test for peptone than the biuret reaction. The precipitate readily dissolves on the addition of a little water or glycerol; it also clears up on heating, and reappears on cooling.

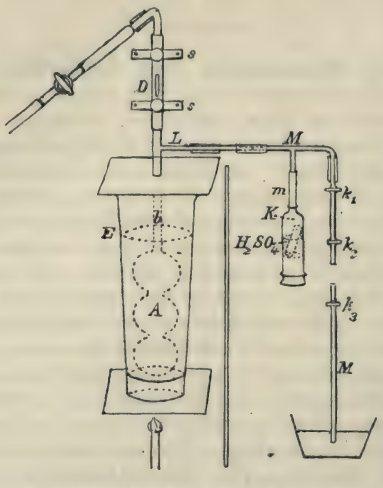
General and Physical Chemistry.

Electrocapillary Phenomena and Differences of Contact Potential. By Gouy (*Compt. rend.*, **114**, 22—24).—Amalgams containing 0·1 per cent. of zinc, cadmium, lead, tin, or bismuth, or 0·03 per cent. of silver, were compared with pure mercury, the conducting liquid being water acidified with sulphuric acid. In a system consisting of non-polarised mercury, water acidified with sulphuric acid, and a more or less polarised amalgam (0·1 per cent. of foreign metal), the superficial tension of the amalgam is a function of the apparent difference of potential δ between the amalgam and the mercury, and this function remains the same if the amalgam is replaced by mercury. This result is a very close approximation to the truth, although the function is not known for amalgams through so wide a range as for mercury. Adopting the views of Helmholtz, it follows that the difference of contact potential between mercury and amalgams containing 0·1 of the other metal is either *nil* or is very small. Amalgams containing a lower proportion of mercury behave differently. For example, the difference of potential between mercury and a solution of 1 part of Darcet's alloy in 4 parts of mercury is +0·15. C. H. B.

Determination of Vapour Densities under Diminished Pressure. By C. Schall (*J. pr. Chem.* [2], **45**, 134—144).—The method is based on the observation that, if gas be evolved in a uniformly-heated bulb, fitted with a capillary and manometer, the rise in the pressure is independent of the place at which the evolution of gas takes place, and is exactly proportional to the amount of gas or vapour produced if the capacity of the space shut off by the manometer can be considered constant.

The pressure, h, due to the evolution of carbonic anhydride from a known weight of pure sodium carbonate G and dilute sulphuric acid is observed, and also the pressure h', due to the vaporisation of a know weight g' of the substance, whose vapour density is to be determined. The density D is then calculated by the formula

$$\text{I.}\quad D = \frac{g' \times h \times 106 \times 1{\cdot}528}{h' \times G \times 44} = \frac{g' \times h \times 3{\cdot}682}{h' \times G},$$

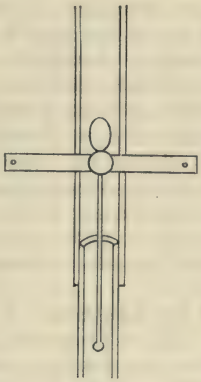


and the molecular weight $M = 28{\cdot}87 \times D$.

$$\text{II.}\quad \therefore M = \frac{g' \times h \times 106{\cdot}3}{h' \times G}.$$

By using equal quantities of carbonate and the substance, g' and G are eliminated from the above equation.

The apparatus consists of a fairly thick-walled bulb A, of about 150 c.c. capacity, twice contracted to hinder the diffusion of the vapour of the substance into the neck b, and fitted with a side tube L. The bulb is connected by means of the tubing D with the air-pump,



the connecting tube being furnished with a glass tap. s and s' are two screw clips, the upper one to close the apparatus; the lower one

to support the small tube containing the substance whose vapour density is required. The manometer M is 3—4 mm. in internal diameter, and dips into a vessel of mercury, having an area of at least 12—20 cm. The bell-tube K is connected by an india-rubber tube m with the manometer tube, and is closed below by a rubber stopper. It serves for the decomposition of the carbonate. The bulb A is suspended by a clamp in a high, narrow beaker, containing a depth of 3—4 cm. of a liquid, by the vapours of which the bulb can be conveniently heated. The top of the bulb is at about 8—9 cm. from the edge of the beaker, which is covered with a paper or asbestos card. The sides of the bulb are about 5 mm. from the sides of the beaker.

After testing the apparatus to see that it is air-tight and dry, the vapour density determination is performed as follows:—The substance whose vapour density is to be determined, contained in a small tube, is introduced into D, and K charged with the necessary quantity of carbonate and sulphuric acid is fastened in position. The pressure is brought to about 300—400 mm., and the top clip s is closed. Then the third, k_3, of the four rubber rings on M is placed so that its top edge is on a level with the mercury in the manometer. If the level of the mercury remains constant, the bulb is heated by boiling a liquid of known boiling point in the beaker, and the flame so regulated that the height of the vapour of the boiling liquid is constant at the level E. The mercury sinks from k_3, and when its height is constant the pressure is again brought to about 300—400 mm., and marked with k_3. If the mercury level does not keep constant, it is probably due to vapour given off from the substance whose density is to be determined. In this case the substance is put into a small bulb filled as full as possible, drawn out to a capillary point, and suspended in the lower clamp s', as shown in figure; then by bending the rubber tube

the capillary can be broken, and the clip being at the same time released, the substance falls into the bulb. If the level of the mercury is constant at k_3, the acid and carbonate are gradually mixed and

shaken until no more carbonic anhydride is evolved, and the mercury level is again constant. This level is marked with k_4, and the distance between k_3 and $k_4 = h$ is measured. The top clip s is then opened, and the pressure brought to the point at which the substance is to be vaporised. The clip is then shut, the mercury level marked with k_1, the substance allowed to fall into the bulb by opening s', and when the level of the mercury is constant it is marked with k_2, and the distance k_1 to $k_2 = h'$ is measured.

If the decomposition of the carbonate and the vaporisation of the substance take place under the same pressure, then formulæ I and II give correct numbers. But if the decomposition of the carbonate takes place under a higher pressure, the following correction must be made. If Dc is the corrected, and D the density calculated by formula I, then

$$\mathrm{D}c = \mathrm{D}\left[1 + \frac{lr^2\pi}{\mathrm{V}\cdot\frac{273}{273+\mathrm{T}} + v}\right],$$

when l = distance between k_1 and k_3 in centimeters; r half the internal diameter of the manometer tube in centimeters; $\pi = 3{\cdot}14$; V = volume of the bulb in cubic centimeters; T the temperature of the bulb; v the volume of the capillary bulb to k_1 in cubic centimeters.

If it is necessary to make the determination in an indifferent gas, the latter is led into the apparatus by means of a tube passing through D to the bottom of the bulb, and the air is allowed to escape through M. When all the air is expelled the tube is withdrawn, the substance quickly introduced, and the apparatus connected as before, with the air-pump. E. C. R.

Depression of the Melting Point by Phenol. By Juillard and Curchod (*Bull. Soc. Chim.* [3], **6**, 237—238).—Two values have been

given for the molecular depression of the melting point by phenol: that of Raoult, who gives 67·5 as the result of experiments made with phenol of melting point 37·8° on naphthalene, camphor, benzoic acid, and thymol, and that of Eykman, who gives 76. The authors, in experimenting with a synthetically prepared sample of phenol (m. p. 41·2), found that the molecular depression varies with the solvent substance; for water, β-naphthol, paratoluidine, aniline, nitrobenzene, phthalic anhydride, diphenic anhydride, α-naphthylamine, amyl alcohol, ricinic acid, and salol, the value 68·5 holds, whereas for normal ethereal salts, and particularly those of bibasic acids, such as methyl diphthalate, ethyl succinosuccinate, ethyl malonate, ethyl succinate, ethyl acetoacetate, the value is 75·81. The authors determined the depression in a long-necked, thick glass flask, of 40—50 c.c. capacity, by noting the solidifying point of the phenol after the addition of the other substance. T. G. N.

Absorption of Gases by Liquids. By L. W. Winkler (*Zeit. physikal. Chem.*, **9**, 171—175).—From his own experiments on the absorption coefficients of various gases in water, the author finds that the percentage decrease of the coefficient between 0° and 20° is approximately proportional to the cube root of the molecular weight of the gas, as may be seen from the following table:—

	Percentage decrease.	Cube root of mol. wt.	Ratio.
H_2	15·32	1·259	12·17
N_2	34·33	3·037	11·30
CO.....	34·44	3·037	11·34
NO	36·24	3·107	11·66
O_2.....	36·55	3·175	11·51

The author considers the change in the internal friction of the water to be the real cause of the decrease of the absorption with rise of temperature. If μ and μ_1 represent the internal friction of water, and β and β_1 the absorption coefficients of a gas at two temperatures, then, if m is the molecular weight of the gas,

$$\frac{\beta - \beta_1}{\beta} = \frac{\mu - \mu_1}{\mu} \frac{\sqrt[3]{m}}{k},$$

or

$$k = \frac{\mu - \mu_1}{\mu} \cdot \frac{\beta}{\beta - \beta_1} \cdot \sqrt[3]{m}.$$

The values of k for the gases above mentioned between 0° and 20° are approximately the same. The coefficients of absorption, calculated by means of this constant from the internal friction of water up to 60°, agree very well with the experimental numbers. J. W.

Measurement of Osmotic Pressure. By G. Tammann (*Zeit. physikal. Chem.*, **9**, 97—108).—The osmotic pressure of salt solutions, for example, of potassium nitrate, has been observed to be smaller than that required on the electrolytic dissociation theory of Arrhenius. This the author shows to be due to the fact that the membrane of

copper ferrocyanide, employed in making the observation, is not perfectly impermeable to the salt (or its ions), and thus the osmotic pressure appears smaller than it really is. If the rate of diffusion of the salt through the membrane is determined, a correction may be applied which brings experiment and theory into harmony.

The author points out that the membrane of copper ferrocyanide may be obtained in two modifications. That prepared from dilute solutions of copper sulphate and potassium ferrocyanide is, when fresh, transparent and extremely thin, allows water to pass through it freely, and is extensible like a thin film of rubber. The membrane prepared by allowing the solutions to remain for a long time in contact with each other on the surface of a porous tile, is opaque, dark-brown in colour, much less permeable to water, and very little extensible. The presence of sodium sulphate in the copper sulphate solution conditions the formation of the second class of membrane. Good results are obtained in depositing membranes within porous cells by taking the solutions much more concentrated than those recommended by Pfeffer, namely, a normal solution of copper sulphate and one-third normal solution of potassium ferrocyanide.

A new method of measurement of the osmotic pressure in solutions is proposed by the author. If two solutions having different osmotic pressures are on the opposite sides of a semipermeable membrane, water will flow into the solution with greatest osmotic pressure. This flow may be counterbalanced by subjecting the hyperosmotic solution to external pressure equal in amount to the difference between the osmotic pressures of the two solutions. An osmotic apparatus on this principle is figured and described in the paper; tables of the results obtained are also given. J. W.

Law of Thermodynamical Coincidence and its Application to the Theory of Solution. By L. Natanson (*Zeit. physikal. Chem.*, **9**, 26—42).—According to Van der Waals, if pressure, volume, and temperature are expressed in terms of their critical values, one and the same equation between any of the values will hold for all homogeneous substances. The author constructs orthobaric curves for carbonic anhydride, nitrous oxide, ether, methyl and ethyl alcohols, expressing temperature and volume in terms of their critical values, and finds that under these circumstances the curves do very nearly coincide. The extension of Van't Hoff's theory of solution by Masson (Abstr., 1891, 791) renders it probable, moreover, that the law of Van der Waals applies equally both to solutions and to gases, and Masson has shown that the orthobar for aniline and water resembles that of alcohol. The author, therefore, constructs orthobaric lines for all pairs of liquids for which data are obtainable. These are phenol and water, isobutyl alcohol and water, aniline and sulphur, and allyl-thiocarbimide and sulphur. When the temperatures and volumes are given in terms of their crititical solution values, the orthobars obtained are found to be coincident, and, on comparing the general orthobar for the solutions with that for gases and vapours, the identity of the two is, in spite of certain differences, rendered immediately apparent. H. C.

Organic Liquids as Solvents of Metallic Salts. By A. Étard (*Compt. rend.*, **114**, 112—115).—The percentage solubilities of mercuric and cupric chlorides in various aliphatic alcohols, acids, ethereal salts, ethers, and ketones are plotted out as functions of the temperature, the observations ranging between −60° and +210°.

The curves of solubility of mercuric chloride in water and methyl and ethyl alcohols have the same general character, all three becoming steeper as the temperature rises, and at a definite temperature, which decreases with increase of molecular weight, changing into straight lines of much slighter gradient, passing when produced through the point corresponding with the melting point of the pure chloride. The experiments with water could not be carried above 150°, owing to the dissociation of the salt, of which the solution at that point contained 80 per cent. With propyl alcohol, the whole curve is rectilinear, and the portion below the point of inflexion is not so steep as that above, and this is the case also with acetic acid, whilst with ethyl acetate the solubility between −60° and +40° is constant, the solution containing about 40 per cent. With isobutyl alcohol and with ethyl ether, the observation extends only to a single rectilinear branch of the curve, which, in the case of the latter, has but a very slight gradient. The curve of solubility of mercuric chloride in ethyl formate is a horizontal straight line as far as 48°—the extent of the observations—whilst with acetone the curve is an inclined straight line up to 0°, and horizontal above that temperature.

The curves of solubility of mercuric chloride in isobutyl alcohol and acetic acid tend to pass through the point corresponding with the boiling point of the pure chloride, and thus seem to establish a direct link between the dissolved and gaseous states.

The curves of solubility of brown, anhydrous cupric chloride in ethyl, propyl, isopropyl, and butyl alcohols, and in acetone, and ethyl formate and acetate are in all cases straight lines without points of inflexion; but the observations extend over temperatures ranging only between −15° and +75°. In the cases of allyl alcohol, acetone, and the ethereal salts, the solubility diminishes as the temperature increases.

The curves of constant solubility mentioned above, and first described in a previous note (this vol., p. 397), were found in several instances to correspond with simple molecular relations between the solid and the solvent. Mercuric chloride, for example, dissolves in ethyl acetate between −50° and +35° in, practically, the proportion $2HgCl_2,9C_4H_8O_2$; and copper chloride, again, dissolves in methyl, propyl, and allyl alcohols in proportions represented by $CuCl_2,7MeOH$; $CuCl_2,5Pr^{\alpha}OH$; and $CuCl_2,8C_3H_5{\cdot}OH$. With methyl alcohol, indeed, an actual crystalline compound, $CuCl_2,2MeOH$, may be prepared by heating the solution of the chloride in the cold alcohol; the brown colour changes to green, and the compound is thrown down as a green, crystalline precipitate, which, when redissolved, forms a green solution. This change of colour occurs also with other of the solvents mentioned. Jn. W.

Theory of the Solubility Curve. By C. M. van Deventer and H. J. van de Stadt (*Zeit. physikal. Chem.*, **9**, 43—56).—In this paper,

the authors discuss the question in how far it is possible to deduce a general law for the connection between solubility and temperature. They discuss the differential equations given by Le Chatelier and Van't Hoff for sparingly soluble substances and by Roozeboom for more soluble salts, and find that none of these equations can be integrated so as to yield a general curve of solubility. They show also that Le Chatelier's law of proportionality between the variation in solubility and heat of solution does not hold generally, and can only be applied in a limited number of cases. H. C.

Theory of Residual Chemical Affinity as an Explanation of the Physical Nature of Solutions. By S. U. Pickering (*Ber.*, **24**, 3629—3647).—The author draws attention to objections raised by himself and others against the theory of electrolytic dissociation in aqueous solutions, and to the fact that his own researches all tend to prove the existence of hydrates in such solutions. He offers an explanation of the facts on which the theory of electrolytic dissociation is chiefly based, taking the theory of residual affinity as his starting point, in the hope that in this explanation, which also takes into consideration the existence of hydrates, there may be eventually found a ground for the reconciliation of the physical and chemical theories of solution.

If the units of valency possessed by each atom are regarded as equal in value, residual affinity may be taken as resulting from incomplete saturation of these units when combination takes place between different atoms. In virtue of the residual affinity of the molecule so formed, it will be capable of combining with other molecules also having residual affinity, with the formation of compounds of a more or less definite character. Hence the dissolution of salt molecules in water with the formation of hydrates, and from the difference in the amount and nature of the residual affinity possessed by different substances, their differences in solubility. If the amount of water present is very large, the residual affinity of each salt molecule may be regarded as exercising an influence over that of a large number of water molecules, but its influence on each separate water molecule would be only small. This influence might, therefore, be readily transferred from molecule to molecule in the solution, the salt molecule thus having a certain freedom of motion comparable with that obtaining in the gaseous state. From this follows the application of gaseous laws to dilute solutions.

A salt molecule which, in virtue of its residual affinity, is combined with a number of water molecules, might be incapable of passing through any porous membrane, in consequence of the size of the complex hydrate, although the porous substance might be permeable by molecules either of the salt alone or of water alone. This view explains the behaviour of so-called semipermeable materials, such materials being probably in reality permeable by molecules of the pure solvent or of the pure dissolved substances. The author finds, in fact, by experiment, that if a solution of alcohol and water is put into a porous vessel and this placed, first in pure water and afterwards in pure alcohol, in the first instance water, and in the second instance

alcohol, enters the vessel, but in neither case does any of the solution pass out, although the material of the vessel is obviously permeable by the molecules of either of the substances present in the solution.

In cases where the salt molecules have very great residual affinity, the attraction of the water molecules for the salt may become nearly equal to that of the component atoms of the salt for one another. A nearly equal distribution of the affinities of the components of a solution would thus take place, and the constituent parts of the salt molecule would have a greater freedom of motion than would otherwise be the case. The freedom of motion would enable an interchange of the positive or negative radicles to take place readily under the influence of a determining force, such as an electric current, and would supply the conditions necessary for electrolysis. The conductivity of a solution would therefore depend on the number of salt molecules present in the above condition, and not, as assumed by the dissociationists, on the number of molecules actually present in a dissociated condition. H. C.

Equilibrium of Double Salts of Lead and Potassium Iodides with their Aqueous Solution. By F. A. H. Schreinemakers (*Zeit. physikal. Chem.*, **9**, 57—77).—This investigation was undertaken with the object of testing the deduction made by Roozeboom from Gibbs' rule for equilibrium between several phases, in the special case of the equilibrium of double salts with their solutions (compare Abstr., 1888, 1147 and 1164). The deductions of Roozeboom have been in every way confirmed. The double salt of lead and potassium iodides crystallises with $2\frac{1}{2}$ mols. H_2O. When brought into contact with water, it can behave in three different ways:—Below 144°, it deposits lead iodide; between 144° and 203°, it is soluble without decomposition; and above 203°, it deposits potassium iodide. At 203°, the solution still contains more than $2\frac{1}{2}$ mols. H_2O, and the melting point of the salt is not yet reached. No dehydration seems to take place below 203°. This salt is remarkable as being the first double salt which has been found to dissolve between wide limits of temperature without decomposition. H. C.

Solubility of Mixed Crystals. By W. Nernst (*Zeit. physikal. Chem.*, **9**, 137—142).—The author applies the osmotic pressure theory to the discussion of the solubility of mixed crystals, which, after Van't Hoff, he treats as solid solutions. He develops equations for the case of isomorphous salts with water as solvent, in which case, of course, electrolytic dissociation has to be taken into account. An application to Roozeboom's observations (this vol., p. 266) on the solubility of thallium chlorate containing potassium chlorate leads to the conclusion that the molecules of the latter substance, in the mixed crystals, must be mostly $KClO_3$; and that the maximum external work obtainable from the expansion by a definite fraction of its volume of a gram-molecule of potassium chlorate in dilute solid solution in thallium chlorate is approximately the same as that obtainable from the expansion of a perfect gas at the same temperature by the same fraction. J. W.

Maximum Tension with which Hydrogen is set free from Solutions by Metals. By G. TAMMANN and W. NERNST (*Zeit. physikal. Chem.*, **9**, 1—11).—When a metal is brought into contact with an aqueous solution, it frequently happens that the metal dissolves, and an equivalent amount of hydrogen is liberated. This reaction is attended by a considerable increase in volume, and, according to the known laws of the influence of pressure on chemical change, it should be possible by applying a sufficiently great pressure to bring about a reversal of the reaction, and precipitate the metal by forcing compressed hydrogen into the solution. There will, however, also be a particular pressure for which the solution of the metal and hydrogen will be in equilibrium with one another, and this pressure may be termed the maximum tension of the liberated hydrogen. This pressure is a measure of the maximum work obtainable by dissolving metals in acids, and since the E.M.F. of so-called reversible cells is a measure for the same quantity, it follows that the above maximum tension is intimately related to the E.M.F. of reversible cells.

If p is the maximum tension, and P the atmospheric pressure, the work which could be obtained from 2 grams of hydrogen by liberation and transference from pressure p to pressure P would be $A = pv + RT \log \frac{p}{P}$, or if the volume is taken in litres and the pressure in atmospheres, $A = 0{\cdot}0819\ T\ (1 + \log \frac{p}{P})$. Therefore the work which could be obtained from a Daniell cell by the dissolution of a gram-molecule of zinc and the precipitation of a gram-molecule of copper is $A_1 - A_2 = 0{\cdot}0819\ T \log \frac{p_1}{p_2}$. This work is equal to the E.M.F., and introducing the ordinary units of measurement we get the expression $0{\cdot}430\ T \times 10^{-4} \log \frac{p_1}{p_2}$ volt for this quantity, containing the directly measurable quantities p_1 and p_2.

In order to test the above relation, the authors endeavoured to measure the pressures under which hydrogen ceased to be evolved from solutions of metals in acids. The experiments were, however, only partially successful, and do not afford definite confirmation of the theoretical deductions. H. C.

Colour and Constitution of Compounds. By M. SCHÜTZE (*Zeit. physikal. Chem.*, **9**, 109—136).—The author has studied a large number of coloured compounds, both organic and inorganic, with view to tracing relations between their colour and constitution. His results may be summed up in the following rules:—

1. The passage of absorption from violet to red in the spectrum usually conditions the following changes of colour: greenish-yellow, yellow, orange, red, reddish-violet, violet, bluish-violet, blue, bluish-green, &c. Going through the colours in this order is called "lowering the tint" by the author; in the opposite order, "raising the tint."

2. Definite atoms or groups of atoms on entering a molecule cause, for compounds of the same chromophore in the same solvent, a

characteristic rise (" bathochromic groups,") or fall (" hypsochromic groups "), of the tint.

3. The hydrocarbon radicles are always bathochromic; consequently in homologous series the shade always deepens as the molecular weight rises.

4. The same is observed in the periodic groups of the elements as the atomic weight increases.

5. Addition of hydrogen causes a raising of the tint.

6. The rise or fall of the tint by substitution of hypsochromic or bathochromic groups, or by addition or loss of hydrogen, is the greater, the nearer the atoms affected by the chemical action are to the chromophore. Judging by this rule the substituents in the para-position in di-derivatives of benzene would sometimes appear to be nearer to each other than substituents in the meta-position.

7. These rules are only valid for monochromophoric compounds, and for such dichromophoric compounds as have two similar active groups influenced by neighbouring atoms in the same way. The colour of an asymmetrical diazo-compound, Y·A·X·A·Z, is approximately the same as that of a mixture of the two symmetrical compounds, Y·A·X·A·Y and Z·A·X·A·Z. J. W.

Tabular Expression of the Periodic Relations of the Elements. By H. Bassett (*Chem. News*, **65**, 3—4, 19).—The author has devised a tabular arrangement of the elements, which he urges removes some of the anomalies of Mendeléeff's table.

Lecture Experiments on the Diffusion of Gases. By H. Biltz (*Zeit. physikal. Chem.*, **9**, 152—157).—An arrangement is described by means of which a glass bulb containing bromine may be broken on the bottom of a covered glass cylinder filled with hydrogen. The bromine vapour diffuses upwards into the hydrogen much more rapidly than it does in a similar cylinder filled with air.

There is further the figure and description of an apparatus designed to show the diffusion of hydrogen through a red-hot iron tube, which is impervious to other gases. The diffusion is indicated by a manometer registering the pressure within the iron tube. J. W.

Oxy-hydrogen Gas. By V. Meyer (*Ber.*, **24**, 4233—4243).—The author describes with the aid of cuts a series of lecture experiments illustrative of the various ways in which combination of the hydrogen and oxygen in electrolytic gas can take place.

A stout glass cylindrical vessel, 9 cm. long and 3 cm. wide, having a tube of 2 mm. diameter and 22 cm. in length attached to one end, is filled with electrolytic gas; a portion of the gas, a few cm. from the end of the tube, is aspirated with the mouth by a capillary tube, and the end, thus filled with air, then quickly sealed in the blowpipe. The cylinder is now held in a horizontal position by a clamp and heated by a Bunsen's burner, two plates of glass being placed on either side of it for the protection of the lecturer and audience. The explosion takes place at the temperature at which the glass commences to soften, and is accompanied by loud detonation, the vessel being

sometimes shattered, but frequently only bulged out or drawn in at the heated portion; the point of the tube is, however, always broken off by the explosion.

If some platinum wire of such a thickness that 10 cm. weighs 0·066 gram be placed in a cylinder at each end of which capillary tubes are attached, these being subsequently sealed in the blowpipe, on heating the cylinder as above, the platinum wire suddenly glows, a flame vibrates within the cylinder, and combination takes place almost silently, and at a temperature much below that at which the glass softens.

When glass cylinders provided with capillary ends are filled with pure electrolytic gas, and after fusing the ends, heated in the vapour of boiling phosphorus pentasulphide for 1—2 hours, and the ends then broken off under water, the quantity of entering water shows the amount of combination of the gaseous mixture which has taken place (see *Annalen*, **264**, 85; Abstr., 1891, 1153).

It has been shown by the author and Krause (*loc. cit.*) that the temperature of explosion of electrolytic gas lies between 518° and 606°; if one of the last-mentioned cylinders, filled with the gas and sealed, be held by one of the capillary tubes in the hand, which is protected by a glove, and then plunged into boiling zinc chloride, combination takes place with the production of flame, but without detonation; the cylinder is not injured, but the point of the capillary tube is frequently shattered off. For the success of this experiment, it is necessary that the zinc chloride should be in violent ebullition, and it is best heated in a thin sheet-iron vessel, with a "No. 15 burner," together with the point of the blowpipe flame. When electrolytic gas is passed in a stream through a cylinder surrounded by boiling zinc chloride, only slow combination of the gaseous mixture occurs, and this is accompanied by a cherry-red glow, which is best observed in a dimly-illuminated room.

The influence of foreign substances on the combination of oxygen and hydrogen in the mixture is seen by the following experiments:—A cylindrical glass vessel, with tubes at each end, is coated with silver on its inner surface, and after thoroughly cleaning and drying, capillary tubes are attached to the ends; it is then filled with electrolytic gas, the ends sealed, and the cylinder suspended in boiling aniline vapour for two hours, when combination to the extent of about 90 per cent. of the contained gas is found to have taken place; whilst when a similar experiment is carried out in an unsilvered glass vessel, no combination whatever is found to have occurred. The author promises further details as to the temperature of combination of oxygen and hydrogen in electrolytic gas in a paper to be published in the *Annalen* in conjunction with Askenasy. A. R. L.

A Lecture Experiment. By T. Wilm (*Ber.*, **25**, 217—219).—The occlusion of hydrogen by palladium can be very conveniently shown in the following manner:—A glass U-tube, on the bottom of which is blown a small bulb, intermediate between the two limbs, is connected by one limb, which is bent at right angles near the top, with a drying bottle, through which hydrogen from a Kipp's appa-

ratus is passing; on the other limb is fastened a good, glass stop-cock by means of thick-walled, india-rubber tubing, diffusion being prevented as much as possible by bringing the two glass surfaces into contact. Palladium sponge (3 to 4 grams) having been placed in the bulb of the U-tube, the metal is first heated in a stream of dry hydrogen, and then the whole tube is carefully warmed with an ordinary burner, in order to expel any water that may be formed. If, after the air has been expelled, and while the palladium is still hot, a light is applied to the hydrogen escaping from the stop-cock, a small, intermittent flame is produced; only by almost closing the cock and turning on a rapid stream of hydrogen is it possible to obtain a small, steady flame. After the palladium sponge has been heated a little more strongly, but still far below a red heat, for a short time longer, the heating is discontinued and, after a few seconds, the stop-cock is closed. The occlusion of the hydrogen then commences; the hydrogen streams through the wash-bottle into the air-tight U-tube, and continues to do so for some minutes, until it ceases to be absorbed. If, now, the stop-cock is opened and the palladium again heated, the stream of hydrogen from the Kipp's apparatus remaining as at the commencement of the experiment, the escaping gas can be ignited at the stop-cock, and will burn with a large, steady flame, which, however, immediately becomes smaller, and quickly goes out if the heating of the palladium is discontinued.

F. S. K.

Inorganic Chemistry.

Complex Salts of Sulphurous Acid. By K. Barth (*Zeit. physikal. Chem.*, **9**, 176—219).—Röhrig and Schwicker have prepared two isomeric salts, $Na{\cdot}SO_2{\cdot}OK$ and $K{\cdot}SO_2{\cdot}ONa$, the former with two molecules of water of crystallisation, the latter with one. When these salts are dissolved in water, the solutions obtained are identical, and have in particular the same conductivity. This follows as an immediate consequence of the theory of electrolytic dissociation, for, according to it, the two salts should give the same products of dissociation in dilute solutions, namely, $\overset{--}{SO_3}$, $\overset{+}{K}$, and $\overset{+}{Na}$.

The double sulphites containing mercury as one of the metals, do not give the ordinary reactions of mercury salts; and Divers and Shimidzu pointed out that they were probably to be considered as salts of a mercury sulphonic acid $Hg(SO_3R')_2$. The electrolytic conductivity and the freezing point of their solutions confirm this view, all the evidence pointing towards a dissociation into three ions R′, R′, and HgS_2O_6.

The author has investigated in detail many cases of double compounds of the mercury sulphonates with other salts. These he finds to be for the most part complex salts, which in solution yield ions containing constituents derived from both the simple salts from which the compound is formed.

J. W.

Metallic Borates. By A. Ditte (*Compt. rend.*, **114**, 71—72).—A discussion with Le Chatelier on a question of priority (see this vol., p. 404). C. H. B.

Carbon. By W. Luzi (*Ber.*, **25**, 214—219).—A peculiar form of carbon can be obtained by heating a porcelain crucible, or crucible cover, in a Fourquignon-Leclercq's blast oven to the highest possible temperature (about 1770°), and then allowing a very smoky flame to play against the white-hot porcelain for 10—15 minutes; if the porcelain is unglazed, it has by this time become covered with graphite, but if glazed, it is coated with a light, lustrous deposit, hardly to be distinguished from a silver mirror. Some portions of this deposit adhere to the porcelain so tenaciously that they can be polished with a cloth; others become detached in the form of mirror-like facets of high lustre. If the loosened portions are pulled off, they curl up into rolls, similar in appearance to metal shavings; these rolls of carbon are exceedingly light, and stick to the fingers and other objects just like silver leaf does. This lustrous form of carbon is free from ash, and seems also to be free from hydrogen; it does not give the nitric acid reaction of graphite (this vol., p. 406), and is quite opaque.

The author has examined 17 varieties of naturally occurring "graphite;" nine samples gave the nitric acid reaction of true graphite, and eight samples did not; the latter must therefore be regarded as graphitite. The grey carbon, obtained by strongly heating the diamond in absence of air, does not give the graphite reaction. F. S. K.

Action of Carbon on Sodium Sulphate in Presence of Silica. By Scheurer-Kestner (*Compt. rend.*, **114**, 117—120).—In the preparation of glass or soluble silicates from alkali sulphate, silica, and carbon, the proportion of the latter is invariably in excess of that required by the usually-accepted equation $2R'_2SO_4 + C = 2SO_2 + CO_2 + 2R'_2O$. The course of the reaction was investigated by heating equal weights of sodium sulphate and silica with various proportions of wood charcoal in sealed Hessian crucibles, and collecting the evolved gases. It was found that the whole of the sulphur of the sulphate was expelled in the free state, and that the gases consisted of a mixture of carbonic anhydride and carbonic oxide. It would thus seem that the silica first decomposes the sodium sulphate, liberating sulphuric anhydride, which immediately splits up into sulphurous anhydride and oxygen, and that the carbon then decomposes the sulphurous anhydride, liberating sulphur, and forming the oxides of carbon. The final result may be represented by the equation $3Na_2SO_4 + 6SiO_2 + 5C = 3S + 4CO_2 + CO + 3(Na_2O,2SiO_2)$. Jn. W.

Lithium Nitride. By L. Ouvrard (*Compt. rend.*, **114**, 120—121).—When commercial lithium, containing 4·5 per cent. of nitrogen, together with silica and other impurities, is heated in an iron boat in a current of nitrogen, no noteworthy absorption takes place until a dull-red heat is reached; but at this temperature the metal becomes incandescent and swells up, forming a mass which is black and

spongy when cold, and appears to consist mainly of *trilithium nitride*, Li_3N. This substance reacts with water to form ammonia, scarcely any hydrogen being evolved, and, when heated in hydrogen, is completely decomposed into ammonia and metallic lithium. Jn. W.

Direct Combination of Nitrogen with Alkaline-earth Metals. By Maquenne (*Compt. rend.*, **114**, 25—26).—Amalgams containing 15 to 20 per cent. of barium, strontium, and calcium were prepared by electrolysing strong solutions of the chlorides, using mercury as the cathode, and, in the case of calcium, concentrating the product by distillation. When these amalgams are heated in an iron or metallic dish in a current of pure and dry nitrogen at a dull-red heat for half an hour until most of the mercury is expelled, and then for a few minutes at bright redness, nitrides of the alkaline-earth metals are obtained as brown products with a semi-metallic appearance. The barium compound, which is obtained the most readily of the three, sometimes forms yellowish, acicular crystals. The nitrides alter rapidly in moist air, and are decomposed by water with evolution of hydrogen and development of heat, ammonia and the hydroxide of the metal remaining in the liquid. The nitrides seem to be somewhat volatile.

The rapid combination between nitrogen and the metals of the alkaline-earths in complete absence of carbon or its compounds indicates the existence of considerable chemical attraction between them. C. H. B.

Magnesium Lead Bromide. By R. Otto and D. Drewes (*Arch. Pharm.*, **229**, 585—588).—A magnesium lead bromide,

$$PbBr_2,2MgBr_2,16H_2O,$$

similar to the double chloride and iodide (Abstr., 1891, 151, 984) is formed by dissolving lead bromide in a boiling concentrated solution of magnesium bromide, and may be obtained in crystals by allowing the solution to evaporate. It forms large, semi-transparent crystals, belonging probably to the monoclinic system; their hygroscopic nature, however, prevented a complete crystallographic examination. In water or in alcohol, the salt separates into its components.

With hydrogen sulphide, it behaves like the double iodide, and the lead is converted into sulphide; the double chloride does not so react.

The double bromide dissolves readily in dilute acetic acid. The water of combination separates at 140°. J. W. L.

Action of Ammonia on Cadmium Chloride. By W. Kwasnik (*Arch. Pharm.*, **229**, 569—572).—The action of ammonia on cadmium chloride in alcoholic solution is exactly similar to that of ammonia on zinc chloride (Abstr., 1891, 1157).

Anhydrous cadmium chloride was dissolved in ammonia; after filtering from the basic chloride, ammonia gas was passed into the solution until no longer absorbed, and the precipitate collected and dried at 50°. This salt, *ammoniocadmium chloride*, $Cd(NH_3Cl)_2$, is a white, crystalline powder, insoluble in ammonia, and resembles the zinc salt very closely.

When heated in a glass retort, ammonia is liberated, after which the residue melts, boils, and the distillate is obtained as a transparent, yellowish, glassy mass, which differs from the corresponding zinc salt only in its being less hygroscopic: its formula is

$$CdCl\cdot NH_3Cl.$$

It requires considerably less heat for its distillation than the zinc salt.

J. W. L.

Behaviour of Hydrogen towards Lead and other Metals. By G. Neumann and F. Streintz (*Monatsh.*, **12**, 642—660).—The authors have previously suggested (*Ann. Phys. Chem.* [2], **41**, 106, *et seq.*) that certain physical phenomena which occur at the negative plate of a secondary battery may be explained by the assumption that lead is capable of absorbing hydrogen. Attempts to prove that such is the case, under conditions which obtain in a secondary battery, have given no satisfactory results. When, however, hydrogen was passed over molten lead, the metal occluded only a small quantity, from 0·11 to 0·15 its volume, of the gas. Comparative experiments with other metals, in varying mechanical condition, showed their power of occlusion to be as follows:—Palladium, 502·35 times its volume; platinum, 6·48—49·30 times its volume; gold, 37·31—46·32 times its volume; copper, 4·78—4·81 times its volume; aluminium, 2·72 times its volume; iron, 9·38—19·17 times its volume; nickel, 16·85—17·57 times its volume; and cobalt, 59·31—153·00 times its volume. Silver does not appear to have the power to occlude hydrogen.

G. T. M.

Lead Chromate. By Lachaud and Lepierre (*Bull. Soc. Chim.* [3], **6**, 230—232).—A solution of lead chromate in warm binormal potassium hydroxide solution deposits, on cooling, orange-yellow, prismatic needles or silky tufts of basic lead chromate, $PbCrO_4,PbO$, which differ only in colour from those obtained by the fusion of lead chromate with potassium nitrate.

When lead chromate is boiled for a few minutes with strong potassium hydroxide solution (45 per cent.), dull, greyish-green scales of lead oxide are formed, of sp. gr. 9·51, and a basic chromate is often formed. Lead chromate, on fusion with potassium hydroxide, yields lead dioxide. An attempt to produce lead dichromate, by boiling together amorphous lead chromate (5 grams) with chromic anhydride (20 grams) and water (70 grams), was unsuccessful, but after a few minutes the whole of the lead salt becomes crystalline. Dark-red, orthorhombic crystals of melanochroïte, $2PbCrO_4,PbO$, of sp. gr. 5·81, are obtained when amorphous lead chromate (10—20 grams) is projected in small portions into a crucible containing fused sodium chloride (200 grams), and the contents maintained at a red heat for two hours; at the same time, orange crystals, of a compound $Pb_4Cr_5O_{16}$, resulting from the decomposition of lead chromate, are formed.

T. G. N.

Thallium Chromate. By Lachaud and Lepierre (*Bull. Soc. Chim.* [3], **6**, 232—235).—Thallium chromate is precipitated by potassium chromate from thallium sulphate solution as an amorphous,

lemon-yellow substance. A litre of boiling binormal potassium hydroxide solution dissolves 3·5 grams of thallium chromate, and, on cooling, deposits microscopic, six-faced prisms, ending in hexagonal pyramids. No basic chromate is formed, differing thus from the corresponding lead salt. Concentrated hot potassium hydroxide solution (31 per cent.) dissolves thallium chromate (18 grams per litre), which is almost entirely deposited as such on cooling. Similarly to the case of lead chromate, fused potassium hydroxide determines the formation of thallium sesquioxide, Tl_2O_3, from thallium chromate; the method of operation is as follows:—Thallium chromate (1 part) is projected into fused potassium hydroxide (10 parts); the liquid is at first yellow, but after fusion for two hours becomes cloudy, and crystals float therein; these are allowed to subside, and after decantation of the supernatant fused hydroxide containing the dissolved chromium sesquioxide, the crystals are again fused with potassium hydroxide, from which they are subsequently separated by washing, any traces of thallium chromate being removed by treatment with hot potassium hydroxide. Thus prepared, thallium sesquioxide is absolutely pure, and forms black, hexagonal plates, of sp. gr. 5·56 at 0°; it is insoluble in fused potassium hydroxide, but dissolves in hydrochloric acid to form thallic chloride, and is soluble with difficulty in sulphuric acid. The authors reserve to themselves the redetermination of the atomic weight of thallium by means of this compound. Thallium chromate is not altered by fusion with potassium nitrate, but recrystallises therefrom in right hexagonal prisms. A double salt, Tl_2CrO_4,K_2CrO_4, results from the fusion of thallium chromate and potassium chromate with potassium nitrate, but no double salt of lead and thallium chromates exists. Thallium chlorochromate is formed by the interaction of thallium chloride (1 part) and chromic anhydride (20 parts) in a small quantity of water; the small, prismatic crystals thus obtained are washed with chromic acid solution and dried in a vacuum on porous tiles; water decomposes this compound with formation of thallous chloride and chromic acid.

T. G. N.

Action of Carbonic Oxide on Iron and Manganese. By Guntz (*Compt. rend.*, **114**, 115—117).—With the view of clearing up the discrepancies between the statements of various writers on this subject, the experiments were repeated with pure metals prepared in a finely-divided state by heating their amalgams in a vacuum.

Iron appears to absorb carbonic oxide at a dull-red heat, carbon being set free, and a small quantity of carbonic anhydride formed. With manganese, the action is simpler, the products being practically only manganous oxide and carbon, no carbonic anhydride being formed. The reaction starts at 400°, and proceeds with such vigour as to render the mass incandescent, and cause a partial vacuum in the apparatus. The absence of carbonic anhydride confirms Moissan's view, that manganous oxide, unlike ferrous oxide, is not reducible by carbonic oxide. This view is also confirmed by the readiness with which manganese burns in carbonic anhydride and by the identity of the products with those which are formed when it is burnt in the monoxide. In the case of iron, the formation of carbonic anhydride,

and also that of ferrous oxide, as observed by Schützenberger, may be explained by means of the known reducibility of ferrous oxide by carbonic oxide, if it is assumed that the action of the metal itself on the monoxide resembles that of manganese. The monoxide is thus first reduced to carbon, and the ferrous oxide formed is then reduced to iron by a further quantity of the gas.

At very high temperatures, it is to be observed, the reactions of carbonic oxide with the metals are reversed, the metallic oxides being easily reducible by carbon, with the formation of carbonic oxide.

The above results furnish an explanation of the action of the blast furnace. The spongy iron reduced by the hydrogen and hydrocarbons in the upper part of the furnace meets carbonic oxide at a comparatively low temperature, and decomposes it, forming ferrous oxide and carbon. As this mass sinks, it enters a region of which the temperature is higher, although still below that at which ferrous oxide is reduced by carbon, and here the oxide meets with more carbonic oxide, and is reduced to the metal, the monoxide being oxidised to carbonic anhydride. Finally, in the lowest and hottest part of the furnace, the carbon which was reduced in the upper part, and with which the iron has remained in contact throughout its descent, unites with the metal to form a fusible carbide. Jn. W.

Hydrated Potassium Manganites. By G. Rousseau (*Compt. rend.*, **114**, 72—74).—When potassium manganate is heated at about 600° with potassium carbonate and chloride, it yields black lamellæ of the composition $K_2O,16MnO_2,6H_2O$. At a somewhat higher temperature, large, black lamellæ of the manganite, $K_2O,8MnO_2,3H_2O$, are formed. In an earlier paper (Abstr., 1887, 892—893), the formula $K_2O,7MnO_2$ was erroneously attributed to this compound, the analysis having been made on material dried at 150—160°. At the highest temperature obtainable with a Bunsen flame, the hydrate, $K_2O,16MnO_2,6H_2O$, is again formed, the changes being periodic, as in the case of sodium, barium, and strontium manganites. The proportions of potassium carbonate and chloride used have no influence on the result, and with the chloride alone the product

$$K_2O,16MnO_2,10H_2O$$

is obtained.

At an orange-red heat the crystals formed have the composition $K_2O,32MnO_2,10H_2O$.

If the materials are heated out of contact with the flame gases, for example, in a platinum dish in a tube through which a current of water vapour is passed, the same three hydrates are at first formed, but the alkali gradually volatilises. When the whole of the manganate has been decomposed, the anhydrous manganite is left, but the latter dissociates into free alkali and manganese dioxide. If the heating is continued, the dioxide gradually becomes completely converted into trimanganic tetroxide. Similar results are obtained in a vacuum at about 1000°. C. H. B.

The Variations in Colour of Cobalt Chloride. By Engel (*Bull. Soc. Chim.* [3], **6**, 239—251).—Although several hydrated

cobalt chlorides are described, only the following appear to be stable:—$CoCl_2 + H_2O$ (dark violet), $CoCl_2 + 2H_2O$ (violet-rose), and $CoCl_2 + 6H_2O$ (dark red).

Some observers ascribe the blue colour assumed by solutions of cobalt chloride, under definite conditions, to the formation of the anhydrous salt, although anhydrous cobalt chloride is bright blue in colour, and its solutions vary from a deep- to an indigo-blue. Hydrochloric acid of molecular constitution $HCl,6{\cdot}5H_2O$ dissolves cobalt chloride to form a blue solution. Cobalt chloride, in combining with 6 mols. of water, develops 21·9 Cal., or 3·5 Cal. per water molecule, whereas hydrochloric acid, having the molecular constitution $HCl,2H_2O$, in combining with 4·5 mols. of water, develops but 4·9 Cal., or only 1·1 Cal. per water molecule, from which thermochemical considerations simple dehydration appears infeasible. The rose-coloured hydrate, $CoCl_2 + 2H_2O$, remains unaltered in a stream of dry hydrogen chloride, but traces of water cause it to turn blue, and this behaviour points to the formation of a hydrochloride of cobalt chloride; this is supported by the fact that the solubility of cobalt chloride in water containing hydrochloric acid varies directly with the amount of hydrogen chloride present; and a saturated solution of cobalt chloride in hydrochloric acid contains less water than would be necessary to hold in solution the separate constituents, whilst if this solution be cooled to −23°, long, blue crystals, having the probable formula $CoCl_2,HCl + 3H_2O$, separate. The stability of this hydrochloride is dependent on the presence of excess of hydrogen chloride, for if zinc chloride be added to the blue solution, it becomes rose-coloured, whereas addition of calcium or lithium chlorides, which form compounds with hydrogen chloride without abstracting water, only determine a blue coloration, since anhydrous lithium or calcium chlorides develop less heat than does anhydrous cobalt chloride, and a blue compound, $CoCl_2,LiCl + 3H_2O$, corresponding with the author's hydrochloride, has been prepared by Chassevent. Wyrouboff has shown that when a saturated solution of cobalt chloride is heated to 100°, it becomes dark-blue, the violet salt, $CoCl_2 + H_2O$, being simultaneously formed; the author explains this as due to the superposition of the colours of the violet hydrate and of the blue hydrochloride of cobalt chloride, and the presence of the latter is dependent on the decomposition of cobalt chloride on heating, since the vapours of the boiling solution contain free hydrogen chloride. Again, the addition of zinc or mercuric chloride to a cobalt chloride solution at 100° determines a violet coloration, which is due to the hydrate $CoCl_2 + H_2O$. The blue coloration produced by alcohol is not a dehydration phenomenon, but is due to the formation of the alcoholic compound indicated by Potilitzin. The latter thinks that the change of colour of paper moistened with cobalt chloride solutions, when exposed to dry air, is due to capillarity, and to this the author offers objections, believing it to be due to the formation of a compound with cellulose, similar to those which this substance yields with the chlorides of aluminium, iron, zinc, copper, and tin, as described by Girard. T. G. N.

The Hydrates of Cobalt Chloride and their Alterations in Colour. By A. Potilitzin (*Bull. Soc. Chim.* [3], **6**, 264—266).—In addition to the hydrate $CoCl_2 + 6H_2O$, two other hydrates, $CoCl_2 + 2H_2O$ (violet-rose) and $CoCl_2 + H_2O$ (deep violet), exist. The former compound is formed at 45—50° or at the ordinary temperature over sulphuric acid, whilst the monohydrated salt is formed when this is heated at 100°, or is deposited as well-formed crystals when a solution of the dihydrate in absolute alcohol is heated to 95°. The alteration in colour of the red crystals of $CoCl_2 + 6H_2O$ is followed by their melting in their water of crystallisation. A perfectly dry crystal of the hexahydrate on being heated, effloresces, without change of colour until it melts at 54°, when it becomes more and more blue. These observations, together with the fact that during this change the hexahydrate loses in weight, point to its dissociation, resulting in the elimination of water and the formation of lower hydrates. $CoCl_2 + H_2O$ dissociates at 90—95°, but at a much lower temperature in aqueous solution, and the temperature at which the corresponding alteration in colour occurs is further lowered by the presence of dehydrating substances, whilst the more dilute the aqueous solution the higher becomes the temperature of dissociation. Hygroscopic substances, such as filter paper and porous inorganic materials, effect the same change. In no case does dissociation proceed further than to determine the formation of the monohydrated salt (compare Étard, this vol., p. 278). T. G. N.

Action of Heat on Solutions of Chromium Salts. By W. N. Hartley (*Chem. News*, **65**, 15—16).—In 1875, the author stated (*Proc. Roy. Soc.*, **33**, 372) that the action of heat on the violet hydrated compounds of chromium is not simply a dissociation of water molecules or of acid from base, but a true decomposition, resulting in the production of a different class of salts with different generic properties.

The thermochemical investigations of Recoura on the action of heat on solutions of chromic oxide (Abstr., 1891, 1430) fully confirm the author's views. L. de K.

Isomorphous Thorium and Uranous Sulphates. By W. F. Hillebrand and W. H. Melville (*Amer. Chem. J.*, **14**, 1—9).—When the oxide U_3O_8 is heated with dilute sulphuric acid (1 part of acid to 5 or 6 of water by volume) in a sealed tube at about 170°, green crystals of uranium sulphate, $U(SO_4)_2 + 4H_2O$, are formed. If uraninite, or mixtures in varying proportions of the oxides U_3O_8 and ThO_2, are decomposed in a similar manner, a green double sulphate of uranium and thorium is obtained, $(U,Th)(SO_4)_2 + 4H_2O$; the percentage of UO_2 and ThO_2 in these crystals varies with the proportions of the oxides in the original mixture; in the actual analyses the limits of the variation are UO_2 49·18, ThO_2 3·59 to UO_2 16·92, ThO_2 36·07 per cent. The thorium dioxide replaces the uranium dioxide isomorphously; the uranium sulphate crystallises in the rhombic system ($a : b : c = 1 : 1·9478 : 2·5755$); the double sulphate of uranium and thorium also crystallises in this system, and has nearly the same

axial ratio ($a : b : c = 1 : 1{\cdot}9194 : 2{\cdot}5563$); its habit, however, is tetragonal. C. F. B.

Alloy of Tin and Sodium. By H. Bailey (*Chem. News*, **65**, 18).—The author was struck by the uniformity in appearance and behaviour of several alloys of tin and sodium which had been prepared by heating a mixture of tin with excess of sodium in a crucible provided with a luted lid, through which a small hole had been drilled so as to allow the excess of sodium to escape as vapour. After cooling in an inert atmosphere, the contents of the crucible were examined and found to consist of a brittle mass externally covered with a slight white scoria, which, on fracture, revealed brilliant, crystalline facets of a beautiful bronze colour, quickly becoming tarnished with a grey powder.

An analysis of the compound gave percentages corresponding exactly with the formula Na_2Sn. The alloy is very suitable for the preparation of hydrogen, being readily decomposed by water.

L. de. K.

Palladious Oxide. By T. Wilm (*Ber.*, **25**, 220—224).—Palladium sponge, prepared by heating the compound $PdCl_2,2NH_3$, first in the air and then in a stream of hydrogen, is very similar in appearance to platinum sponge, except that it has a more silvery lustre. When it is heated in an open porcelain crucible with an ordinary burner, it rapidly darkens and turns a variety of colours, but on further heating it gradually assumes a dark, dirty, bluish-green hue, and then consists of a mixture of palladium and palladious oxide. When palladium sponge is heated in a stream of dry oxygen until its weight is constant, it is completely converted into palladious oxide, PdO; this compound is a dark, bluish-green powder, insoluble in acids, even in boiling aqua regia; it is readily reduced by hydrogen even at comparatively low temperatures, and it decomposes into oxygen and palladium when strongly heated. F. S. K.

Mineralogical Chemistry.

Theories of the Structure of Crystals. By A. Schönflies (*Zeit. physikal. Chem.*, **9**, 158—170).—In his work *Krystallsysteme und Krystallstruktur* (Leipzig, 1891), the author has discussed the classification of crystals according to symmetry and the theory of their structure chiefly from the geometrical standpoint. The present paper contains some explanatory observations bearing on the physical side of the question.

A uniform subdivision of the ordinary systems is proposed, namely, holohedral forms, enantiomorphous, hemimorphous, and paramorphous hemihedral, and tetartohedral forms. Thus the tetragonal system would be subdivided as follows:—

Holohedry.

Enantiomorphous (trapezohedral) hemihedry.

Hemimorphous hemihedry (hemimorphism).
Paramorphous (pyramidal) hemihedry.
Tetartohedry (hemimorphous tetartohedry).
Hemihedry with axis of the second species (sphenoidal hemihedry).
Tetartohedry with axis of the second species (sphenoidal tetartohedry). J. W.

So-called Amber of Cedar Lake, Canada. By B. J. Harrington (*Amer. J. Sci.*, **24**, 332—335).—The occurrence of mineral resins, resembling amber, in some of the coals and lignites of Canada has been known for many years. In 1890, on the west shore of Cedar Lake, near the mouth of the North Saskatchewan, a mineral of this character was found in large quantity, mixed with sand and fragments of partly decayed wood. It had evidently been washed up on the shore by the waves. On analysis, this so-called amber yielded :—

C.	H.	O.	Ash.	Total.
79·96	10·46	9·49	0·09	100·00

Although resembling amber in some of its characters, it may be classed provisionally as *retinite*, on account of its differing from amber in its behavionr with acids, its not yielding crystals of succinic acid on distillation, and its somewhat different ultimate composition. Although the origin of this resin is not known with certainty, there can be no doubt that it was derived from one of the tertiary or cretaceous lignites occurring on the Saskatchewan.

B. H. B.

Tourmaline from Siberia. By R. Prendel (*Zeit. Kryst. Min.*, **20**, 93).—A specimen of red tourmaline (sp. gr. 3·116) from the Urulga, in Siberia, gave on analysis the following results :—

SiO_2.	TiO_2.	F.	B_2O_3.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.
38·36	0·13	0·56	9·54	40·10	0·24	0·58	4·06	1·69

MgO.	Li_2O.	K_2O.	Na_2O.	H_2O.	P_2O_5.
0·48	0·45	2·20	0·24	2·94	0·56

The formula is, therefore,

$$12SiO_2,8Al_2O_3,3B_2O_3,2(FeO,MnO),Na_2O(K_2O,Li_2O),3H_2O.$$

B. H. B.

Action of Water on Mica. By A. Johnstone (*Quart. J. Geol. Soc.*, **45**, 363—368).—In this paper the author gives details of the observations noted, and results of experiments carried out in an investigation into the nature of the changes produced by pure distilled water, and also by water saturated with carbonic anhydride, on the principal members of the mica family. He classifies the micas into two great classes, anhydrous and hydrated micas. The anhydrous micas include muscovite and biotite, and never contain more than 2·5 per cent. of water. The passage micas contain from 2·5 to 4 per cent. of water, and have intermediate physical characters. The hydrous micas contain at least 4 per cent. of water, and include

hydromuscovite and hydrobiotite. Under muscovite are included the varieties, potash or ordinary muscovite, soda muscovite, lepidolite, zinnwaldite, cryophyllite, and fuchsite. Under biotite are included rubellane, anomite, phlogopite, aspidolite, lepidomelane, and astrophyllite. Under hydromuscovite are included margarodite, euphyllite, paragonite, oellacherite, gilbertite, damourite, sericite, pregrattite, and cossaïte. Lastly, under hydrobiotite are included voigtite, vermiculite, jeffreysite, and pyrosclerite. The specimens of the anhydrous micas were exposed to the action of water, pure and carbonated, for a year, and at the end of that period it was found that all the chemical change effected was hydration, and that the hydrating process went on as readily in the pure water as in the aqueous solution of carbonic anhydride. The author noted that whenever anhydrous micas become hydrated, they always, at the same time, increase in bulk. B. H. B.

Hot Mineral Spring at Finca Huracatao, Salta, Argentine Republic. By F. Canzoneri (*Gazzetta*, **21**, ii, 462—465).—This water issues at a temperature of about 40° and has a sp. gr. of 1·0009 at 25°. It is colourless and transparent, and gives no deposit; it has a slight saline taste and a faint odour of hydrogen sulphide. It contains 0·035 gram per litre of free carbonic anhydride and 0·0036 gram of free hydrogen sulphide. The total weight of carbonic anhydride per litre is 0·082 gram. The residue from a litre, when dried at 100°, weighs 1·981 grams.

1 litre of the water contains, in grams:—

SiO_2.	Cl.	SO_3.	Na_2O.	K_2O.
0·050	1·050	0·025	0·487	0·073

CaO.	MgO.	Al_2O_3 and Fe_2O_3.
0·257	0·005	0·004

Organic Chemistry.

Exchange of Chlorine, Bromine, and Iodine between Inorganic and Organic Haloïd Compounds. By M. Wildermann (*Zeit. physikal. Chem.*, **9**, 12—25).—The action of the iodides of copper, silver, mercury, tin, lead, arsenic, and antimony on the bromides of isobutylene, isoamylene, trimethylene, propylene, and ethylene was investigated, more particularly by determining, with standard sodium thiosulphate solution, the amount of iodine liberated in each reaction. The results obtained led the author to include other bromides in his investigations, and thus to the general result that the separation of iodine takes place not only in the case of isobutylene and isoamylene, which form no additive compounds with iodine, but with the halogen derivatives of the paraffins generally of the compo-

sition $C_nH_{2n}X_2$, $C_nH_{2n-1}X_3$, $C_nH_{2n-2}X_4$. Even in the case of the monohalogen derivatives, $C_nH_{2n+1}X$, decomposition takes place in perceptible amount. Generally, therefore, the interaction of inorganic and organic haloïd compounds is reciprocal. Comparing the action on trimethylene bromide with that on other compounds of the composition $C_nH_{2n}Br_2$, it appears that two iodine atoms which are united with neighbouring carbon atoms more readily combine with and are eliminated from the hydrocarbon molecule than when attached to non-neighbouring carbon atoms. The influence of the organic radicle on the velocity of the reaction is very marked, the velocity being, at any moment, proportional to the amounts of unchanged bromide and iodide still present. The separation of iodine in the free state by the action of certain metallic iodides on bromides of the composition $C_nH_{2n}Br_2$, $C_nH_{2n-1}Br_3$, and $C_nH_{2n-2}Br_4$ is apparently general when the bromine atoms are united to neighbouring carbon atoms, unsaturated hydrocarbons or their halogen derivatives being at the same time formed. It forms, therefore, a general method for preparing unsaturated hydrocarbons from their bromides. H. C.

Nitration of Hydrocarbons of the Methane Series. By KONOVALOFF (*Compt. rend.*, **114**, 26—28).—When normal hexane is heated in sealed tubes at 130—140° with nitric acid of sp. gr. 1·075, it yields 50 per cent. of the theoretical quantity of crude nitrohexane, which, when fractionated, yields 30 per cent. of the theoretical quantity boiling at 175—177°. The greater part distils at 176°; sp. gr. at 0° = 0·9509, or at 20° compared with water at 0° = 0·9357. The nitrohexane dissolves in boiling, concentrated, aqueous potash, and with development of heat in alcoholic potash. With nitrous acid, its solutions give a blue-green coloration, indicating the formation of a pseudo-nitrol, but it yields no nitrolic acid. When reduced with zinc and acetic acid, it yields methyl butyl ketone and secondary hexylamine. It follows that the nitrohexane is a secondary derivative with the formula $NO_2{\cdot}CHMe{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Me$.

Normal octane, under similar conditions, yields a secondary nitrooctane, which, when reduced, yields a ketone and an amine.

C. H. B.

Aliphatic Nitro-compounds. By V. MEYER (*Ber.*, **24**, 4243—4245).—A preliminary notice on experiments which are being carried out by the author and his pupils.

Iodomethylene, on treatment in ethereal solution with silver nitrate, gives an oil from which, on addition of sodium ethoxide, an explosive white *salt*, $NO_2{\cdot}CHINa$, is obtained. Iodallyl, when treated in the same way, yields a very explosive salt, $NO_2{\cdot}C_3H_4Na$; this, on acidification, gives *nitropropylene* as a light, mobile oil, volatile with ether vapour; whilst on treatment with diazobenzene sulphate, it furnishes a crystalline *azo*-derivative, $NO_2{\cdot}C_3H_4{\cdot}N_2{\cdot}Ph$. When boiled with silver nitrate, ethylene bromide yields an oil giving an explosive salt with sodium ethoxide. The investigation is proceeding.

A. R. L.

Action of Ammonia on Mercuric Cyanide and Haloïd Combinations of this Salt. By R. VARET (*Bull. Soc. Chim.* [3], **6**,

220—230).—In addition to the compounds which have been previously examined by him (compare Abstr., 1890, 351; 1891, 161, 655, 1441), the author describes the preparation of some simple additive compounds which ammonia yields with mercuric cyanide.

The salt $2HgCy_2,4NH_3,H_2O$ is obtained by treating a saturated ammoniacal solution of mercuric cyanide with gaseous ammonia and, after filtration, cooling the filtrate in a freezing mixture. It forms long, white, prismatic crystals, which lose ammonia and water on exposure to the air, and decompose at 100°, leaving a residue of mercuric cyanide.

The salt $2HgCy_2,2NH_3,H_2O$ separates at 0° in small, white, granular crystals from a saturated ammoniacal solution of mercuric cyanide to which ammonia gas (one-tenth part by weight) is added. It is an unstable substance, is very soluble in aqueous or alcoholic ammonia, and decomposes at 100°.

The compound $HgCy_2,2NH_3$ is deposited from a saturated alcoholic ammoniacal solution of mercuric cyanide after saturation with dry ammonia gas and subsequent cooling. It loses half its ammonia on exposure to air, and the whole on warming for a few hours at 100°.

The compound $HgCy_2,NH_3$ is produced by warming, in a stoppered bottle at 40°, a saturated ammoniacal solution of mercuric cyanide with excess of the salt. The filtered solution deposits the compound as small, hard, granular crystals, which are more stable than the preceding salts. It is soluble in water and in ammonia solution, and is resolved at 100° into its constituents.

The salt $HgCy_2,2NH_3$ is obtained as an amorphous, white substance by passing ammonia gas over dry mercuric cyanide at 100° for 30 hours. The compound evolves ammonia and absorbs water on exposure to the air, but the water may be again displaced by the action of a current of dry ammonia gas. T. G. N.

Polymerisation of Nitriles. By E. v. Meyer (*J. pr. Chem.* [2], **45**, 63—64; compare Abstr., 1889, 114, 577).—Hanriot and Bouveault (*Bull. Soc. Chim.*, **51**, 170; compare Abstr., 1889, 841) regard the evolution of ethane from ethyl cyanide and sodium as due to the presence of ether, and have overlooked the formation of sodium cyanide. So far from ether being essential to the production of the ethane, the reaction takes place in exactly the same way in benzene, ethane being evolved and sodium cyanide formed. Whether the sodium in the polymerisation product is united to the nitrogen or to the carbon is as uncertain as whether the sodium is attached to the carbon or oxygen in ethyl sodacetoacetate. A. G. B.

Thermal Value of the Hydroxyl Groups of Glycol. By De Forcrand (*Compt. rend.*, **114**, 123—126).—Monatomic primary alcohols, as a rule, give off a constant quantity of heat, +32 Cal., when sodium is substituted for the alcoholic hydrogen (all substances except hydrogen calculated as solid). The first hydroxyl group of glycol, however, gives more than this, namely, +39 Cal., whilst the second gives less, +27·7 Cal.

By assuming, however, that monosodium glycol forms a compound

with glycol similar to that which sodium methoxide forms with methyl alcohol, the apparent anomaly may be explained, for the heat evolved in the formation of the molecular compound will increase the amount evolved in the first stage, whilst that absorbed in its decomposition will diminish the amount evolved in the second stage. The values calculated in this way, due allowance being made for heat of fusion and solidification, agree satisfactorily with the normal value.

Jn. W.

A New Mode of Formation of Symmetrical Tribromhydrin. By A. Kronstein (*Ber.*, **24**, 4245—4247).—When equivalent quantities of trimethylene bromide and bromine are heated at 120° in a sealed tube for nine hours, and the product washed and thrice fractionated, symmetrical tribromhydrin is obtained as a colourless oil of sp. gr. 2·44 at 25°; it boils at 219—222°, and solidifies to a crystalline mass on cooling to 0°. If the bromination is conducted in the presence of iron wire (see next abstract) at 100°, the yield of tribromhydrin is almost quantitative. The tribromhydrin is likewise obtained in almost quantitative yield by brominating propylene bromide at 100° in the presence of iron wire; the same compound is produced by similarly treating propyl bromide and isopropyl bromide, employing bromine (2 mols.). Experiments are in progress on the preparation of higher symmetrical brominated derivatives of hydrocarbons, and the related polyhydric alcohols. A. R. L.

Substitution in the Aliphatic Series. By V. Meyer and F. Müller (*Ber.*, **24**, 4247—4250).—The production of symmetrical tribromhydrin (preceding abstract) is not in accordance with the rule that, by the introduction of a second halogen atom into a compound, the newly entering halogen atom attaches itself to that carbon atom which carries the other halogen atom. Linnemann has shown that compounds of the type of ethylene bromide are formed when ethyl bromide is brominated, but Tawildarow (*Annalen*, **176**, 12) obtained ethylene bromide together with ethylidene bromide by brominating ethyl bromide at 200°; whereas Städel (*Annalen*, **195**, 182) obtained ethylidene chloride exclusively by chlorinating ethyl chloride, and the production of ethylene bromide observed by Tawildarow has been generally regarded as due to secondary reactions taking place at the high temperature. The author finds that when ethyl bromide and bromine are heated together in molecular proportion with iron wire in a sealed tube at 100° for an hour, ethylene bromide is the sole product; similarly ethyl chloride and antimony pentachloride yield exclusively ethylene chloride. Propyl and isopropyl bromide are readily converted into propylene bromide, $CHMeBr{\cdot}CH_2Br$, and it is unnecessary to employ sealed tubes. Experiments are in progress on the bromination of the fatty acids by this method. A. R. L.

Production of Dextrin. By P. Petit (*Compt. rend.*, **114**, 76—78).—The author has heated starch at definite temperatures for different lengths of time with different proportions of nitric acid, and has determined the rotatory power and reducing power of the product.

Direct experiments showed that if the products were digested with water at 40—50° for half an hour, the whole of the glucose and dextrin was dissolved, whilst the starch could be filtered off, dried, and weighed. The rotatory power of the solution is the sum of the rotatory powers of the glucose and dextrin present. Fermentation with pure yeast, after addition of ammonium phosphate and potassium sulphate, destroys all the glucose, and the loss of rotatory power gives the proportion of glucose present.

The starch, previously moistened with 30 per cent. of water, was mixed with 0·2, 0·3, 0·5, 0·8, and 2·0 per cent. of nitric acid, dried at 50°, passed through a sieve, and heated at 125°. The following table shows the proportion of glucose (as determined by reducing power) per 100 parts of dextrin.

Percentage of nitric acid.	Time of heating.				Unaltered starch per 100 parts dextrin.
	1 hr.	2 hrs.	3 hrs.	4 hrs.	
0·2	3·9	5·06	3·6	2·8	0·003
0·3	7·2	5·3	3·6	3·0	0·002
0·5	7·3	6·07	4·2	3·1	0·001
0·8	8·06	6·3	4·5	4·0	traces
2·0	9·5	7·1	5·4	4·5	traces

With 0·8 and 2·0 per cent. of acid, the whole of the starch disappears after an hour's heating at 125°. For a given quantity of acid, the reducing power diminishes as the time of heating is prolonged. For a given time of heating, the reducing power increases with the quantity of acid. For a given quantity of acid, the diminution of reducing power is more rapid the higher the temperature.

The product contains a small quantity of some substance which reduces Fehling's solution, but is not fermentable. C. H. B.

Fixation of Iodine by Starch. By E. Rouvier (*Compt. rend.*, **114**, 128—129).—When iodine is added to a clear aqueous solution of starch in the presence of ammonium chloride, iodide of starch is precipitated, and may be collected. The amount of iodine needed to exactly precipitate the starch, as determined by the absence of the latter from the filtrate, is directly proportional to the amount of starch present, and the iodide thus formed is capable of taking up more iodine, the amount of which appears to be dependent on the quantity of ammonium chloride present. Jn. W.

Unsaturated Aliphatic Amines. By C. Paal (*Ber.*, **24**, 4253).—The author has recently, in conjunction with A. Heupel (this vol., p. 30), described dibromopropylcarbamide, but overlooked the previous description of this compound by Andreasch (Abstr., 1884, 732). The compound melts at 111·5°, which agrees practically with the value given by Andreasch, whereas the melting point (163°) recorded by the author and Heupel is incorrect. When an aqueous solution of the compound is evaporated, bromopropylenecarbamide hydrobromide is obtained which agrees in every respect with Andreasch's description.

Bromopropylenecarbamide probably belongs to the pentoxazoline class (Gabriel and Elfeldt, this vol., p. 212), a view which is favoured by the observation of Andreasch (*loc. cit.*), that the bromine atom is not displaced by treatment with tin and hydrochloric acid; the formation of the hydrobromide from dibromopropylcarbamide would therefore be represented thus:—

$$CH_2Br\cdot CHBr\cdot CH_2\cdot NH\cdot CO\cdot NH = CH_2<\begin{matrix}CHBr\cdot CH_2\\ O-C(NH)\end{matrix}>NH,HBr.$$

A. R. L.

Nitroguanidine. By G. Pellizzari (*Gazzetta*, **21**, ii, 405—409).—Jousselin (Abstr., 1878, 132; 1879, 613, 914) obtained a substance which he termed nitrosoguanidine by dissolving guanidine nitrate in fuming nitric acid, treating with concentrated sulphuric acid, and precipitating by pouring into cold water. The author has prepared this compound, and finds that it is certainly not nitrosoguanidine, but most probably *nitroguanidine*, $NO_2\cdot N{:}C(NH_2)_2$. It crystallises from water in colourless needles which decompose at 225° with evolution of ammonia, and do not give the reactions for a nitrate or a nitrite. It dissolves in cold aqueous potash, and is precipitated unaltered by acids; on heating or allowing the solution to remain for some time, carbonic anhydride, ammonia, and nitrous oxide are liberated, 1 mol. of the compound yielding approximately 1 mol. of nitrous oxide. On reducing nitroguanidine in very dilute solution by warming with stannous chloride, ammonium chloride and guanidine hydrochloride are obtained, together with traces of a base which very readily reduces ammoniacal silver nitrate. This substance may be amidoguanidine. W. J. P.

Some Reactions of Trithioformaldehyde and Formaldehyde. By G. Pulvermacher (*Ber.*, **25**, 304—311).—With the object of preparing methylenediacetamide (diacetylmethylenediamine), the author boiled Baumann's trithioformaldehyde (m. p. 216°) with an aqueous solution of acetamide in a reflux apparatus, but after several hours no reaction had taken place; freshly precipitated mercuric oxide was then added to the mixture, and it was again boiled, the products being in this case mercuric sulphide, formaldehyde, and unaltered acetamide.

Methylenediacetamide (*diacetylmethylenediamine*), $CH_2(NHAc)_2$, is obtained as follows:—Dry mercury acetamide (3 mols.) is heated with somewhat more than the calculated quantity (1 mol.) of trithioformaldehyde in a bath of sulphuric acid; darkening commences at 150°, and an energetic reaction sets in at 195°, and the now black melt froths up with the evolution of vapour having the penetrating odour of formaldehyde, and burning with a violet flame; the volatile products (see below) are condensed in a ∪-tube, attached to the flask and surrounded by water. The contents of the flask are extracted repeatedly with boiling water, the aqueous solution evaporated, and the residue dissolved in boiling alcohol, the solution being treated with animal charcoal and filtered, when the compound separates in four-sided prisms; it melts at 196°, boils with partial carbonisation at

288° (uncorr.), is extremely soluble in water, fairly so in alcohol, sparingly in light petroleum, benzene, and chloroform, but insoluble in ether. When the compound is boiled with dilute hydrochloric acid or sodium hydroxide, it is decomposed into formaldehyde, ammonia, and acetic acid; its aqueous solution has a neutral reaction. The *aurochloride*, $CH_2(NHAc)_2,HAuCl_4$, separates in large, six-sided crystals, when the compound is added to a solution of auric chloride in hydrochloric acid; it is very readily soluble in water and alcohol. The liquid which condensed in the U-tube (see above) was found to consist of formaldehyde, water, and acetonitrile.

Methylenedithioacetamide, $CH_2(NH{\cdot}CSMe)_2$, is formed when methylenediacetamide (5 mols.) is boiled with phosphorus pentasulphide (2 mols.) on the water-bath for two hours; the benzene solution is decanted from resinous products, evaporated, and the crystalline residue boiled with carbon bisulphide to remove the admixed sulphur; it is then crystallised from boiling water, whereby almost the whole separates, on cooling, in yellowish-white, spear-shaped needles; it is odourless, is soluble in alcohol, ether, and chloroform, and sparingly so in benzene; it dissolves in cold alkalis and is precipitated unaltered by hydrochloric acid. The aqueous solution gives an amorphous, yellow precipitate with mercuric chloride which becomes black on heating; the sulphur is removed by mercuric oxide, with the formation of acetamide. When treated at the ordinary temperature with alcoholic hydrochloric acid, or if boiled with aqueous alkalis or acids, the compound decomposes into formaldehyde, acetic acid, ammonia, and hydrogen sulphide; whilst methyl iodide reacts on a solution in chloroform with the production of a solid substance insoluble in indifferent solvents, but decomposed by water, alcohol, and glacial acetic acid, a penetrating, mercaptan-like odour being evolved.

Methylenedibenzamide, $CH_2(NHBz)_2$, is formed by heating trithioformaldehyde with benzamide at 200°; it separates from alcohol in white needles, melts at 219°, and decomposes when heated with dilute hydrochloric acid into formaldehyde, ammonia, and benzoic acid.

When aqueous solutions of formaldehyde and acetamide are mixed, a few drops of hydrochloric acid added, the mixture repeatedly agitated, and after three days evaporated on the water-bath, a certain quantity of methylenediacetamide is obtained. Benzamide does not react with formaldehyde in the presence of hydrochloric acid in aqueous solution, but in alcoholic solution methylenedibenzamide is formed. A. R. L.

Crotonaldoxime and Allyl Cyanide. By T. Schindler (*Monatsh.*, **12**, 637—638; compare this vol., p. 32).—The author has previously shown (*loc. cit.*) that crotonaldoxime is converted into the nitrile of crotonic acid when heated with acetic anhydride. In order to determine whether the oxime has the α- or β-configuration, he has treated the crystalline substance with acetic anhydride in the cold (compare Hantzsch, Abstr., 1891, 443). The product consisted chiefly of the nitrile, which indicates that the oxime has the β-configuration; but, at the same time, a small quantity of a viscid, colourless, odourless oil was formed. G. T. M.

Water of Crystallisation. By T. Salzer (*Arch. Pharm.*, **229**, 629—631).—The author gives a complete list showing the proportion of water of crystallisation which occurs in the salts of formic and acetic acids (see also this vol., p. 140). Four salts of both acids crystallise without water, and copper formate crystallises with 2 mols. H_2O. The formates of barium, strontium, and calcium crystallise with more water than the corresponding acetates, and in all the other cases (10) the formates contain less water than the corresponding acetates. J. W. L.

Alkyl and Acidyl Sulphides. By S. H. Davies (*Ber.*, **24**, 4251).—In the description of the preparation of thioacetic anhydride (this vol., p. 300), acetic acid was erroneously printed for acetic anhydride. A. R. L.

Preparation of Methylpropylacetic Acid from Ethyl Acetoacetate and from Diethyl Malonate. Solubility of the Salts of Methylpropylacetic Acid and of Trimethylacetic Acid. By E. Stiassny (*Monatsh.*, **12**, 589, 601).—The author has obtained methylpropylacetic acid in small quantity by the hydrolysis of methyl methylpropylacetoacetate, COMe·CMePr·COOMe (b. p. 200—205°), which results from the methylation of ethyl sodiopropylacetoacetate, with excess of methyl iodide in methyl alcoholic solution. Methylpropylacetic acid is readily obtained in quantity from diethyl malonate by propylation, methylation, and subsequent hydrolysis of the resulting acid (compare Conrad and Bischoff, *Annalen*, **204**, 121). The best yield was obtained as follows:—Propyl iodide was mixed with diethyl malonate, and added little by little to sodium ethoxide. The resulting diethyl propylmalonate, $CHPr(COOEt)_2$, boiled at 219—222°, and on hydrolysis with potash gave propylmalonic acid. The methylation of the propyl derivative was induced in a similar way, and the resulting diethyl methylpropylmalonate boiled at 220—223°. The product was hydrolysed with potash, and converted into the calcium salt, which was purified by recrystallisation, decomposed with hydrochloric acid, and the liberated acid separated by shaking with ether. On evaporation of the ethereal solution, a white, crystalline mass of methylpropylmalonic acid, $CMePr(COOH)_2$, which crystallised well from benzene and melted at 106—107°, was obtained. The acid is very soluble in water, chloroform, and ether, and is readily converted into methylpropylacetic acid, when heated in an oil-bath until no more carbonic anhydride escapes.

Silver methylpropylacetate crystallises from water in gleaming, feathery flocks; the solubility is given by the formula $S = 0{\cdot}51166 + 0{\cdot}00172\,(t-1) + 0{\cdot}00001512\,(t-1)^2$; the *calcium salt* crystallises with 3 mols. H_2O (compare Lieben and Zeisel, *Monatsh.*, 1883; and Kelbe and Warth, (*Ber.*, **15**, 308), and has the solubility $S = 16{\cdot}4994 - 0{\cdot}08375\,(t-1) + 0{\cdot}0006424\,(t-1)^2$.

Silver trimethylacetate has a solubility given by the formula $S = 1{\cdot}1038 + 0{\cdot}005131\,(t-1) + 0{\cdot}00004642\,(t-1)^2$. G. T. M.

Derivatives of Daturic Acid. By E. Gérard (*J. Pharm.* [5], **25**, 8—13; compare Abstr., 1890, 1395).—Normal potassium daturate forms transparent, crystalline grains, soluble in a little boiling water; the solution forms a lather when shaken, and gives a precipitate with common salt. The addition of much water decomposes the salt, setting free the alkali, and retaining an acid salt in solution, which crystallises out in colourless, crystalline laminæ. The corresponding sodium salts are very similar. Copper daturate obtained from alcoholic solutions of the acid and copper acetate forms crystalline needles, which dry to a light granular powder of a bluish-green colour. This salt is anhydrous, insoluble in water and ether, scarcely soluble in cold 90° alcohol. Normal lead daturate is obtained as a heavy, white, amorphous powder, which is not moistened by water. The salt is insoluble in cold alcohol and dry ether, and only very slightly soluble in boiling alcohol or dry ether. It melts at 104—105° without decomposition. Silver daturate, $C_{17}H_{33}AgO_2$, obtained by precipitating an aqueous solution of the sodium salt by means of silver nitrate, forms a very voluminous, white precipitate, which, when moist and exposed to light, rapidly becomes dirty grey. When crystallised from alcohol and dried in a vacuum, it forms small, nacreous scales, which are scarcely affected by exposure to light. The salt is insoluble in water and ether, but soluble in aqueous ammonia.

Daturone, $C_{33}H_{66}O$, is obtained by distilling the acid over excess of slaked lime, when the oily distillate solidifies on cooling, and is purified by crystallisation from hot 90° alcohol. It forms beautiful spangles with a pearly lustre, and melts at 75·5—76°. It is insoluble in water and in cold 75° alcohol, soluble in boiling alcohol, and very soluble in ether, benzene, and chloroform.

Monobromodaturic acid, $C_{17}H_{33}BrO_2$, was obtained by heating daturic acid with bromine and water in a sealed tube at 134—140° for 18 hours. Neither this acid nor its sodium salt could be crystallised.

J. T.

New Acid of the $C_nH_{2n-4}O_2$ Series. By A. Arnaud (*Compt. rend.*, **114**, 79—81).—The seeds of a shrub belonging to the genus *Picramnia* or *Tarari*, widely distributed in Guatemala, contain 67 per cent. of a fatty compound easily soluble in carbon bisulphide. The crude substance melts at 47°, and crystallises readily from ether in large, nacreous crystals. When saponified, it yields 95 per cent. of an acid and a quantity of glycerol corresponding with a triglyceride. The crude acid melts at 49—50°, and by repeated crystallisation from alcohol of 90°, the melting point is raised to 50·5°. It has the composition $C_{18}H_{32}O_2$, and is monobasic; the potassium salt is only slightly soluble in cold alcohol, but crystallises well from hot alcohol; the silver salt is amorphous and insoluble.

When treated with bromine in presence of chloroform, it yields an additive product $C_{18}H_{32}Br_2O_2$, which forms a crystalline mass very soluble in chloroform, alcohol, and ether. The bromo-acid is monobasic, and the potassium salt crystallises in long, very deliquescent needles. The direct action of bromine on the solid acid yields a

tetrabromide, $C_{18}H_{32}Br_4O_2$, which separates from strong alcohol in small, brilliant, waxy crystals melting at 125°.

The author calls the new acid *tariric acid;* the fat of the tariri being a triglyceride of the formula $C_3H_5(C_{18}H_{31}O_2)_3$. C. H. B.

Ethyl Acetoacetate. By J. W. Brühl (*Ber.*, **25**, 366—370).—A reply to a recent paper by Nef (this vol., p. 140) on the constitution of this compound. The fact that on treatment with sodium in ethereal solution ethyl diethylacetoacetate is reduced, whilst ethyl acetoacetate is unchanged, does not prove that the one compound is a ketone, and the other an unsaturated alcohol; it merely shows that some ketones are less stable than others towards reducing agents. The action of sodium on ethyl acetoacetate is similar to its action on ethyl camphocarboxylate, the ketones becoming converted into the salts ONa·CMe:CH·COOR and $C_8H_{14}<\begin{matrix}C\cdot COOR\\ \|\\ C\cdot ONa\end{matrix}$ respectively.

Ethyl malonate being insoluble in soda, whilst ethyl acetoacetate readily dissolves, proves that the sodium salt of the latter compound is more readily formed than that of the former; no conclusion can be drawn as to the presence or absence of a hydroxyl group, since phthalic, succinic, and cinnamic acids do not react with sodium in ethereal solution; the same applies to terpineol, whilst menthol and borneol react far less readily than either camphor or menthone, which are undoubtedly ketones.

The recent syntheses of ethylcamphor and of ethyl camphocarboxylate show Nef's assumption, that the sodium in carbonyl compounds is never directly linked to a carbon atom, to be erroneous; this is still more strikingly exhibited in the case of menthone, which combines with two atoms of sodium, and yields a dicarboxylic acid; Pechmann (this vol., p. 431) has arrived at similar conclusions from his study of the potassium salts of ethyl acetonedicarboxylate.

The author has recalculated his determination of the molecular refraction of ethyl acetoacetate, employing the expression $\left(\frac{n^2-1}{n^2+2}\right)\frac{P}{d}$; the result proves, as before, that at ordinary temperatures, and in the free state, the compound is represented by the ketone formula.

J. B. T.

Nitro-derivative of Methyl α-Hydroxypropionate. By G. de Varda (*Gazzetta*, **21**, ii, 359—361).—The nitro-derivative of methyl α-hydroxypropionate, NO_2·O·CHMe·COOMe, is prepared by dropping methyl α-hydroxypropionate into a mixture of 2 parts of sulphuric acid (sp. gr. 1·84) and 1 part of nitric acid (sp. gr. 1·4), the temperature being kept at 0° during the reaction. The pure product is a colourless liquid, with an ethereal odour and a sweetish but subsequently pungent taste. Its sp. gr. at 7° = 1·2488. It distils at 166—168° (uncorr.), dissolves in alcohol, ether, acetic acid, &c., but is insoluble in water. It is decomposed by hot hydrochloric or sulphuric acid; when ignited, it burns with an olive-coloured flame.

S. B. A. A.

Cotton-seed Products. By G. Papasogli (*L'Orosi*, **14**, 217—229).—Crude cotton-seed oil contains 65·2 per cent. of solid and 34·8 per cent. of liquid fats; the former consisting mainly of tripalmitin, which, after repeated crystallisation from absolute alcohol, melts at 46° and solidifies at 45° (Chittenden and Smith found the melting point of tripalmitin to be 62°). On saponifying the oil and decomposing the soap thus formed by means of a mineral acid, the product contains 60·24 per cent. of solid fatty acids, 30·36 per cent. of liquid fatty acids, and 9·4 per cent. of glycerol.

The solid portion consists almost entirely of palmitic acid, but on recrystallising it from benzene, a small quantity of a white fat of waxy appearance is left undissolved. The liquid portion, after separation of the small quantity of palmitic acid in solution, is converted into a barium salt, and this, on decomposing it with an aqueous solution of tartaric acid, leaves a straw-yellow acid oil, soluble in alcohol, benzene, and ether. This has the composition $C_{20}H_{36}O_3$ ($C_{20}H_{38}O_3$?), and is termed by the author *cotonoleïc* acid. It has an acid reaction, and becomes very thick at −17°, but without solidifying. It deepens in colour on exposure to the air, acquiring a reddish tint, and gradually thickening; when exposed to an atmosphere of oxygen, the latter is rapidly absorbed. The *potassium* salt is very freely soluble in alcohol and water; the *silver* salt, $C_{20}H_{37}O_3Ag$, is yellowish-white, insoluble in water, and unaffected by light; when dry, it acquires a pale-maroon colour; it decomposes at 110—140°. The *barium* salt, $(C_{20}H_{37}O_3)_2Ba$, is white and soft when freshly prepared, but rapidly hardens and becomes brittle.

Besides the combinations of glycerol with palmitic and cotonoleïc acids, there exists in cotton-seed oil a compound isomeric with paraldehyde, $(C_2H_4O)_3$. This is best isolated by saponifying the oil with baryta-water, separating the insoluble barium soaps, precipitating the barium in solution by sulphuric acid, extracting the clear liquid with ether, and evaporating the extract. The residue is of a syrupy consistency, and of the same colour as the oil; it dissolves readily in alcohol and water, the aqueous solution having an acid reaction and reducing Fehling's solution; it readily combines with alkalis, forming compounds which have a resinous appearance when dry. The *lead* compound is a brownish-red, vitreous substance; the *silver* derivative, $C_6H_{11}O_3Ag$, is white when freshly precipitated, but rapidly turns black, even in the dark.

The author has found that the alcohol employed in Bechi's method for the detection of cotton-seed oil in olive oil is occasionally able to reduce silver nitrate on warming, especially if pure colza oil is added to it; such alcohol may be purified by distilling over potash or lime, and rejecting the first portions of the distillate, but a blank experiment is always necessary as a check. S. B. A. A.

Dehydracetic Acid. By F. Feist (*Ber.*, **25**, 315—335; compare following abstracts).—Bromodehydracetic acid, $C_8H_7BrO_4$, is prepared according to Perkin's method, by the action of bromine (35 grams) on dehydracetic acid (5 grams) dissolved in chloroform (50 grams); the

yield is 81—82 per cent. of the theoretical; the acid may be purified either by sublimation or by recrystallisation from methyl alcohol.

Oxydehydracetic acid, $C_8H_8O_5$, is obtained by treating the bromo-compound with mercuric cyanide, or with alcoholic potash; in the latter case, the finely divided acid is intimately mixed with two parts of powdered potassium hydroxide and a little absolute alcohol, and allowed to remain for 5—8 days; the yield is 75 per cent. of the theoretical. The electrolytic conductivity of the acid is $k = 0{\cdot}159$, $\mu\infty = 360$; it appears to contain only one carboxyl group, together with a replaceable hydrogen atom, since on titration one equivalent of soda is required with methyl-orange as indicator, but when phenolphthaleïn is employed nearly two equivalents of alkali are neutralised; the molcular weight of the acid, determined by Raoult's method, is 195·5. It yields oxalic acid on oxidation with alkaline permanganate, and on heating with water at 120° complete decomposition ensues.

The *sodium salt*, $C_8H_7O_5Na + H_2O$, is crystalline, the increase in the conductivity $\Delta = 10{\cdot}9$ from $v_{32} - v_{1024}$ shows it to be a normal salt. The *barium salt*, $C_8H_6O_5Ba + 5H_2O$, is also crystalline. With orthotoluylenediamine, the corresponding salt $C_8H_8O_5,C_6H_3Me(NH_2)_2$ is formed; this is sparingly soluble, and melts at 147° with decomposition. The *ammonium salt* melts at 178°. Phenylhydrazine reacts with the oxy-acid; the product is pale-yellow, melts at 185° with decomposition, and is readily soluble in alcohol, ether, or alkalis; it has the formula $C_{20}H_{18}N_4O_3$, and cannot be recrystallised.

On fusing the oxy-acid with ammonium acetate, a compound is obtained crystallising from alcohol in needles which melt at about 20°, and giving a deep-blue coloration with ferric chloride; the yield is very small. Three compounds, $C_{12}H_{12}O_8$, $C_{10}H_{10}O_7$, and $C_{10}H_8O_6$, are obtained by heating oxydehydracetic acid with concentrated hydrochloric acid in a sealed tube for several hours at 50—56°. The first of these, $C_{12}H_{12}O_8$, is a yellow, crystalline powder soluble in alcohol; it melts at 246° with decomposition, and gives an intense, deep-violet coloration with ferric chloride; determinations of the molecular weight agree with the above formula, and the electrical conductivity proves the compound to be a bibasic carboxylic acid; it is obtained in small quantity as a bye-product in the preparation of hydroxydehydracetic acid, and also by the action of sodium in alcoholic solution on bromodehydracetic acid. The *barium salt* is a pale, rose-coloured, crystalline powder; the *sodium salt* is yellow in solution; the *ammonium salt* is colourless, and melts at 185°. No definite compounds could be isolated by the action of orthotoluylenediamine, phenylhydrazine acetate, or soda on the acid. On heating the ammonium salt with 60 parts of concentrated alcoholic ammonia in a sealed tube for several hours at 100°, a compound is obtained crystallising from alcohol in colourless, lustrous plates which melt at 280—285°, give a violet coloration with ferric chloride, and a red coloration with isatin and sulphuric acid; it has the formula $C_{24}H_{27}N_3O_{13}$, and appears to be formed by the substitution of three oxygen atoms by three imido-groups in 2 mols. of the preceding acid; it is insoluble in hydrochloric acid, but dissolves in soda, and the vapour imparts a carmine-red coloration to a pine-shaving

moistened with hydrochloric acid. The substance sublimes with partial decomposition when cautiously heated, and yields a product which crystallises in colourless, lustrous plates, melts at 250°, and yields a blue coloration with ferric chloride. On heating the above ammonium salt (m. p. 185°) with a larger proportion of alcoholic ammonia, a second salt is obtained in crystals; this melts at 263—264°, and gives a pale-brown coloration with ferric chloride; on treatment with acids, the original salt is regenerated.

By the action of hydroxylamine in alkaline solution at ordinary temperatures on the compound $C_{12}H_{12}O_8$, a substance is obtained in colourless crystals; it is sparingly soluble in acids, readily dissolves in alkalis, and may be recrystallised from alcohol; it has the formula $C_{12}H_{10}O_8$, melts at 251—252°, and gives a deep-violet coloration with ferric chloride; the author regards it as a derivative of dihydroxyterephthalic acid, and points out that its formation affords an instance of hydroxylamine acting as an oxidising agent.

Experiments on the action of halogens and acids on the compound $C_{12}H_{12}O_8$ led to no definite result. The compound $C_{10}H_{10}O_7$, obtained from oxydehydracetic acid (see above), may also be prepared by cautiously heating the compound $C_{12}H_{12}O_8$ with hydrochloric acid; it is readily soluble in alcohol or chloroform, and is deposited in small, yellow, lustrous crystals which melt at 145° with decomposition, and sublime at lower temperatures; with ferric chloride, a dark-brown coloration is produced. On treatment with phenylhydrazine acetate, a complicated reaction occurs, and a substance is obtained crystallising in small, pale-yellow needles melting at 207—207·5°.

The third compound, $C_{10}H_8O_6$, is very sparingly soluble, and crystallises in groups of straw-coloured needles, which melt at 271° with decomposition; it may be prepared by the prolonged action of hydrochloric acid at 120° on the compound $C_{12}H_{12}O_8$. A deep-brown coloration is formed with ferric chloride.

The author discusses the constitution of dehydracetic acid and of oxydehydracetic acid; since the latter compound is a monocarboxylic acid and not an oxymethylacetopyronone, it follows that it contains a ring consisting of five atoms; the action of hydrochloric acid, above described, shows, however, that this ring cannot be a pentamethylene one; hence oxydehydracetic acid is either a ketofurfuran or a diketofurfuran derivative with one of the formulæ $\begin{matrix} O & -- & CMe \\ | & & \\ CHAc\cdot CO & & \end{matrix}\!\!>\!C\cdot COOH$,

$\begin{matrix} O\cdot C(CH_2Ac) \\ | \\ CH_2 -- CO \end{matrix}\!\!>\!C\cdot COOH$, or $\begin{matrix} CH_2 -- O \\ | \\ CO\cdot CH_2 \end{matrix}\!\!>\!C{:}CAc\cdot COOH$.

The work already accomplished does not enable the author to distinguish between these, but he is inclined to regard the first as the most probable. Assuming this to be correct, the compound $C_{12}H_{12}O_8$ (see above) is formed by the elimination of two acetyl groups from 2 mols. of the acid, and is, therefore, a *diacetodiketohexamethylenedicarboxylic acid*, $CO<\begin{matrix} CH(COOH)\cdot CHAc \\ CHAc\cdot CH(COOH) \end{matrix}>CO$; the second compound, $C_{10}H_{10}O_7$, formed from this by the elimination of an acetyl group, is *acetodiketohexamethylenedicarboxylic acid*,

$$CO<\begin{matrix}CH(COOH)—CH_2\\ CHAc\cdot CH(COOH)\end{matrix}>CO,$$

whilst the third, $C_{10}H_8O_6$, is probably a lactone,

$$O<\begin{matrix}CMe{:}C\cdot CO\cdot CH\cdot COOH\\ CO\cdot CH\cdot CO\cdot CH_2\end{matrix}.$$

J. B. T.

Dehydracetic Chloride. By F. Feist (*Ber.*, **25**, 335—339; compare preceding abstract).—Dehydracetic chloride, $C_8H_6O_2Cl_2$, does not react with potassium cyanide, mercuric cyanide, hydrogen cyanide, or phenyl cyanate. Similar negative results were also obtained by distillation of the chloride with zinc dust, by heating it with tin and hydrochloric acid, and by the action of alcoholic ammonia.

On treatment with alcoholic hydroxylamine at ordinary temperatures, reaction takes place accompanied by evolution of gas, and after removal of the alcohol and treatment of the residue with water, a compound is deposited in small, colourless, lustrous needles; this melts at 167° with decomposition, and is readily soluble in water, alcohol, and soda, but insoluble in carbon bisulphide. It reduces neutral silver solution on warming, and gives no coloration with ferric chloride; it probably has the formula $C_8H_{15}N_2ClO_6$, and appears to be a hydroxylamine salt of the compound immediately to be described.

On extracting with ether the aqueous filtrate from the preceding compound, two substances are obtained melting at 205° and 220° respectively. The former can also be prepared by heating the preceding compound at a temperature above its melting point, or by dissolving it in water, acidifying, and extracting the liquid with ether. The compound probably has the formula $C_8H_8NClO_3$; it is readily soluble in carbon bisulphide, does not reduce silver solution, and gives a dark, violet coloration with ferric chloride. The second compound (m. p. 220°) crystallises in lozenge-shaped plates, and yields no coloration with ferric chloride.

On reducing the first of the above compounds (m. p. 167°) with sodium amalgam, an acid is obtained in very small quantity, crystallising from alcohol in long needles which melt at 165°; it gives an olive-green coloration with ferric chloride, and contains nitrogen but no chlorine.

An amorphous compound of the formula $C_{16}H_{22}O_4$ is formed by the reduction of dehydracetic chloride with sodium amalgam; it decomposes at 202°, is insoluble in water or chloroform, dissolves readily in soda, and gives precipitates with several of the heavy metals.

The author concludes from these results that dehydracetic chloride is not a simple pyronone derivative. J. B. T.

Constitution of Dehydracetic Acid. By F. Feist (*Ber.*, **25**, 340—346; compare preceding abstracts).—The author criticises some recent papers of Collie on this subject (Trans., 1891, 172, 179, 607, 617); he considers that at present there is no proof of the formation of orcinol from dehydracetic acid. Since dehydracetic chloride is not

a simple derivative of dehydracetic acid, its formation does not show the presence of two hydroxyl groups in the latter compound; the balance of evidence points rather to the opposite conclusion, since dehydracetic acid behaves towards phosphoric acid as a monhydric alcohol.

When compounds containing the group $CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO$ undergo condensation, it is usually the methylene rather than the methyl group which reacts; apart from this objection, Collie's explanation of the condensation of ethyl acetoacetate is inapplicable to ethyl benzoylacetate; the two reactions have, however, been shown to be strictly analogous. The recent synthesis of dehydracetic acid by Pechman (this vol., p. 296) from acetic anhydride and acetonedicarboxylic acid is then referred to, and is considered to be in itself sufficient proof of the formula $CO<^{CH:CMe}_{CHAc{\cdot}CO}>O$.

The phosphate above mentioned has already been partially described; it crystallises in colourless, slender, lustrous needles, melts at 205° with decomposition, and is extremely stable towards hydrolysing agents. J. B. T.

Action of Phosphoric Chloride on Ethyl Oxalate. By A. Fauconnier (*Compt. rend.*, **114**, 122—123).—When a mixture of diethyl oxalate (1 mol.) and phosphoric chloride (2 mols.) is heated at 125° in a flask provided with a fractionating column, a violent reaction sets in, a large amount of ethyl chloride and a little hydrogen chloride being evolved; and when the temperature is raised to 150—155°, a mixture of ethyl chloride, phosphorus oxychloride, and oxalic chloride, $COCl{\cdot}COCl$, passes over, from which the last may be separated by fractionation. It is not practicable, however, to remove all the phosphorus oxychloride in this manner.

Impure *oxalic chloride*, as thus prepared, is a colourless, mobile liquid, which fumes strongly in the air, has a very irritating odour, recalling that of carbonyl chloride, and boils at about 70°. It is violently decomposed by water, with the formation of oxalic acid and hydrogen chloride, and by methyl alcohol, with the formation of dimethyl oxalate. Jn. W.

Dissociation in Dilute Solutions of Tartrates. By S. Sonnenthal (*Monatsh.*, **12**, 603—619).—With the object of ascertaining the influence of concentration on their rotatory power, the author has examined very dilute solutions of the normal and acid salts which tartaric acid forms with potassium, sodium, ammonium, and lithium. He finds that aqueous solutions of both normal and acid tartrates undergo a change of condition when a certain degree of dilution has been attained, and that this change occurs, in the case of solutions of the normal tartrates, when they contain between 0·4 and 0·3 per cent. of the salt, whilst in the case of solutions of the acid tartrates the change does not occur until between 0·3 and 0·2 per cent. of the salt is present. The commencement and the magnitude of this change depend on the nature of the salt-forming metal or radicle; the greater the atomic weight of the metal or the molecular weight of the radicle,

the greater the concentration at which the change begins, and the greater, also, the departure from the normal condition. The rapidity with which the change in condition occurs appears to depend entirely on the greater or less solubility of the salt in question.

The author regards the results he has obtained as evidence that the change in condition is due to dissociation, since relatively large quantities of water must be present in order to bring about the change, and further, because the greater the atomic weight of the metal, the sooner the change commences. G. T. M.

Cause of Acidity in Green Grapes. Tartromalic Acid. By C. Ordonneau (*Bull. Soc. Chim.* [3], **6**, 261—264). The author has isolated calcium tartromalate from green grape juice and from the wine resulting from grapes attacked by mildew. The salt separates, together with calcium tartrate, when the acid liquor is almost neutralised with lime, as asbestiform groups of needles, which are purified by successive recrystallisations. This double salt is a mixture of lævogyrate calcium tartrate and dextrogyrate calcium malate, and has the formula $CaC_4H_4O_6,CaC_4H_4O_5 + 6H_2O$; sulphuric acid converts it into calcium tartrate and calcium hydrogen malate. The author has prepared the double salt synthetically, by neutralising solutions of dextrogyrate hydrogen tartrate (1 mol.) and lævogyrate hydrogen malate (1 mol.) with an alkaline hydroxide, and subsequently precipitating with calcium acetate. Calcium tartromalate, on treatment with sulphuric acid, yields deliquescent crystals of tartromalic acid, and the author thinks this acid was mistaken by Erlenmeyer for glycollic acid and by Brunner for glyoxalic acid in their investigations on grape juice. Malic acid exists in some white wines to a greater amount than tartaric acid, the former disappearing as the grape ripens.

Calcium hydrogen malate, $Ca(C_4H_4O_5)_2 + 6H_2O$, dissolves in all proportions in boiling water; 100 grams water at 17° dissolve 1·25 grams; when heated at 100°, it melts in its water of crystallisation, and forms a gummy mass; when treated with boiling milk of lime, it is converted into calcium malate, and the author thinks that malic acid might be manufactured thus from grape juice and the lees of white wine by making use of this method. T. G. N.

β-Methylmalic Acid. By W. Wislicenus (*Ber.*, **25**, 196—203). —Just as inactive malic acid can be prepared by the reduction of ethyl oxalacetate (compare this vol., p. 147), β-methylmalic acid can be obtained by the reduction of ethyl methyloxalacetate. The acid obtained in this way is isomeric with the α-methylmalic acid or β-hydroxyglutaric acid prepared by Demarçay (*Compt. rend.*, **82**, 1337) from the cyanhydrin of ethyl acetoacetate.

β-Methylmalic acid, COOH·CHMe·CH(OH)·COOH (α-hydroxyglutaric acid), is prepared by gradually adding 3½ per cent. sodium amalgam (700—720 grams) to a mixture of ethyl methyloxalacetate (50 grams) and water (500 grams), with constant shaking, the solution being kept nearly neutral by frequently adding dilute sulphuric acid. When the whole of the amalgam has been decomposed, the neutralised solution is shaken with ether to extract ethyl β-methyl-

malate, and then evaporated to dryness; the residue contains sodium ethyl β-methylmalate and sodium β-methylmalate; the former can be extracted with boiling alcohol, from which it is deposited on cooling in colourless needles, and the β-methylmalic acid can then be isolated by means of its lead salt, after first precipitating the sulphuric acid present with barium hydroxide.

β-Methylmalic acid, prepared from its lead salt, is a thick, colourless syrup, miscible with water and alcohol, and readily soluble in ether. The *lead* salt, $C_5H_6O_5Pb + H_2O$, is sparingly soluble in hot water, from which it separates almost completely, on cooling, as a colourless, amorphous powder; it loses the whole of its water at 110°. The *silver* salt, $C_5H_6O_5Ag_2$, is a colourless, amorphous compound, very sparingly soluble in hot, and insoluble in cold water; it is moderately stable in the light, but is decomposed on prolonged boiling with water. The *calcium* salt, $C_5H_6O_5Ca + 3H_2O$, is amorphous, and moderately easily soluble in hot water; it does not become completely anhydrous at 140°. The *dihydrazide*, $C_{17}H_{20}N_4O_3$, is crystalline, melts at 231—232°, and is moderately easily soluble in hot alcohol and glacial acetic acid, but only very sparingly in cold water, alcohol, and ether; its solution in concentrated sulphuric acid gives a red coloration on the addition of ferric chloride. The *ethyl* salt, $C_9H_{16}O_5$, is a thick, colourless oil, boiling at 250° under a pressure of 745 mm. (at 175°, 78 mm.; 143°, 21 mm.; 138°, 17 mm.). The *sodium ethyl salt*, $C_7H_{11}O_5Na$ (see above) sinters together at 161°, melts at 166—167°, and is very readily soluble in water; its aqueous solution gives, with silver, cadmium, and mercurous salts, colourless precipitates, which crystallise from hot water in needles, and, with lead acetate, a colourless, amorphous precipitate. F. S. K.

Additive Products of Ethyl Sodacetoacetate and Sodiomalonate with Ethereal Salts of Unsaturated Acids. By A. Michael and O. Schulthess (*J. pr. Chem.* [2], **45**, 55—63; compare Abstr., 1891, 914).—The ethyl salts, $C_3H_4(COOEt)_4$, obtained by the action of ethyl sodiomalonate on ethyl fumarate and ethyl maleate, respectively, are apparently identical; they boil at 202—203° at 16—17 mm. When heated with potassium hydroxide solution, they yield potassium tricarballylate and potassium carbonate; with barium hydroxide solution, the barium salt of the corresponding tetracarboxylic acid is obtained without the elimination of carbonic anhydride, and from this salt the acid may be obtained as a colourless syrup, which evolves carbonic anhydride and yields tricarballylic acid (m. p. 155—156°) when heated at 120—130°.

The reaction between ethyl citraconate and ethyl sodiomalonate yields a colourless oil, $C_4H_6(COOEt)_4$, which distils at 204—205° at 20 mm. Another sample distilled at 201° at 17 mm. It distils at 300° at the ordinary pressure with partial decomposition. The barium salt (with 2 mols. H_2O) of the corresponding acid was prepared by hydrolysis with barium hydroxide, and from this the acid itself was obtained. The acid forms slightly coloured crystals, which decompose at 120—130° with loss of carbonic anhydride; the change has not been further investigated.

The additive product obtained from ethyl mesaconate and ethyl sodiomalonate boils at 204—206° at 20 mm., and is apparently identical with that obtained from ethyl citraconate.

The ethereal salt, $C_{16}H_{26}O_8$, from ethyl itaconate and ethyl sodiomalonate, boils at 211·5—212·5° at 17 mm., and the same product is obtained from ethyl itachloropyrotartrate (b. p. 139° at 17—18 mm.) and ethyl sodiomalonate. The treatment of these two ethyl tetracarboxylates with ammonia produces a crystalline amide, which melts with decomposition at 250°. The ethyl tetracarboxylate obtained from ethyl mesaconate gave no amide, whilst that from ethyl citraconate gave very little, which was traced to the presence of itaconic anhydride in the citraconic anhydride used in the preparation of the ethyl salt.

The action of ethyl allylmalonate on ethyl sodiomalonate gave no additive product. A. G. B.

Trimethylenetrisulphone. By R. Camps (*Ber.*, **25**, 233—247). —The *sodium* derivative of trimethylenetrisulphone (compare Baumann and Camps, Abstr., 1890, 478) is deposited in transparent, rhombic plates, when the trisulphone is dissolved in warm 10 per cent. soda, and the solution then allowed to cool; it has the composition $C_3H_5NaS_3O_6 + H_2O$, and decomposes on exposure to the air. The *potassium* derivative, $C_3H_5KS_3O_6$, crystallises in small, compact prisms, and is only sparingly soluble in cold water. The *lithium* derivative, $C_3H_5LiS_3O_6 + 4H_2O$, and the *barium* derivative,

$$(C_3H_5S_3O_6)_2Ba + 4H_2O,$$

crystallise in slender needles. The *silver* derivative, $C_3H_5AgS_3O_6$, crystallises from hot water in slender needles, and is moderately stable in the light.

When the sodium derivative of trimethylenetrisulphone (1 mol.) is treated with methyl iodide (1 mol.) in dilute alcoholic solution, a mixture of the *di-* and *tri-methyl*-derivatives is obtained, a considerable quantity of the trisulphone remaining unchanged; the two methyl derivatives cannot be easily isolated in a pure condition, owing to the similarity of their behaviour towards solvents, but they can be partially separated by fractional crystallisation of their potassium derivatives; both compounds are soluble in hot water, alcohol, and glacial acetic acid, and sublime without melting.

When molecular proportions of ethyl iodide and the sodium derivative of trimethylenetrisulphone react in dilute alcoholic solution, a mixture of the *mono-* and *di-ethyl* derivatives is obtained, but the two compounds could not be separated.

Hexethyltrimethylenetrisulphone, $C_3Et_6S_3O_6$, is obtained, together with the tetrethyl derivative, when an alcoholic soda solution of the trisulphone is heated with excess of ethyl iodide at 100°; the two compounds are separated by treatment with soda, in which the hexethyl derivative is insoluble. It crystallises from alcoholic benzene in long needles, melts at 208°, and is almost insoluble in water, and only sparingly soluble in hot alcohol, chloroform, ethyl acetate and acetone, but more readily in benzene; it crystallises unchanged from hot, concentrated sulphuric acid, and is not decomposed by boiling alkalis. The

tetrethyl derivative, $C_3H_2Et_4S_3O_6$, crystallises from hot alcoholic benzene in lustrous prisms melting at 175°.

Dipropyltrimethylenetrisulphone, $C_3H_4Pr_2S_3O_6$, is formed when a dilute alcoholic solution of molecular proportions of propyl iodide and the sodium derivative of the trisulphone is heated for 24 hours; it crystallises from alcohol in slender needles, melts at 297°, sublimes above 300° with partial decomposition, and is only sparingly soluble in ether, benzene, and chloroform, but rather more readily in boiling alcohol and hot glacial acetic acid. The *hexapropyl* derivative, $C_3Pr_6S_3O_6$, crystallises from alcohol in compact prisms, melts at 133°, and is moderately easily soluble in alcohol, benzene, and hot glacial acetic acid, but insoluble in boiling soda.

Tetrabenzyltrimethylenetrisulphone, $C_3H_2S_3O_6(CH_2Ph)_4$, is obtained when the trisulphone is heated with excess of benzyl chloride and alcoholic soda for half an hour at 100°; it crystallises from glacial acetic acid in slender, colourless needles, melts at 171—172°, and is insoluble in soda.

Hexabromotrimethylenetrisulphone, $C_3Br_6S_3O_6$, is produced when the trisulphone is rubbed to a paste with water, and bromine-water added until a permanent coloration is produced; it crystallises from dilute acetic acid in compact prisms, melts at 146°, and decomposes at a higher temperature. It dissolves freely in benzene, ether, chloroform, and acetone, but is almost insoluble in water; it is slowly decomposed by hot alcohol, more quickly by warm ammonia, alkalis, and alkali carbonates, with formation of sulphuric acid and hydrobromic acid.

The *hexachloro*-derivative, $C_3Cl_6S_3O_6$, prepared by passing chlorine-water into water containing the trisulphone in suspension, in presence of direct sunlight, crystallises from glacial acetic acid in lustrous prisms, melts at 252° with decomposition, and is soluble in benzene, ether, and chloroform, but insoluble in water; it resembles the hexabromo-derivative in its behaviour with alcohol and alkalis.

Trimethylenedisulphonesulphide. By R. Camps (*Ber.*, **25**, 248—257).—*Trimethylenedisulphonesulphide*, $SO_2<\begin{matrix}CH_2—S\\CH_2\cdot SO_2\end{matrix}>CH_2$, is obtained, together with trimethylenetrisulphone, in the oxidation of trithioformaldehyde with potassium permanganate in presence of dilute sulphuric acid (compare preceding abstract, also Abstr., 1890, 478); the mixture of the two compounds is dissolved in excess of hot potash, the crystalline potassium derivative of the trisulphone separated, the mother liquor acidified with hydrochloric acid, and the precipitated trimethylenedisulphonesulphide separated from small quantities of the trisulphone by recrystallisation from boiling water. It forms slender needles, is only sparingly soluble in hot glacial acetic acid, alcohol, and benzene, and does not melt at 340°; on oxidation with potassium permanganate in dilute sulphuric acid solution at the ordinary temperature, it is slowly converted into the trisulphone. It is slowly decomposed by hot concentrated nitric acid with formation of sulphurous acid and sulphuric acid, and when

heated with concentrated sulphuric acid it undergoes complete decomposition with separation of sulphur and evolution of sulphurous anhydride; it dissolves freely in ammonia, alkalis, and alkali carbonates, but separates from the concentrated solutions unchanged, and, on prolonged heating with alkalis, it undergoes decomposition. The *dimethyl* derivative, $C_3H_4Me_2S_3O_4$, is formed when the disulphonesulphide is warmed with alkali and excess of methyl iodide in dilute alcoholic solution; it crystallises from glacial acetic acid in lustrous, slender needles, melts at 319°, and is readily soluble in hot alcohol and benzene, but only sparingly in hot water, and insoluble in alkalis; it is not acted on by bromine in hot acetic acid solution.

Dimethyltrimethylenetrisulphone, $C_3H_4Me_2S_3O_6$, is formed when dimethyltrimethylenedisulphonesulphide is oxidised with potassium permanganate; it crystallises from acetic acid in compact needles, does not melt at 340°, and is only very sparingly soluble in hot water, ether, benzene, and chloroform, but rather more readily in boiling alcohol and glacial acetic acid; when treated with methyl iodide in alkaline alcoholic solution, it is converted into hexamethyltrimethylenetrisulphone. The *tetrabromo*-derivative, $C_3Br_4Me_2S_3O_6$, crystallises from glacial acetic acid in slender needles, melts at 231° with decomposition, and is sparingly soluble in most ordinary solvents; it is decomposed by ammonia and alkalis with formation of sulphuric and hydrobromic acids.

Ethyltrimethylenedisulphonesulphide, $C_3H_5EtS_3O_4$, crystallises from glacial acetic acid in lustrous needles, melts at 280°, and is only sparingly soluble in hot water, but more readily in boiling benzene, ether, alcohol, and glacial acetic acid; it is decomposed by boiling nitric acid and by concentrated sulphuric acid, but it crystallises unchanged from boiling soda. The *bromo*-derivative, $C_3H_4BrEtS_3O_4$, crystallises from glacial acetic acid in needles, melting at 204° with decomposition.

Ethyltrimethylenetrisulphone, $C_3H_5EtS_3O_6$, prepared by oxidising the preceding compound with 5 per cent. potassium permanganate in dilute sulphuric acid solution, crystallises from glacial acetic acid in slender, lustrous needles, does not melt at 340°, and is only sparingly soluble in boiling alcohol and hot water. The *pentabromo*-derivative, $C_3Br_5EtS_3O_6$, crystallises from glacial acetic acid in slender needles, melts at 221° with decomposition, and is only very sparingly soluble in most ordinary solvents; it is readily decomposed by warm ammonia and warm alkalis. The *pentamethyl* derivative, $C_3Me_5EtS_3O_3$, separates from alcoholic benzene in compact needles, melts at 241°, and is soluble in glacial acetic acid, ether, and chloroform, but insoluble in water; it is very stable towards boiling alkalis, and crystallises unchanged from hot concentrated sulphuric acid.

Dibromotrimethylenedisulphonesulphide, $C_3H_4Br_2S_3O_4$, is formed when excess of bromine is added to a hot saturated solution of the disulphonesulphide in 90 per cent. acetic acid, from which it crystallises after some time in short, compact, lustrous prisms; it does not melt at 330°, and is almost insoluble in water, and is only sparingly soluble in benzene and ether. The *hexabromo*-derivative, $C_3Br_6S_3O_4$, prepared by adding excess of bromine to an aqueous solution of the disulphone-

sulphide, saturated at 30—40°, crystallises from glacial acetic acid in nacreous, yellow plates, melts at 132°, and decomposes at a higher temperature; it is readily soluble in hot glacial acetic acid and benzene, and, like the dibromo-derivative, is decomposed by warm alcohol and by alkalis; on prolonged boiling with glacial acetic acid, it is converted into the dibromo-derivative. F. S. K.

Reduction of Benzene Hexachloride. By J. Meunier (*Compt. rend.*, **114**, 75—76).—Benzene hexachloride, when reduced with glacial acetic acid and zinc, yields benzene perfectly free from thiophen, but benzene hexahydride is not formed. C. H. B.

Friedel-Crafts Synthesis. By M. Schöpff (*Ber.*, **24**, 4252).—The author was unaware when he published his paper (this vol., p. 337) that a similar conclusion had been arrived at by Claus (Abstr., 1891, 911), namely, that by treating certain halogen derivatives of benzene with acid chlorides in the presence of aluminium chloride, the acidyl group takes the para-position relatively to the halogen; the author found, however, that when this position is already substituted, no reaction occurs, whereas Claus stated that in this case the acidyl group takes the ortho-position relatively to the halogen, although he had not isolated the ketone in the pure state. The author is willing to discontinue the further study of this subject, as also that of parabromometatoluic acid and parabromisophthalic acid; he has, however, been engaged for a considerable time in investigating the amido- and anilido-derivatives of the latter compound. A. R. L.

First Reduction Products of the Nitro-group. By C. Willgerodt (*J. pr. Chem.* [2], **45**, 145—153).—A further examination of the reduction product obtained by the action of potassium iodide on picryl chloride in alcoholic solution, which the author has described as dinitrosonitrophenol (Abstr., 1891, 688), shows that it is not a dinitrosophenol, but the isomeric hydroxylamine compound *dinitrophenylenehydroxylamine*, $C_6H_2(NO_2)_2{:}NOH$. It is extremely stable towards acids and acid chlorides, and can be boiled with phosphoric chloride, acetic chloride, and hydrochloric acid without decomposing. If heated to boiling with sulphuric acid, it is precipitated unchanged on the addition of water in beautiful white crystals. When heated with alcoholic potash, it is decomposed with formation of an ethylamine, and with aqueous potash it yields ammonia. It quickly reduces Fehling's solution on heating. The *ammonium* salt is obtained by leading ammonia into an ethereal solution of the compound, and has a beautiful green lustre like magenta crystals. The *silver* and *lead* salts are obtained as orange-red precipitates on adding silver or lead nitrate to a solution of the ammonium salt, and when dry are stable in light and air. The silver salt explodes violently when treated with fuming nitric acid. The lead salt also explodes when heated with sulphuric acid. With aniline, dinitrophenylenehydroxylamine yields an additive compound of the formula $C_6H_3N_3O_5,NH_2Ph$,

which crystallises in beautiful red prisms or needles, melts at 125—126°, and slowly loses aniline when exposed to the air, more quickly on heating. The paratoluidine compound has the formula $(C_6H_3N_3O_5)_3,(C_6H_4Me{\cdot}NH_2)_2$, crystallises in dark bluish-brown needles, and melts at 101—102°.

α-Nitronaphthalene, when reduced with potassium iodide and formic acid in a sealed tube at 230—270°, yields a white compound which melts at about 130°, and does not reduce Fehling's solution.
